Animals (Scientific Procedures) Act 1986

Non-technical summaries for project licences granted January – June 2022

Contents

1. The role of tissue-resident immune cells in health and disease.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

immunology, tumour immunotherapy, cancer, wound healing

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We will investigate the roles of organ-resident immune cells in regulating local inflammation, which is critical in both beneficial processes such as wound repair, or disease states such as fibrosis and cancer formation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We know that immune cells circulate in the blood, and can enter organs in response to different diseases such as infections and cancer. It is becoming clear that there are certain immune cells that reside as 'tissue-resident' cells in specific organs, although relatively

little is known about how these cells are locally regulated, and what their functions are. Recent findings show that the microenvironment of the organ can instruct how some of these tissue-resident immune cells behave; therefore it is likely that tissue-resident immune cells are tuned to respond to organ-specific challenges. We are specifically interested in a recently discovered tissue-resident immune cell, called group 2 innate lymphoid cells (ILC2). We know that ILC2 play an important role in parasite infection and allergic disease, but still little is known about their roles in cancer or tissue repair. We will build on our expertise in ILC2 immunology, tissue repair and cancer modelling in mice to better understand how ILC2 can locally influence inflammation in these important disease conditions. Ultimately, we hope to control the function of ILC2 to improve anti-tumour immunity or wound repair, which may result in better clinical treatments.

What outputs do you think you will see at the end of this project?

We will generate:

A better basic understanding of the regulation and role of tissue-resident immune cells within specific organs.

A better understanding of the roles of tissue-resident immune cells in tissue repair, fibrosis and cancer development.

New reagents that will be shared with the scientific community (i.e. new genetically engineered mice, or cell lines/organoids derived from mice).

Data that will be shared with the scientific community (uploaded to open-access data repository).

Who or what will benefit from these outputs, and how?

The following people will benefit:

In the short-term (1-5 years), new basic scientific research will benefit the scientific community.

In the medium-term (>5 years), new information will lead to increased use, or development, of new reagents (benefit industry), or result in translation of pre-clinical research (benefit patients).

How will you look to maximise the outputs of this work?

We will maximise the output by:

Publishing all findings in a timely manner. We only publish in open-access journals to ensure free access to our findings.

We will openly share reagents, data and expertise with collaborators. Valuable reagents will be deposited in open-access repositories, or maintained in easily shareable formats at our Institute. Published datasets will be deposited in open-access repositories. Expertise will be shared via detailed methods publications in open-access journals, or on our website.

We generally include negative findings in our publications.

We disseminate new knowledge related to animal use at local or national animal-users meetings, or scientific conferences.

Species and numbers of animals expected to be used

- Mice: 25000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have many similarities with humans in terms of genetics, immunology, and cancer formation. Most current anti-tumour immunotherapies were developed using basic scientific research in mice. Laboratory mice are widely used to study immunology and cancer, and there are many important genetically engineered mouse models available to carefully investigate the function of specific immune cells in health and disease. Similarly, cancer development can be accurately studied using different mouse models.

For tumour studies, we require the use of adult mice because: 1) the tumours we study occur primarily in adults, and 2) we study the interactions of the adult immune system with cancer. For studying the tissue-resident immune system we primarily use adult mice (>95%), although some studies will involve neonatal or juvenile animals where early activation or modulation of the immune system is induced to study the early development of tissue-resident immune cells.

Typically, what will be done to an animal used in your project?

We will perform two lines of investigation:

We will investigate the basic biology of tissue-resident immune cells. For this work we will manipulate tissue-resident immune cells to understand how they are turned on/off, and what their function is. We will expose mice to stimulants (i.e. injection of a protein, or exposure of mice to inhaled substance), or administer a test drug to understand if we can block activation. To translate our findings to human disease conditions, we will use models of disease where tissue-resident immune cells play a role (i.e. fibrosis of specific organs, which involves several administrations of substances that reproduce human fibrotic disease). While the majority (80%) of these experiments are short (1-2 weeks), some disease models take longer (several months).

We will investigate how tissue-resident immune cells are involved in cancer. For this work we will combine our methods from the previous section (where we understand how to control tissue- resident immune cells), and apply it to mouse models of cancer. Cancer models generally fall under a) genetically engineered mice that spontaneously develop cancer, or b) mice that are implanted with tumour cells. Regarding the latter, we will inject mice with tumour cells (into the blood, or another relatively painless route), or surgically implant mice with tumour cells into a specific organ (i.e. pancreas). The majority of cancer experiments will last less than 3 months (80%), although some models that accurately mimic tumour formation will take longer (3-18 months).

What are the expected impacts and/or adverse effects for the animals during your project?

Related to the two lines of investigation:

We will investigate the basic biology of tissue-resident immune cells: These experiments will cause short-term discomfort associated with the administration of reagents (i.e. injection of substance). Some of these experiments will cause short-term (<1 day) discomfort caused by activation of immune cells (i.e. inflammation), which may include mild localised pain or irritation. Mice will be given painkillers in experiments that are known to cause persistent (>1 day) or more serious acute discomfort (i.e. pancreatitis).

We will investigate how tissue-resident immune cells are involved in cancer: These experiments will cause short-term discomfort associated with the implantation of tumour cells (i.e. injection); Surgical implantation of tumour cells will cause medium-term discomfort, that will be managed by painkillers given before and after the surgery. Tumour formation will cause long-term discomfort associated with cancer; this can include:

a) physical hindrance due to tumour mass
b) impaired organ function due to tumours, such as shortness of breath (lung cancer), or gastrointestinal malfunction - leading to weight loss or ascites (pancreatic cancer)
c) pain due to tumour growth. We will carefully monitor mice in these studies, and have specific thresholds to limit adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Some mice will be kept for breeding, or experiments without any procedures performed (sub-threshold) (30%)

Some mice will be exposed to procedures that cause mild adverse effects (40%)

Some mice will be exposed to procedures that cause moderate adverse effects (30%)

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tissue-resident immune cells, and their role in wound repair and cancer development can only be accurately studied in animal models. Mice represent the best model organism, given the similarities between mice and humans.

Major specific reasons for using mice are:

There are many shared reagents available to immunologists and tumour biologists that work for mice, including antibodies for mouse proteins, or genetically altered mouse models that specifically focus on immunology or tumour biology.

There are many disease models available in mice already, which are known to accurately model human disease.

Which non-animal alternatives did you consider for use in this project?

We use non-animal methods, or methods that reduce animal use, wherever possible. For example, we generate cell-lines from mouse tissues, which can be used in experiments that don't use mice. We also developed 'organoid' or 'explant' cultures, where one mouse organ is made into many small organs, or organ slices, which can be used for many future experiments (thus essentially replacing mice).

We also use bioinformatic methods to study, and model, immune cells and tumours. For these experiments we still require small numbers of animals to obtain immune and tumour cells; however, these experiments generate very rich datasets, which can be used to predict how cells interact, or react in different diseases. Importantly, these are only predictions that need to be validated in either cell-lines or in mice.

Why were they not suitable?

However, to accurately model the microenvironment of tissue-resident cells, one needs to consider the complex interactions that occur in a live animal. For example, the immune system relies on constant interaction with blood-derived cells, and lymphatic drainage, which cannot be accurately studied outside of the body. Tumour development also behaves very differently inside our bodies compared to cell-lines, which are not exposed to the selective pressures of the tumour-microenvironment.

Therefore, while we use non-animal models wherever possible to address more simple questions, we also need mouse models to study how immune and tumour cells behave within the body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The majority of the lines in the colony will be maintained on the C57BL/6 mouse strain background which is optimised for immunological studies. This has been used as the basis for our breeding strategies. An assessment of the reproductive performance of the C57BL/6 strain has been detailed in the Laboratory resource: ‘Breeding Strategies for Maintaining Colonies of Laboratory Mice’ produced by The Jackson Laboratory.

As standard, our breeding stock will be maintained at minimal levels with 1-2 breeding pairs of different ages at any one time. Breeding pairs are mated typically at 6-8 weeks old and allowed to have 5-6 litters (approx. 30 week breeding period). Replacement breeders will be taken from the stock mice produced or bought in from commercial breeders (for inbred wildtype strains). We try to avoid sibling mating where possible. During the course of the proposed work we estimate we will breed a combination of approximately 30 mouse strains carrying modified immune genes at any time, split between our Mild and Moderate Breeding Protocols (Protocols 1 and 2). When colonies are expanded for experimental purposes, breeding trios tend to be used to maximise pup numbers of similar age and provide appropriate littermate controls. The majority of mice bred from the expanded colonies will be used for tissue collection for ex vivo work or in subsequent protocols, however there will be the production of unwanted experimental mice which may be used for replacement breeders or culled unused as excess. We currently have 30 mouse lines on each of our mild and moderate breeding protocols - some lines are for breeding purposes only and some lines are expanded for experimental mice. An estimation of the number of breeding females at any one time is given in Table 1.

Table 1: Estimated Breeding Females for Mild and Moderate Breeding Protocols

Mild Breeding (Protocol 1) #	Moderate Breeding (Protocol 2) #
Breeding only (continuation of line/breeder for experimental crosses) 3	Breeding only (continuation of line/breeder for experimental crosses) 1
Experimental crosses 60	Experimental crosses 6
Total breeding females 63	Total breeding females 7

From these numbers, we have estimated the number of mice which will be produced from our breeding strategy over the next five years, taking into account that breeding females will be replaced every 30 weeks (a replacement factor of 1.73 a year). This has given us estimated mice numbers for Protocol 1 19530/5 years and Protocol 2 2170/5 years shown in Table 2, allowing an additional 10% for variations in breeding numbers over the five years.

Table 2: Estimated mouse numbers produced on Mild and Moderate Breeding protocols over 5 years.

	Mild Breeding (Protocol 1)	Moderate Breeding (Protocol 2)
Active breeding females	63	7
Replacement factor (per year)	1.73	1.73
Breeding females per year	108	12
No. of litters perfemale	5.4	5.4
Average litter size	6.09 (born), 5.60 (weaned)	6.09 (born), 5.60 (weaned)
No. pups born per year	3,551	395

No. mice born over 5 years	17,755	1,973
Protocol No. (+10%)	19,530	2,170

For many of our experimental models our initial calculation, in consultation with the establishment statistician, have suggested we require 7-9 mice per group per experiment. Depending on the controls required for individual experiments, this means the use of an average of 20 mice per experiment, 10 mice per group (control and test) allowing an additional 10-20% per group for experimental losses (such as from tumour engraftment problems or technical dosing issues etc). This will be amended as we gain more information from our experiments and will also vary depending on the number of test groups required per experiment (we may, for example, have a control and 2 test groups in some instances). Most of our proposed disease models are well established and robust, however for some cancer studies, for example, there may be a more variable onset and this may necessitate larger cohorts to demonstrate significant differences. Estimated number of experiments to be performed on each experimental protocol are detailed in Table 3 below.

Table 3: Estimated number of experiments and mice used on experimental protocols.

Protocol Number and Name	No. mice per experiment	No. experiments per year	No. mice per year	No. mice over 5 years
Protocol 3 (immune response)	20	50	1000	5000
Protocol 4 (chronic lung inflammation)	20	10	200	1000
Protocol 5 (chronic pancreatitis)	20	10	200	1000
Protocol 6 (subcutaneous tumour)	20	5	100	500
Protocol 7 (intravenous tumour)	20	25	500	2500
Protocol 8 (intraperitoneal tumour)	20	25	500	2500
Protocol 9 (mammary tumour)	20	10	200	1000
Protocol 10 (orthotopic pancreatic tumour)	20	25	500	2500
Protocol 11 (orthotopic lung tumour)	20	10	200	1000

Protocol 12 (orthotopic ovarian tumour)	20	10	200	1000
Protocol 13 (naturally progressing tumour model)	20	10	200	1000

These are our current estimates for the project licence over the next five years, but will be adapted and refined as we increase our understanding of the field and our breeding and experimental requirements.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing experiments we will initially perform pilot studies to determine the observed effect sizes to ensure that we use the minimum number of mice per group that will be informative. In addition, we will consult with statisticians within the establishment before starting the experiments and throughout when required to ensure statistical confidence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We intend to run the administration of our mouse strains centrally, using the PI and laboratory manager as a central communication point between all users working under the licence and the animal unit staff where the mice are housed. This ensures we can optimise strain breeding to support multiple studies. Should excess mice arise, these can be shared with other researchers who have the authority on their licence to receive them. Collaborating in this way avoids mice being bred and not used, and also avoids duplication of breeding strains within the same facility. The strict control of mouse stock ensures excess breeding is avoided and all mice bred are used as productively as possible. We have quarterly dedicated laboratory meetings to manage breeding strategy to suit the demand.

All mouse lines not in current use are kept on minimal breeding. Where possible, the mice are bred as homozygous lines (providing they do not have a harmful phenotype) and when breeding heterozygotes, littermates are used as controls for experimental work. We have the facility and expertise at the Transgenic Unit of the establishment to freeze embryos/sperm, and this will allow us to store those lines needed for future studies but where no research work is planned in the immediate future.

Every opportunity will be taken to decrease the number of animals used for each experiment, whilst still maintaining the statistical significance of the subsequent data. We would undertake pilot studies when using procedures and models new in our hands, to ensure they are optimised before large scale experiments are carried out. To maximise information, multiple body sites will be examined from each animal and multiple analysis types will be conducted on each sample, where possible. Samples can also be archived, e.g. we have optimised cryopreservation of immune cells and created a bank of peripheral immune cells and bone marrow, which can be retrieved and used for future in vitro functional studies, adoptive transfer for in vivo disease models and for production of

chimeric mice. RNA and protein samples can also be stored, allowing us to revisit a previous study to perform further analysis without the need to repeat the experiment.

We have setup a clinical research study and have optimised protocols to phenotype and analyse various immune functions in various human immune cells from cancer patients, and healthy blood donors. This will reduce our need for some animal models since work can be accomplished in human immune cells obtained from blood and tissues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our models and methods fall into five main categories:

Inflammatory models. The majority (80%) of these models target specific organ sites, and cause transient localised inflammation that mimics human disease. Our models are well-characterized in pilot studies, and when appropriate, reagents are titrated to avoid systemic or overt inflammation.

Chronic inflammation models. These models mimic serious human disease (chronic lung inflammation, and chronic pancreatitis) in the majority of mice (75%); we have refined our protocols to cause the least amount of inflammation necessary to model human disease, to limit inflammation to the organ of interest wherever possible, and include prophylactic pain management in models where we anticipate pain.

Tumour metastasis models. These models mimic the spread of cancer to other organs; here we have established specific protocols where the site of metastasis is more predictable. While these models cause suffering associated with tumour spread, the effective targeting of specific organs ensures maximum collection of data per mouse.

Tumour formation models (orthotopic): These models involve the implantation of tumourigenic cells into a specific organ site. While these mice will be exposed to serious harm due to the implantation procedure, these models present the most refined method to study tumour-immune interactions, and are also very robust in terms of disease penetrance. Tumour formation in these mice also follows a more predictable trajectory, and is amenable to more refined monitoring of cancer progression (i.e. bioluminescent imaging).

Tumour formation models (spontaneous): These are the most accurate mouse models of tumour formation. Some experiments require us to look at early stage disease, which is not accurately modelled in the orthotopic models. The majority of these mice (75%) will be humanely killed at an early stage of cancer development, and therefore won't suffer significantly from cancer-related adverse effects.

As we are interested in the role of immune cells, and tissue-resident inflammation in cancer, we will very often (75%) combine tumour models with immune modulation. This may have a protective or detrimental effect on cancer, and we will always perform tumour or inflammatory models independently first to establish a baseline understanding.

Why can't you use animals that are less sentient?

The diseases or biology related to tissue-specific immune regulation and inflammation apply mainly to the mature, adult, immune system. As these disease or immunological processes occur over the course of several days to months, it is impossible to use terminally anaesthetised animals in most cases. A small aspect (<2%) of our work will involve asking very focussed questions about tissue-specific immune interactions by visualising these interactions in terminally anaesthetised mice.

The processes of tumour metastasis or tumour development are also mainly associated with adults, particularly the cancers we study. As cancer development and metastasis are processes that take time, it is not feasible in most cases to use terminally anaesthetised mice. Nevertheless, we have developed protocols to look at early metastatic seeding in a small number (<2%) of terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use several approaches:

Foremost, we perform pilot studies to define the expected harm; we work closely with animal technical staff to then design the most comprehensive management and monitoring plan.
We communicate very effectively with animal technical staff to capture unexpected adverse phenotypes, or incorporate feedback into our animal protocols. For example, we worked with animal technical staff to improve the non-invasive delivery of post-surgery analgesic and animal housing conditions.
We work with the NVS and other expert users to refine our surgical procedures. For example, our attendance at AWERB and user meetings resulted us identifying a specific expert in orthotopic lung tumour models who shared more refined techniques with us.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Unless otherwise specified, the work in this project will be undertaken in accordance with the principles set out in the Guidelines for the Welfare and Use of Animals in Cancer Research: British Journal of Cancer (2010) 102:1555-1577 (referred to subsequently as the 'NCRI Guidelines') and in the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery (2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use several strategies:

We attend, and present, at dedicated meetings of animal users (i.e. monthly animal users meetings, Animal Welfare Ethical Review Body (AWERB), meetings, national and international scientific conferences). Here we will share and discuss our experiences with

animal experiments, and actively search for more refined methods. We have used this approach to refine some of our existing protocols (i.e. orthotopic implantation of the pancreas and lung), which have led to PPL amendments to incorporate such advances.

We regularly search the literature for more refined protocols, and discuss these with our animal technical staff. We have used this effectively to set up an assay to study early metastatic engraftment of the lung, which was performed under terminal anaesthesia.

We actively engage the animal technical staff, and work closely with technicians, NACWO, and NVS to refine our protocols and are very open to quickly adopting new approaches.

2. Orthopaedic Infection

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Infection, Implant, Orthopaedics, Trauma, Reconstruction

Animal types	Life stages
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop implantable medical devices and device coatings that demonstrate the ability to eliminate any bacteria that adhere to the implant, preventing the development of bacterial infection. The resulting decrease in infection rates and the subsequent human and financial costs would be substantial justifying the use of animals in technology development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infection following repair of broken bones or joint (e.g. hip and knee) replacement is recognised as a significant problem in orthopaedic surgery. Despite the care taken during

surgery bacteria can occasionally invade the implant surface resulting in failure to heal the fracture or new joint being unstable and the need for further surgery to rectify the situation. Current failure rates are up to 2% of initial implantation surgeries (and significantly higher in secondary implant replacement procedures following previous infection), with treatment methods involving removal, prolonged strong antibiotic treatment and eventual replacement of the implant through further surgery. The impact of these infections is wide reaching with significant patient discomfort, increased healthcare costs and in severe cases, amputation of the infected limb.

What outputs do you think you will see at the end of this project?

The primary purpose of this project is to address the issue of orthopaedic implant infection, which meets the definition of “control of disease, ill-health or abnormality” from the permissible purposes of the Act. If a technology proves successful in this project and the subsequent clinical trial then it would be coated onto the non-articulating bone contacting/indwelling portions of orthopaedic reconstruction (Hip and Knee replacements) and trauma fixation products producing a significant reduction in the rate of infection associated with these procedures. In time the intention would also be to further disseminate the scientific knowledge gained through peer reviewed publications.

Who or what will benefit from these outputs, and how?

This work intends to provide benefits to the patient in terms of reduced morbidity, hospital stays or even mortality. Additionally the technology has the potential to reduce the cost burden to healthcare systems caused by these infections (estimated in the USA to be $1.89bn per year and in UK calculated to be £29.5m per year between 2015 and 2020 , increasing all the time due to the rise of antibiotic resistant organisms and increasing co-morbidities). These benefits should begin to be realised from the point a product utilising the technology is launched, which dependent on development timescales and regulatory requirements such as clinical trials should take place within 5 years of completion of successful animal studies on final product.

The project will also look to benefit the “advancement of biological science” in further development and assessment of the clinical relevance of models for the assessment of antimicrobial coatings for orthopaedic implants. This work will hopefully be published in future, adding to understanding within the literature of orthopaedic device related infections and technologies/strategies that may prevent them. This publication is likely to take place in parallel with product launch, so is likely to take place within 5 years of the completion of successful animal studies on final product.

How will you look to maximise the outputs of this work?

The outputs of the project will be fully exploited through a number of different mechanisms. For example; (a) product support data, (b) pre-clinical regulatory support data, (c) conference abstracts and posters, (d) scientific publications outlining new experimental models of bone repair. Model development may also involve the support of either academics or clinicians, which will assist with knowledge transfer.

Species and numbers of animals expected to be used

- Rabbits: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Live mammalian vertebrates are required that closely mimic the immune systems and bone repair pathways in humans as much as possible to ensure that any data generated can be translated to the clinical situation. Maturity of the immune system and skeletal maturity are also required for this reason meaning adult animals are required.
The rabbit is a suitable model for the investigation of infection prevention due to their relative susceptibility to infection compared to other small animals (rat, mouse etc.) which allows a more clinically relevant dose of bacteria to be used to generate infection and keeps down the number of animals required to demonstrate significance.

Typically, what will be done to an animal used in your project?

Surgically, under general anesthesia with recovery, an entry hole will be made through the tibial crest to the medullary canal of the tibia. The bone marrow is then flushed from canal and the canal is then reamed with a pin of marginally bigger size than the test implant before the canal is flushed for debris. A bacterial suspension is then introduced either prior to implantation of the test pin or in conjunction with this pin. The entry point is then sealed and the soft tissue closed over the site. The estimated time of the surgical procedure is approximately 1 hr. Once the animal has recovered from the effects of general anesthesia it will be carefully monitored by qualified animal husbandry staff until the live phase of the study is completed up to 4 weeks later. At the end of the study, the animals will be humanely euthanised.

What are the expected impacts and/or adverse effects for the animals during your project?

The project will involve the surgical implantation of a metal pin into a bone canal, which may lead to some degree of discomfort following surgery, although this will be reduced by the use of a minimally invasive technique and the absence of a fracture in the bone which is not required for this work. Any discomfort will be minimised with the use of appropriate pain relief. The establishment of a bacterial infection in the bone of the test animals may lead to some moderate discomfort, however efforts will be made to minimise this with the use of circulating antibiotics and appropriate pain relief. At the end of the studies the animals will be humanely euthanised. In addition any animal showing severe signs of suffering whilst on study (e.g. excessive weight loss, signs of uncontrolled pain, significant lameness) will be humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?
It is expected that greater than 80% of animals will experience moderate harm in work under this protocol. The remaining 20% or less of animals will be classified as non-recovery by failure to recover from anaesthesia due to either adverse reaction to the anaesthetic itself, respiratory failure due to production of bone marrow emboli caused by the nature of the procedure or being euthanised due to irreparable surgical complications.

It is hoped that based on most recent experience with revised anaesthetic and surgical procedures that this will be reduced below 10% of animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

There is no suitable *in vitro* alternative to the animal model for assessment of infection prevention.

However prior to animal testing the basic antimicrobial properties of the coating against the strain of bacteria that we propose to use in *in vivo* studies will be assessed via *in vitro* methods. Bacterial kill away from and at the implant surface will be analysed, ensuring that only once a formulation has shown efficacy (within the limitations of *in vitro* testing) will it be considered for animal studies.

In vitro methodologies, whilst providing a screen to optimise coating formulations, cannot replicate the complexity of device related infection within a host organism. Cellular repair mechanisms, immune defence, inflammation and host animal/microbe interactions cannot be accurately replicated by *in vitro* cell culture/microbiology studies. In order to truly assess the potential of a coating that can reduce implant infection in the human population, *in vivo* studies in the presence of these complex elements, are required. Additionally, prior to granting a licence to carry out the clinical trial and before launch, the final product will require animal testing within the model described in Protocol 1 of this licence application, demonstrating efficacy as detailed in the requirements of “FDA Decisions for Investigational Device Exemption (IDE) Clinical Investigations”, section 8.1 – non-clinical testing, UK Medical Devices Regulations 2002 (SI 2002 No 618, as amended) (UK MDR 2002) the EU Medical Device Directive (93/42/EEC) and EU Medical Devices Regulation (Regulation 2017/745).

Which non-animal alternatives did you consider for use in this project?

As stated previously *in vitro* methodologies are used to screen potential test formulations, but these have limitations when it comes to truly assessing the anti-infective efficacy of technologies.

Why were they not suitable?

To date there are no *in vitro* approaches, even those using tissue explants or co-culture of bacteria and immune cells, that can fully replicate the complex interactions of test article, host immune system, circulating antibiotics, inflammation and host animal/microbe interactions. All these elements are required to ensure an accurate replication of the environment a product will be required work in in the clinical setting.

The Project consists of an extensive laboratory based safety and microbiology testing regime to select the most appropriate anti-infective coating for implant surfaces (e.g. an

intermedullary nail), allowing selection of the best formulation(s) for development. While this testing will allow accurate selection of prototypes, it cannot replicate the complex biological interactions at work within the body, thereby making performance testing in animals an essential part of the plan before human trials can commence. Demonstration of efficacy and safety in an animal model is also a requirement of regulatory agencies prior to clearance for human trial and eventual product launch.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals per species required will be determined from a number of sources;

The experiences gained from previous licences.

Advice and approval of protocols by regulatory agencies.

Our statisticians input at the planning stage of the *in vivo* studies to advise on study design, post live phase analysis and to determine the minimum number of animals required to provide sufficient likelihood of a meaningful outcome.

Previous studies or studies reported in the literature will be used to provide variability data to aid this process, or pilot studies will be conducted to generate such data. This will reduce the numbers of animals used in total without compromising the data/information obtained.

Our organisation's AWERB, which will assess all protocols and experimental design prior to the start to ensure a minimum number of animals are used to the meet the study objectives.

Our AWERB review every proposed study in addition to reviewing the protocols proposed in this licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?
Our organization will adopt multiple strategies that will help ensure that the fewest number of animals will be used in the research to address the scientific questions outlined in the project.

SUBJECT VARIABILITY: Variability will also be reduced through the procurement of animals of consistent breed, sex, age and weight ranges and through application of animal acceptance criteria for each study.

BIOSTATISTICS/POWER ANALYSIS: Statisticians will be consulted in the planning stage of the *in vivo* studies to determine the minimum number of animals required to for

statistical analysis and to answer a scientific question being asked. This will reduce the numbers of animals used in total without compromising the data/information obtained. Consultation with a statistician will comprise setting clear study objectives, and ensuring appropriate output measures are collected and analysed using appropriate statistical methods. Sample sizes will be determined based upon the needs of the study which may be tailored for either welfare, pilot, validation or efficacy/non-inferiority/equivalence. Where powered, historical data will be used to determine the appropriate sample size to achieve the required study power. In order to minimise animal numbers used across the project every effort will be made to test as many candidates as possible in a single experiment against a single control group. Based on previous experience with this model the rate of infection/colonisation in control animals is known and so the number of animals in a given study required for a technology to show statistically significant improvement in this rate is also known. This defines the number of animals required per study. This approach, in terms of being an appropriate level of confidence of efficacy, has been provisionally agreed with regulatory agencies.

Where historical information is available the study size will be determined by the minimum numbers required to provide sufficient power (at least 80%) to achieve the desired outcome.

To further minimise numbers, where possible, one sided statistical tests will be used. The objectives dependent on the outcome measures may be to show superiority to a control, non-inferiority to a predicate or gather device performance data. Sources of variability will be controlled by giving careful thought to potential sources of error, bias and variation in measurements, and making every effort made to minimise them. This will include (a) using well-characterised implants that are within specification, (b) defining the success criteria of the study, (c) adopting a consistent surgical technique across the studies, (d) providing adequate time for acclimatization, (e) training of staff, (f) blinding observers and participants to the study hypothesis, and (g) adopting a randomisation schedule in order to reduce bias and interference caused by irrelevant variables.

LOCAL ETHICS (APPROPRIATE EXPERIMENTAL DESIGN): Our organisation's AWERB will assess all protocols and experimental design prior to the start to ensure a minimum number of animals are used to the meet the study objectives. Our AWERB review every proposed study in addition to reviewing the protocols proposed in this licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

IN VITRO TESTING: Prior to studies covered by this project licence extensive laboratory based microbiology testing will be used to ensure that only the most promising technologies will put forward for testing in animals.

QUALITY ANIMALS/VETERINARY CARE/PRE-SCREENING: Health screening of the animals prior to surgery will help screen out individuals that are deemed to be unsuitable for surgery. The loss of animals can also be minimized by providing good post-operative care, use of quality regulated animal suppliers, and planning ahead so that the appropriate number of animals needed for the studies are ordered.

PILOT WELFARE STUDIES: Pilot studies can be used to estimate variability and evaluate procedures and effects. Where the primary output measure of the pilot study is to establish acceptable welfare of animals subject to new procedures under this licence, no more than four animals will be used.

PILOT "POWERING" STUDIES: Where there is no adequate data to power a study, a pilot will be used to gather sufficient data to design a definitive study. Typically, these will be designed to provide a minimum of 10 degrees of freedom to estimate the error. For example, a study with two groups would have a sample size of 6 per group. Where historical information is available the study size will be determined by the minimum numbers required to provide sufficient power (at least 80%) to achieve the desired outcome.

APPROPRIATE USE OF ENDPOINTS - TISSUE SHARING: Where possible, harvested tissues will be recycled for multiple testing, e.g. blood draws, biopsies, CT and histology.

SHARING ANIMALS: For instance, animals euthanized by one investigator can provide tissue for use by another investigator on another licence or protocol.

NEW INSTRUMENTATION AND TECHNIQUES: Using new instrumentation or innovative techniques that can improve precision can reduce the number of animals needed for a study. This has the added benefit of also being a refinement technique for the protocol.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The surgical techniques have been refined and our previous experience provides reassurance that no long term lameness/significant pain should result. In addition work carried out under the previous project licences has further refined the surgical technique, anaesthesia and experimental parameters.

Assay methods and *in vitro* testing of test materials for antimicrobial efficacy, biocompatibility, etc. have been developed and used to optimise the materials/factors to be implanted. *In vivo* procedures required to optimally deliver and fix the factor/materials have been fully developed and surgery successfully carried out previously at the our facility. All analysis techniques, including histology have already been fully developed.

Aseptic surgery will be carried out using inhalation anaesthesia. The animals will be sedated using premedication prior to inhalation anaesthesia (e.g. Alfaxalone) with analgesia (e.g. Meloxicam). Analgesia (e.g. Buprenorphine and NSAIDs) will be given post-surgery for a minimum of 24 hours. Previous work has shown no contraindications of the probable analgesics of choice.

Why can’t you use animals that are less sentient?

Live mammalian vertebrates are required that closely mimic the immune systems and bone repair pathways in humans as much as possible to ensure that any data generated

can be translated to the clinical situation. Maturity of the immune system and skeletal maturity are also required for this reason meaning adult animals are required.

The rabbit is a suitable model for the investigation of infection prevention due to their relative susceptibility to infection compared to other small animals (rat, mouse etc.) which allows a more clinically relevant dose of bacteria to be used to generate infection and keeps down the number of animals required to demonstrate significance.

Time (days to weeks) is required for the development of implant colonisation/infection in order to differentiate between successful test technologies and the negative control group therefore recovery from surgery and a live phase are necessary.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement applies to all aspects of animal use, from housing and husbandry to the scientific procedures performed on them. Continued investigation into animal refinement will be sought through several sources, e.g. (a) careful choice of animal model, (b) adoption of a multi-disciplinary team with expertise in animal husbandry, housing and care, veterinary science, pain management, engineering and project management, (c) improvements in animal procurement, transportation and quarantine, (d) improvements in animal husbandry such as training of animals and group housing to habituate animals to study procedures to minimise any distress, (e) implementation of housing, e.g. micro- and macroenvironment, (f) increased monitoring and surveillance, (g) refinement in surgical techniques, e.g. minimal invasive surgery that minimize animal pain and distress, (h) appropriate anaesthesia, analgesia and sedatives to minimise pain and (i) post-operative care/recovery and (j) pain management (anesthesia, analgesia).

SOPs will also be regularly updated and documented within our Quality Management System, which is accredited to ISO9001. Staff training will also be made available through attending courses and conferences and integrating with key opinion leaders.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice approaches will be used to enhance animal well-being, minimize or avoid pain and distress, and reduce the number of animals required to obtain the desired research objectives.

Best practice on animal care and husbandry will also be achieved through several sources including

(a) our facility's Animal Welfare and Ethical Review Body (AWERB) with an advisory function on ethical matters,

(b) UK Home Office guidelines on Animal Testing and Research https://www.gov.uk/guidance/research-and-testing-using-animals,

(c) NC3Rs, which is a UK-based scientific organisation dedicated to replacing, refining and reducing the use of animals in research and testing (the 3Rs) https://www.nc3rs.org.uk and

(d) consultation of the Guide for the Care and Use of Laboratory Animals (Source: National Research Council of the National Academy of Sciences 2011).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The subject matter experts that are employed within the animal facility will engage in continuous professional development that will ensure best practices in pharmacology, radiography, animal husbandry and welfare are regularly adopted during the lifetime of the project.

3. The mechanisms of modulating nerve cells networks and their implications for neuronal excitability

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Autism, nervous system, development, excitability, animal models

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate
Rats	neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This study aims to determine how specialized regions of nerve cells control overall brain excitability. We will elucidate the molecular mechanisms that governs the structural modifications of these specialized regions and how such modifications lead to altered nerve cell excitability under normal circumstances and in autism spectrum disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The numerous nerve cells in the brain termed “neurons” modulate the excitability of the brain. This modulation of brain excitability is important for brain development, learning, memory formation, and social interaction. There is growing evidence to suggest that the excitability of neurons may also be regulated by a distinct region of the neuron - the axon initial segment (AIS). The AIS is a dense network of several proteins including ion channels and membrane proteins. Importantly, several autism spectrum disorder susceptibility genes

encode AIS proteins. The structural modifications to the AIS have been reported in several mouse models of autism such as Fragile X and Angelman syndrome.

Hence, the underlying mechanisms of AIS alterations and how it influences neuronal excitability are key questions relevant to the function of neural networks in health and autism. This may eventually offer possible targets for influencing excitability-associated behaviour such as repetitive and restrictive behaviour in patients with autism.

What outputs do you think you will see at the end of this project?

The overall research objective is to pursue a detailed analysis of mechanisms of activity-dependent changes to the AIS. This ability to activity-dependent change is called 'plasticity'. Our research will generate considerable data on protein localisation, transport and how these influence AIS plasticity to regulate neuronal excitability. This will be critical for identifying new targets to manipulate neuronal excitability in physiological and pathological conditions.

The novel findings will be published through primary research publications that are available to the wider academic community.

Who or what will benefit from these outputs, and how?

The people who will primarily benefit from this research are neuroscientists, cell biologists, developmental biologists, and students. The structural organization and function of the AIS regulating neuronal excitability are fundamental research questions. This study on activity-dependent changes in the AIS will benefit researchers investigating mechanisms of neuronal development, functions, and excitability. Further, this work may reveal how other specialized regions of neurons are assembled and regulate neuronal excitability. This will benefit all researchers who are studying the development of the nervous system and neuronal excitability-related disorders such as intellectual disability, epilepsy, and attention deficit hyperactivity.

The larger community including cell biologists and those who are studying protein transport will be interested in the mechanisms of protein transport and targeting of proteins to specific locations. Disturbances to protein transport have been implicated in several diseases, including Alzheimer's disease and multiple sclerosis. Therefore, my research on how neuronal activity modulates protein transport and facilitates protein targeting can boost that area of research.

How will you look to maximise the outputs of this work?

I will have several collaborations within and outside the institution. This will help in efficiently establishing live-cell imaging and further analysis. I will attend conferences both international and within the UK/EU to share and discuss my research with the wider scientific community, including neuroscientists, cell biologists, and developmental biologists. Our centre regularly publishes articles about the research activities of the centre. I plan to write articles about my scientific research to reach a wider audience of students, scholars, and other institute members interested in research activities. Further, I will participate in science festivals and the Open Day to engage with the general public. I will disseminate our ideas and research to generate enthusiasm about scientific research. Finally, I plan to have regular updates/newsletters about my research activities on my personalized laboratory webpage and on social media platforms to engage with the wider research community, students, and the general public across the world.

Species and numbers of animals expected to be used

- Mice: 2000
- Rats: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

However, to understand anatomical changes of the brain, we need to have a model with a sufficiently developed network of nerve cells. Currently, the mouse and rats are the only mammals where it is feasible and practical to perform the genetic manipulations required for our analysis. Postnatal days (0-
2) days can generate excellent neurons that can grow in a dish. For experiments with brain slices, animals at an appropriate age are chosen. At this stage, the animals will have mature nerve cells and developed networks of nerve cells. This will be important to determine how activity can modulate specialized regions of the brain cells.

Typically, what will be done to an animal used in your project?

In order to grow neuronal cells in a dish, animals aged postnatal days 0-2 will be decapitated and brain tissue will be used.

The animals will be humanely killed by an overdose of anaesthetics. Following that, brain slices will be generated for the study.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will be humanely killed rapidly to avoid any adverse effects. The genetically altered animals used in this project should not develop any conditions that will cause them any significant harms. They will be bred and maintained at the facility under standard protocols. The animals exhibiting any unexpected harmful abnormal phenotypes will be humanely killed. In the cases of individual animals of particular scientific interest, we will promptly seek advice from the Home Office. At the end of each experiment or at the end of their breeding life, animals will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

100% of the animals (both genetically altered and wild-type (i.e. normal)) used on this project should experience only a very low level of harm.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand behavioural/anatomical changes resulting in neuronal excitability, we need to have a model with a sufficiently developed network of nerve cells. Currently, the mouse is the only mammal where it is feasible and practical to perform the genetic manipulations required for our analysis.

Whilst elements of neurodegeneration and neurodevelopment can be modelled in cell culture (growing brain cells in a dish), complex intercellular interactions in the nervous systems must always be referenced to the processes as they occur in either the intact animal or in tissue culture taken from animals, in the case of this project, mice, and rats. The use of live animals is required to achieve the scientific aims. Only mammals have a sufficiently developed nervous system to readily compare to humans. Nevertheless, we aim to make extensive use of cell culture and brain slices recapitulating neuronal development from postnatal mice and rats aged P0-10. These will be ideal for live imaging.

Which non-animal alternatives did you consider for use in this project?

We take advantage of several non-animal alternatives and routinely use immortal cells and computer- assisted analysis that do not involve the use of animals.

Why were they not suitable?

The intact nervous system is a prerequisite to study the general excitability of the neurons and hence non-animal alternatives are not suitable for this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
The experimental designs and methods of analysis have been discussed with statisticians and fellow collaborators. We will use the least number of animals to generate scientifically valid data, generally based on the power calculation and existing published literature.

We will generate neuronal cells from the postnatal animals to grow them in a dish for the investigations. This will reduce the number of animals significantly.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Generally speaking, statistical analyses generally by 2-tail Student's t-test or one-way ANOVA require no more than 4-5 animals per condition totalling 8-15 animals per experiment because, fortunately, the effects tend to be so clear cut.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use rat and mice pups to generate our cell culture and slice culture models. This means we can use fewer animals as the breeding pair can be reused for the experiment.

In order to seed 4 imaging chambers with neuronal cells, 2 mouse pups and 1 rat pup are required. However, these chambers can be repetitively imaged for up to 4 weeks. This is extremely efficient and means we do not have to keep generating new neuronal cell culture to study longitudinal changes with time in neuronal development.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using genetically altered mice to understand the function of genes that regulate fast communication of the nervous system network. The genetically altered mice will be maintained by breeding with wild-type mice. They will also be bred for analysis by generating mice where the activity of genes will be removed.

For cell to cell communication in a developmental context, such as in neuronal development, it is essential to look at in vivo biology. The most efficient and most effective way of assessing the function of proteins in this context is to either increase or remove the activity of their genes using genetic alteration techniques.

In general, the severity level of our genetically altered mice is Mild. It should also be noted that none of the genetically altered animals where the activity of the gene of interest is either removed or increased has adverse phenotypes. We will use wild-type rats (e.g Sprague Dawley) at postnatal days P0-10 to generate our slice culture and cell culture systems using brain tissue. These are excellent model systems to study neuronal excitability.

Why can't you use animals that are less sentient?

Postnatal days (0-2) days can generate excellent brain cells that can grow easily in a dish. For slice culture, animals at an appropriate age are chosen. At this stage, the animals will

have mature nerve cells and a developed network. This will be important to determine how neuronal network activity can modulate the specialized regions ofthe nerve cells.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The severity limit is mild, and only competent and highly trained staff will conduct the experiments. We take advice from the local veterinary team in the facility to minimize welfare concerns.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To improve the welfare of the animals, anaesthesia, analgesia and general protection will be provided to the mice to avoid any suffering prior to manipulation or killing for the experimental procedures, using approved methods.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review the scientific literature and consult veterinarians to alleviate adverse effects. We constantly have discussions with colleagues and attend scientific seminars to stay informed about advances in the 3Rs.

4. Pathobiology and treatment of brain tumours

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain Tumour, Nanoparticle, glioblastoma, cancer therapy, CRISPR Cas9

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

In this study we generate brain tumours in mouse models, which are engineered to be as similar as possible to malignant human brain tumours. These human tumours, glioblastoma and astrocytoma, are still difficult to treat, and we will use the mouse model to find novel ways of getting treatment drugs into the brain tumour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Over the last 10 years much has been learned about how human brain tumours can be diagnosed more reliably. This was possible through genetic studies which have identified tumour-related genes that are unique to certain types of glioma. We are re-creating these tumours in mice to find better ways to treat these tumours. To do this, we need to find novel drugs, and we need to bring them in small vehicles (so- called Nanoparticle) into the

tumour cells. This method is too early to be tested in humans and we first need to find out what works well and what is unsafe, using our models

What outputs do you think you will see at the end of this project?

At the end of this project we will have a better model for a certain type of human astrocytomas, a brain tumour that grows diffusely into the brain and is difficult to control. We will also have tried novel treatments using encapsulated drugs that we can deliver to these brain tumours without causing too much harm to the healthy parts of the body.

Who or what will benefit from these outputs, and how?

The primary beneficiary will be the scientific community, including basic scientists, oncologists and members of the medical community involved in clinical trials. Even though it sounds very ambitious, it may be possible that there are early clinical trials at the end of this project (i.e. in 5 years) using these nanoparticles. Medical safety tests for these nanoparticles have already been passed, and in this project we want to use the nanoparticles to deliver certain drugs to the tumour and test how effective this method is.

How will you look to maximise the outputs of this work?

We have an established track record in publicising our work on national and international conferences, and of course through peer reviewed publications. Through our work with brain tumour charities, we can also communicate such results with charities, who often have a wide network of patient interest groups.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is a well characterized model system to mimic human diseases. We have chosen to use a genetic approach to study brain tumour formation, as it allows for controlled and predictable experimental conditions as compared for example to carcinogen-induced mutagenesis, which has been often used in the past.

To mimic the human brain tumours arising in young adults (astrocytoma) we need to mimic the time at which these tumours start growing, also in mice. Therefore, the induction of tumours happens in very young mice, and the tumours become mature in middle aged mice (60-80 days of age).

Typically, what will be done to an animal used in your project?
The first step to create animals of the desired genetic make up, is the breeding of several strains of genetically modified animals. These animals are basically healthy and show no adverse effects. The experiment starts with an injection of very small volumes (1 µL) of a

solution containing a virus which causes genetic changes in specific brain cells. This leads to the growth of these brain cells into a tumour.

Typically, such tumours are induced in newborn mice and tumours develop after 30 -60 days, depending on the combination of genes. Once these tumours grow, we inject nanoparticles, which are harmless, biodegradable substances. However, these nanoparticles can contain treatment drugs which are designed to reach the brain tumour. Whilst this is happening, animals may be monitored by imaging methods, to show the growth or shrinkage of these brain tumours.

At the end of an experiment, the animal will be humanely killed (schedule 1 method) and cells will be derived to be grown in the laboratory, or brains will be analysed using histological and immunohistochemical methods.

Number of procedures: breeding, intracerebral injection (tumour induction), intraperitoneal injection on multiple occasions (delivery of nanoparticles), and schedule 1 killing. Optional additional procedures are imaging and behavioural tests

What are the expected impacts and/or adverse effects for the animals during your project?

The main aim of this project is to understand the growth of brain tumours in a mouse model. Therefore, our experiments need to form cancer cells in the brain, which eventually will grow into tumours. A Brain tumour has a side effect on the behaviour of these animals. These include weight loss, reduced movements, and withdrawal from the group. Therefore, our trained animal staff monitor these animals on a regular basis (daily) and specifically watch out for these signs. Once a mouse shows one or more of these signs such a sign, it will be humanely killed and used for further analysis, which includes a thorough tumour analysis with molecular biology methods, growing cells from it or the analysis by a pathologist. The expected level of severity in the above circumstances is moderate.

A proportion of the animals will be treated with nanoparticles, a method to deliver cancer drugs to brain tumours. In these experiments we will establish if the drug has any tumour delaying effect. These experiments are devised as follows: (i) treatment and control cohorts are culled at the same time, as soon as one of the cohorts shows clinical signs. This is to establish by histological analysis if the treatment group has a smaller tumour size. (ii) each of the cohorts (treatment/therapy and control) will be culled when neurological signs appear, to establish the survival differences between control and treatment group.

Imaging experiments on the treatment and control cohort will be performed before the expected onset of symptoms. These timelines will be established prior to planning the imaging experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Production of genetically altered mice: severity: moderate (5%), all other animals mild severity.

Neural development and neoplasia: severity moderate (80%), all other animals mild severity

Superovulation: severity mild (all animals)

Embryo recipients: severity moderate (20%), all other animals mild severity

Generation of founders: severity mild (all animals)

Vasectomy: severity moderate (all animals)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The main aim of this project is to understand the growth of brain tumours in a model that can be genetically modified but also has sufficient similarities to the human brain to be realistic. To study the growth of a tumour, we need a model in which the tumour growth can be followed with methods similar to those used for human brain tumours, such as magnetic resonance imaging.

Complex diseases such as CNS development and tumourigenesis can only be studied in whole organisms and the mouse is a commonly used and well characterised model system to mimic human diseases. The generation of new mouse models, closely mimicking the human neoplasms, are essential models to understand the cell of origin and pathogenesis of brain tumours, study the direct interaction with the central nervous system, and evaluate how the tumour response to therapeutic approaches

Which non-animal alternatives did you consider for use in this project?

We are already using alternatives to *in vivo* models. Often, some hypotheses are generated by cells or cell lines that are derived from such mice, or indeed from human tumours. Once we have identified biomarkers identified in vitro, we validate them by inducing or repressing genes in our *in vivo* models.

We have successfully replaced some of the *in vivo* experiments with organoids, which can be grown from tumour stem cells, in a cell culture dish. Other methods use organoids derived from human brain cells and tumour cells interact with the non-neoplastic organoids. However, the treatment of a brain tumour with a drug, delivered via nanoparticles, can only be simulated in a live organism. This live organism must have developed a tumour that is sufficiently similar to human tumours and therefore the organism must be amenable to genetic manipulation.

Why were they not suitable?

The use of three-dimensional organoids is very good to study some basic behaviours of tumour cells, such as clonal expansion and tumour cell diversity (in fact we found that for studying these features, in vitro approaches are superior to animals). However, the in vitro (i.e. in a cell culture dish) cells or organoids cannot replace a live system in which nanoparticles are transported through the body to reach the brain. Also, such in vitro models cannot replicate the appearances and growth of human tumour, in particular the interactions with the surrounding normal brain.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals were estimated based on previous experimental data, efficacy and efficiency that we established with previously tested methodologies.

This number needs to be supplemented by a contingency to allow for testing experimental variables, new drugs that become available during the course of the project, and to account for additional genes that need to be examined in the mouse models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

By using live animal imaging (for example MRI, magnetic resonance imaging), we can follow the growth of tumours at various time points in development without the need of killing these mice, thus reducing the number of mice.

We derive stem cells from genetically modified mice, which can then be further studied in cell culture. This has already the previous license reduced the number of mice that would have undergone an invasive procedure. The benefit of this approach is the generation of differential expression data, which will subsequently be evaluated and validated *in vivo*.

We have determined that 12 mice are needed per group in our xenograft studies (transplantation of human cells into mice) in order to achieve statistically significant and reproducible results.

We constantly evaluate our methodologies and aim at best practices in relation to the 3Rs. For example, we found that by injecting a new type of virus into newborn mice significantly speed up the development of the tumour. Previously it took nearly one year to form a tumour, and now it is just above a month. Also, the rate of tumour formation is now nearly 90%, in comparison with 20% previously. This considerably saves on mouse numbers and on cost.

We have replaced the need for complex breeding schemes by a faster, simpler gene modification using the CRISPR Cas9 method

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are using an optimised model system allowing for an assessment of an experimental outcome after only 4-6 weeks. This allows a quick modification of experimental variables where appropriate. The optimisation is the use of a highly effective gene delivery system to the brain to induce tumours, and a genetic construct that generate brain tumours at almost 100% efficacy. Any modification of a system reducing the efficacy will be identified within very short periods of time.

The xenografting model uses established values for efficacy of tumour growth and this allows us to adapt the number of recipient animals accordingly, and with the aim to minimise overall experimental animals.

Finally, our overall genetic approach to induce tumours leads to a substantial reduction of experimental animals, by obviating the need of many breedings and intercrossing to generate desired genotypes.
Many of our tumours are now induced using the CRISPR Cas9 method, allowing targeted and specific tumour induction, with substantially reduced numbers of animals with unwanted genotypes

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is a well characterized model system to mimic human diseases. We have chosen to use a genetic approach to study brain tumour formation, as it allows for controlled and predictable experimental conditions as compared for example to carcinogen-induced mutagenesis, which has been often used in the past. The 2nd approach is the use of mice receiving patient-derived xenografts, which is a worldwide accepted, and standardised procedure. Such standardised procedures are important for the comparability of data and eventually for publication.
Why can’t you use animals that are less sentient?

We are indeed using newborn animals for nearly all inductions of intrinsic brain tumours. This is a significant change from previously used protocols where 6-week-old mice were used. For the injection of patient-derived glioma initiating cells (“xenografts”) we have however to use an internationally accepted and validated standard method, to be able to compare our data with those generated by other groups.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures are regularly reviewed by the named veterinary surgeon and the NACWO. Also our team continuously strives to minimise harm by refining procedures, establishing safer anaesthetic methods, and using effective (daily) surveillance of all experimental animals, we avoid gaps during which animals could develop neurological signs caused by brain tumours.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are following institutional guidelines and we follow the recommendation of the AWERB. The application has been formally peer-reviewed, and follows guidance published in RSPCA, the NC3Rs' ARRIVE Guidelines 2.0, and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project licence holder and all members of the team with personal licences participate in monthly animal committee meetings. During these meetings such advances are being discussed, encouraged, and continuous review of practice ensures we are up to date with the 3R's, and this is documented in summaries, actions points and minutes of these meetings. 3R's are also encouraged by funders of the project, and any reduction will also have beneficial financial impact on the project.

We also receive NC3R newsletters, and are part of a department-wide incentive scheme to reward individual members of staff for improving the use of the 3Rs in their work. I encourage my staff members to attend NC3R talks and trial any new methods that would improve our adherence to the 3Rs.

5. The impact of integrin a1b1 signalling on polycystic kidney disease

Project duration

3 years 0 months

Project purpose

- Basic research

Key words

Kidney, ADPKD, integrin, Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine if the integrin a1b1 receptor is required for cell proliferation in a mouse model of Autosomal dominant polycystic kidney disease (ADPKD)

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Autosomal dominant polycystic kidney disease (ADPKD) is the most common, potentially life threatening hereditary disorder, affecting 1 in 1000 individuals in the UK and around the world. There is currently no cure for ADPKD and new treatments are required to relieve the burden placed on the NHS and other healthcare systems worldwide.

What outputs do you think you will see at the end of this project?

The major output from this project will be new knowledge regarding the importance of a molecule, integrin a1b1 (introduced below), in cyst formation.

Cysts are fluid-filled sacs that are a major feature of ADPKD and prevent the kidney from performing its vital function of filtering toxins out of the blood. My previous findings implicate a role for integrin receptors in the formation of cysts. Integrins are receptors on the surface of cells that interact with proteins outside of the cell. These interactions influence many diverse processes inside the cell (and also allow the cell to influence the environment outside of the cell). There are 24 different types of integrin receptor, they are composed of one alpha subunit and one beta subunit. The integrin receptor that I am interested in is the alpha 1 beta 1 (a1b1) receptor as its expression is much higher in zebrafish and mouse models of ADPKD and in human ADPKD patient tissue. Investigating the role of integrin a1b1 further, in a physiologically relevant animal model of ADPKD, will rigorously test if targeting this receptor is a viable future therapeutic option to prevent cysts forming in the kidney.

The findings of this work will be disseminated in peer-reviewed publications, to scientific audiences at conference meetings, and to the lay public via forums such as Twitter and presentations/conversations at events held by the UK PKD charity. Should integrin a1b1 be (as predicted) found to be important in cyst formation, a new target for therapeutic treatment of ADPKD will be revealed.

Who or what will benefit from these outputs, and how?

In the short-term (3-5 years), the scientific research community (in particular researchers involved in cystic kidney diseases) will benefit from the outputs of the project. New targets for therapies to treat cystic kidney diseases (such as ADPKD) will be revealed, thus in the mid- to long-term (5-15 years) these targets will be able to be further tested with the aim to develop them for clinical application that will benefit patients with ADPKD and potentially other cystic kidney diseases.

How will you look to maximise the outputs of this work?

All data accrued in the project will be disseminated regardless of the outcome. This will primarily be in the form of scientific publication (preferably in high-impact open-access journals). To carry out the project I have already developed collaborations with world-leading researchers in the USA and Europe, and I will use their guidance and expert input to maximise the outputs from the work. The results of the work will also be of keen interest to other world-leading experts and I will interact with these individuals in the hope of fostering new collaborations and to ensure the results are disseminated to the widest audience. I am also passionate about disseminating the work to lay audiences, in particular to patient groups. To this end, I will present my findings to attendees at workshops setup by the UK PKD charity.

Species and numbers of animals expected to be used

- Mice: Up to 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse model is the most rigorous system to study ADPKD and is the most comparable to the human disease. The mouse model of ADPKD that will be used develops cysts in its kidneys in the first 4-weeks of life, and so this life stage will be used to carry out most of the investigations. A small proportion of animals will be grown to 6 months of age to determine the longevity of protection that integrin a1b1 depletion offers in the mouse ADPKD model. 6 months of age has been chosen as it is prior to the onset of kidney failure and liver damage that occurs in the ADPKD mouse model. This older time-point will permit comparative analysis of the effects that the presence or absence of integrin a1b1 has in ADPKD mice over a longer lifespan.

Typically, what will be done to an animal used in your project?

The mice will be bred and maintained using standard protocols. ADPKD mice will be crossed to a mouse strain that is depleted of integrin alpha 1. All mice to be used for data gathering will be killed using Schedule 1 methods at the desired life stage. Mice will also be genotyped, which will most likely be done by ear biopsy, or by sampling either the blood or hair, or by mouth swabbing.

What are the expected impacts and/or adverse effects for the animals during your project?

The ADPKD mice may experience kidney failure, liver damage, abdominal discomfort, kidney infection, and rapid weight loss due to cyst formation in the kidneys. These adverse effects are unlikely to occur as the ADPKD mice will be humanely killed at either 4-weeks or 6-months of age, prior to their onset.

The mice that are singly-deficient in integrin alpha 1 experience no adverse impacts and/or effects. The crossing of ADPKD mice to mice deficient in integrin alpha 1 is predicted to reduce the adverse effects present in the ADPKD mice, primarily by reducing cyst size and maintaining kidney function.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All strains that contain the ADPKD genotype will be classed as moderate severity due to the potential that these mice have the adverse effects described above. To reduce harmful effects, I will be mainly focussing my research on an early stage of life (4-weeks of age). At this time-point, the mice have developed cysts but have limited adverse effects as a consequence of their genotype. If ADPKD mice at 4-weeks of age show improvement in their symptoms as a consequence of deletion of integrin alpha 1, I will grow some mice to 6 months of age to test the longevity of protection that loss of integrin alpha 1 provides. Even at this stage of life, kidney failure will not have begun and other symptoms that are characteristic of ADPKD are not predicted to be experienced at 6-months of age. However, the ADPKD mouse model I am using can cause harmful effects, including abdominal discomfort, kidney infection, kidney failure, and other non-kidney abnormalities (such as liver and bile duct damage). This is why I am denoting the severities of the mice as moderate even though the life-stages I will use will minimise the number of mice that experience moderate severities.

The Integrin alpha 1 depleted mice are a mild severity.

For the experiments, inheritance is Mendelian and so a quarter of the mice used will have the adverse effects associated with the ADPKD mouse strain.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The integrin a1b1 receptor interacts with molecules in the outside of the cell that make up the extracellular matrix. The extracellular matrix is the term used to describe the proteins and other molecules that exist in the space outside of cells that makes up our body. The extracellular matrix is very important to overall health. In cyst formation, the extracellular matrix provides signals that enable cysts to grow in ADPKD. Non-animal models do not form an extracellular matrix that is present in animal models and so animals are required for this specific project. Non-animal alternatives do not have functioning kidneys that filter toxins out of the blood, and so do not allow for any changes in kidney function to be assessed. This is of paramount importance as ultimately, the maintenance of kidney function is the key outcome of any potential future therapy that involves inhibition of the integrin a1b receptor signalling.

Which non-animal alternatives did you consider for use in this project?

Pre-independent feeding zebrafish models of ADPKD

Spheroid cultures

Kidney organoids

Why were they not suitable?

Pre-independent feeding zebrafish models of ADPKD - No model of ADPKD is available in pre- independent feeding zebrafish that recapitulates the human disease. Zebrafish will continue to be used to understand the earliest stages of the disease and how molecular changes, caused by a loss of integrin a1b1, may benefit the disease progression. As such, the use of mice in this project licence application is a partial replacement for the work being performed in pre-independent stage zebrafish embryos.
Spheroid cultures - Spheroid cultures contain cells from a specific region of the kidney called the proximal tubule. However, they do not have flow and do not contain other structures important to the formation of cysts in a fully-formed kidney. As such, spheroid cultures cannot be used for functional analyses and are not comparable to the human kidney.

Kidney organoids - Kidney organoids are a highly valuable tool that have become an important part of the toolkit for many kidney researchers. However, they are restricted by the

fact that they do not filter blood because no bloodflow is present inside them. This means that no physiological functional analysis (such as observing if the kidney is working better) can be performed in kidney organoids. If the integrin a1b1 receptor is discovered to be a viable therapeutic target, kidney organoids might be best used to test specific therapeutic options.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

To get statistically significant results we require to perform a number of crosses as we will need to first cross the integrin a1 knockout mice to the ADPKD mice, and then cross these mice in order to begin getting the genotypes we require. Only 25% of the offspring will have the features of ADPKD.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As this project is based around breeding and maintenance, we have established a breeding plan that will yield the required numbers of mice with the smallest number of crossings.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding will be used to reduce the numbers of mice used in the experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project I will breed two mouse models. These are a mouse depleted of integrin a1 and a mouse ADPKD model. These mice will be crossed together to generate the mouse models required to test the involvement of integrin a1b1 in ADPKD. I will use efficient breeding and maintenance methods to yield these mouse models. Most mice will be humanely killed at 4-weeks of age as this is a time-point when cysts are present in the kidney of ADPKD mice but is before the onset of harmful adverse effects. Some mice will also be grown up to 6 months of age to determine the longevity of the predicted protection

that integrin alpha 1 depletion offers to ADPKD mice. The ADPKD mice I will use can live up to a year, but develop end-stage kidney disease from 9-12 months of age, therefore humane killing ADPKD mice at 6 months will minimise the pain, suffering, distress, and harm associated with this genotype.

Why can't you use animals that are less sentient?

No models of ADPKD exist in other, less sentient animal models (such as zebrafish).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Post-genotyping, all ADPKD mice will be monitored closely for adverse effects such as end-stage kidney disease, abdominal discomfort, kidney infection, dramatic loss of weight, and loss of appetite.

I have refined my experimental design to minimise the welfare cost to the animals. Most animals will be humanely killed at 4-weeks of age, and only a small proportion of ADPKD mice will be grown past this stage, these will be humanely killed at 6-months of age or earlier if signs of adverse effects are observed. This is prior to the onset of end-stage kidney disease and other serious extra-renal abnormalities. Furthermore, the 6-months of age protection experiment will *only* be performed if ADPK mice that have no integrin a1b1 receptor show reduced cyst size and improved kidney function at the 4- weeks life stage. This will minimise the welfare cost to the animals by not performing an experiment needlessly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs website (https://nc3rs.org.uk/3rs-resources) will provide invaluable information regarding best practice guidance, in particular with breeding and maintenance plans. The PREPARE guidelines will also be adhered to (https://norecopa.no/prepare). Their major theme is to ensure proper planning of experiments so as to reduce waste, promote alternatives, and increase reproducibility in research involving animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Consultation with the staff in the animal facility and with the NC3Rs regional officer will ensure advances in 3Rs are captured. All lab members will be required to use the online resources available at the NC3Rs website before beginning experimentation. In particular, the resources on breeding and colony management will be utilised (https://nc3rs.org.uk/breeding-and-colony-management).
Attendance at 3Rs workshops organised by the animal facility will be expected.

6. Strategies for the restoration of sight in retinal dystrophies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

retina, stem cells, photoreceptors, photoreceptor replacement

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Photoreceptors are the retinal cells in our eyes that transform light into electrical activity. Loss of these cells can result in severe vision impairment and blindness. New photoreceptors can be generated in the laboratory from stem cells. The main aim of this work is to test if the transplantation of new photoreceptors can bring vision back.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Recent estimates indicate that the global number of people with sight loss is 285 million, of whom 39 million are blind. Currently, there are no effective therapies to treat photoreceptor loss; therefore, there is a requirement for new therapies to replace the lost photoreceptors as proposed herein. The results from this work will allow us to test the effectiveness of photoreceptor replacement on the vision. The optimised methods from this work can then

be tested in higher models (e.g., non- human primates) and further translated into clinical trials for patients with photoreceptor cell loss and dysfunction.

What outputs do you think you will see at the end of this project?

We would like to see at least two high impact factor publications and at least 6-10 presentations/posters in national and international meetings during this project. We intend to optimise and define the best photoreceptor transplant strategy, which can then be translated in non-human primates and finally to human patients. With this in mind, we aim to be in a strong position to apply for funding to pursue early phase trials in human patients.

Who or what will benefit from these outputs, and how?

Blindness has a significant impact on the quality of a person's life often resulting in depression, social isolation and premature death. This poses a major burden to society due to lost productivity and earnings as well as the costs of treatment, rehabilitation and education of the visually impaired and provision of visual aids. Recent estimates indicate that the overall number of people with sight loss is 285 million globally, of whom 39 million are blind. Diseases affecting the retina account for approximately 26% of blindness. The final impact in retinal diseases is the loss of photoreceptors, a specialised type of photosensitive neurons that are capable of light processing. To date there are no treatments to restore lost photoreceptors and visual function, hence there is a pressing need for research into the replacement and/or reactivation of dysfunctional photoreceptors as proposed herein. Successful completion of this project will pave the way for producing and testing photoreceptor transplants in non-human primates and ultimately in human clinical trials. In view of this, the proposed research will benefit first and foremost the patients with retinal disease, their families and carers and society as a whole.

The proposed research will benefit researchers in the fields of retinal sciences in health and disease and clinical applications of vision restoration. Researchers will have an increased understanding of how newly transplanted photoreceptors restore vision in animal models of retinal disease.

Members of the research team will benefit from attending national and international conferences to disseminate results and to maintain existing collaborations and foster new ones. This work will also contribute to the training of several early-career researchers including state-of-the-art molecular, stem cell, and neuroscience and bioinformatics techniques. The proposed work will comprise the excellent further experience of cutting-edge scientific research for the researchers funded by this proposal, providing further development of their careers in academic biomedical research.

How will you look to maximise the outputs of this work?

We plan to disseminate our research findings by presentations at national & international meetings (ARVO Ophthalmic Research conference), Society for Neuroscience (SfN), European Retina Meeting (ERM) and FASEB Retinal Neurobiology and Visual Function meeting. Publication in relevant high impact journals will disseminate our data to academic audiences. We consistently publish original research papers, reviews, and commentaries in relevant journals (Nature Medicine, Stem Cells, Neuron, Nature Communication, Cell Reports, and Biomaterials). We organize national and international networks and societies and maintain regular engagement with patient charities (Macular Disease Society, Fight for Sight, Retina UK, Yorkshire Eye Research, British RP Society and Northern Alliance)

during patient-focused research days. Our Institute and research themes run external and internal seminar series, to which we invite collaborators and experts to present their work and to develop collaborations. Through these meetings and informal contacts, we will maintain existing and foster new collaborations with academic and clinical researchers. We will present at meetings that mark Rare Disease Day, Retina UK information days and we plan meetings to continue discussion of inherited conditions and medical research organised by the Biosciences Institute Public Engagement Committee several times per year. We will contribute to public engagement activities organised by International Centre for Life at Newcastle, British Science Festivals and other university Research Days as well as the charities working in this area (Retina UK, Fight for Sight etc).

Species and numbers of animals expected to be used

- Mice: 613

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of mammals is essential, as the retina of most other species either differs substantially from the human retina from a structural/functional point of view or is too small to allow reliable subretinal cell injections (e.g. zebrafish). Easy breeding and fast development (especially compared to primates) makes mice a valuable tool for performing multiple experiments in which various parameters can be measured with sufficient statistical power within a relatively short time span. Results can then be translated to higher models (for example non-human primates) where animal numbers used for research are lower due to slower development and longer lifespan as well as cost and various ethical considerations. Mouse models of retinal degeneration are widely used to study retinal pathologies and the models to be used in this proposed project have been well characterised by many scientific groups including ours. These studies have shown that these models mimic very well the photoreceptor loss incurred in retinal disease in humans, justifying why they provide the ideal model to perform transplantation-based studies of vision restoration.

Typically, what will be done to an animal used in your project?

The animals will be purchased from commercial suppliers or obtained from collaborating labs. Following a period of settlement in our animal facility, photoreceptors will be transplanted in their retinas under general anaesthesia. The animals will be immunosuppressed to stop human cell rejection. Approximately 50% of transplanted mice will be used to investigate how well the new photoreceptors have settled into the mouse retinas. The other 50% will be implanted with a head fixation device and up to two recording chambers. A tracer construct will be injected in their brain visual areas to enable the assessment of light-driven brain activity at the later stages. Behavioural tests (e.g., light avoidance, optomotor reflex and visual cliff), electrophysiological recordings and/or 2-photon microscopy will be carried out on transplanted animals and controls. The animals will be sacrificed at the end of these recording sessions to enable tissue collection for further assessment of cell engraftment in retina and visual activity in brain. Some of the

animals will be dark adapted before sacrifice so their retinas can be used for ex vivo electrophysiological recordings using high density microelectrode arrays.

What are the expected impacts and/or adverse effects for the animals during your project?

From our previous experience we anticipate that adverse effects due to surgical complications (< 1%: duration 3 days), anaesthesia (1%, duration 3-4 hours), fluid control (< 1%: duration 5 days), injection of genetic construct (1-5% 7 days), implantation of head fixation, indwelling electrodes or recording chambers (1-5%: duration 7 days), stress during behavioural training (~10%: duration 2 days) or recording chamber infection (~10%: duration 7 days) and loss of implant following implantation (5-10% depending on how long the implant has been implanted) may occur. In our recent projects performing subretinal cell injections we have not observed tumour development, abnormal behaviour, weight loss of any other signs of animal distress due to subretinal cell injections. Adverse effects due to surgical complications can be bleeding or infection/inflammation of the wound margin following surgery with associated tenderness and changes in behaviour and body scores. Changes in behaviour and body scores will be monitored as described in our score sheets included in each Protocol. Complications due to anaesthesia can be reduced body temperature and/or slow recovery from anaesthesia.

Complications from implantation of head fixation, indwelling electrodes or recording chambers can be infection/inflammation following surgery with associated tenderness and changes in behaviour and body scores (monitoring see above). Injection of genetic constructs could result in intracerebral bleeds, which could result in changes in behaviour and body scores (monitoring see above). Stress during behavioural training can result in agitation and post testing behavioural changes and body score changes (monitoring see above). Recording chamber infection can occur after implantation and can result in behaviour and body score changes (monitoring see above). Loss of implant would result in exposed bone with possible infection but would always result in termination of the animal. All procedures are of mild or moderate severity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for both subretinal injections and in vivo electrophysiological cell characterisation is moderate. 95%, 85% and 100% of the animals will undergo this severity in Protocols 1, 2 and 3 respectively.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Both the photoreceptor engraftment and light processing through the eye to retina, optic nerve and finally to visual cortex cannot be performed in vitro, thus in vivo investigations are required to answer these questions. Recording from isolated retinas will allow us to assess restoration of light responses in retinal ganglion cells, the output cells of the retina. It will give us important information on the nature of retinal receptive fields, the range of light sensitivities, and perhaps even colour perception. These experiments cannot be performed on patients, but their outcome will provide extremely valuable new knowledge, paving the way for future clinical trials.

Which non-animal alternatives did you consider for use in this project?

We have considered application of retinal organoids as a non-animal alternative.

Why were they not suitable?

Non-animal alternatives are not possible because we work with neural networks involved in visual processing (both at retinal and cortical levels), which can only be investigated in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals was calculated based on experimental design in our funding application to MRC and power stats performed in collaboration with chartered statistician. We have also considered possible losses due to anaesthesia (1%), corneal oedema (7%), surgical complications (1%), subretinal cell injection (20%), fluid control (< 1%), injection of genetic construct (1-5%), implantation of head fixation, indwelling electrodes or recording chambers (1-5%), stress during behavioural training (~10%) or recording chamber infection (~10%).The animals that cannot be used for surgery (for example due to corneal oedema) will be used as controls for immunofluorescence studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have performed pilot studies which have shown that 80% of subretinally transplanted mice display engraftment of cone precursors. Of these, 50% of the mice, perform the behavioural tests and 33% of the latter show light sensitivity in at least one eye. These pilot data were used for power calculations performed in close collaboration with chartered statistician, enabling us to assess accurately experimental group size (see below).

Reproducibility and Statistical Design Annex

This proposal will make use of animal models for investigating the engraftment of rod and/or cone photoreceptors and RPE and their ability to restore vision.

To investigate the engraftment of hESCs-derived rod precursors alone and/or in combination with hESC-derived cone precursors and hESC-derived RPE cells at the early and advanced stages of retinal degeneration. The number of mice for each transplanted group is based on our current data with subretinal injections of CRX-GFP+ precursors obtained from day 90 retinal organoids, indicating an 80% success rate in cell engraftment (PMID: 33657251).Given this pilot success rate, to test for a >50% success engraftment rate at a 90% power with a type 1 error rate of α=0.05, a total of 20 animals per group is needed (1 tailed test of proportion, normal approximation).

To assess the impact of hESC-rod transplantation alone and/or in combination with -cones and -RPE cells to restore vision at the early and advanced stages of retinal degeneration. To calculate the number of mice for each group, we rely on our current data, which show that 80% of subretinally transplanted mice show engraftment of CRX-GFP+ precursors. Of these, 50% of the mice, perform the behavioural tests and 33% of the latter show light sensitivity in at least one eye. The number of mice in each class (failed engraftment; engrafted and fail behaviour; engrafted, pass behaviour with no light sensitivity; engrafted, pass and show light sensitivity) are modelled by a multinomial distribution and the marginal distribution of mice that have engrafted cells, perform behavioural tests, and have light sensitivity in at least one eye is binomial with probability 0.132. Our current experience also indicates that 10 mice are needed to obtain sufficient data for recordings from the visual cortex. This procedure requires injection of a AAV5.Syn.GCaMP6f.WPRE.SV40 constructs at multiple sites in V1 and has ~80% efficient (including the follow up transparent window implantation) in our hands, thus requiring 12 injected mice to end up with 10 for visual recording. To obtain an average number of 12 mice that fulfil all the above, a sample of 90 mice is needed. The table of the chance of seeing 6 or less, 7 to 14 and 15 and above is below for one experiment when starting with 90 mice. The combined chance of seeing 7-16 responders is 88%.

Mice	Expected %
6 or less	3.6
7	3.9
8	6.2
9	8.7
10	10.9
11	12.1
12	12.3
13	11.3
14	9.6
15	7.5
16	5.4
17 or more	8.5

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to improve the method and efficiency of our transplant protocol. To achieve this, we will keep track of relevant literature in this field reporting on transplant volumes and methods. On the day of transplant, we use a multi team approach where one member performs cell sorting, the second transports the cells to the facility, counts cells and loads them to syringe, thus speeding up the procedure and ensuring cells are not clumping. The third and fourth members of the team will administer anaesthesia and perform subretinal transplants as well as animal monitoring. We will continue to improve this technique and ensure that the cell sorting and prep facility is adjacent to the animal transplant rooms. We will test the effect of hydrogels on cell survival and engraftment with the aim of improving transplant efficiency and reducing animal numbers. We will also share tissue between projects so we can maximise outputs from animal procedures and minimise numbers of animals used. We will work closely with the colony management team to reduce numbers and employ efficient breeding strategies and where possible, we will use both male and female mice to minimise numbers. To maximise animal usage, we will perform several tests on the same animals (e.g., light avoidance, visual cliff, optokinetic reflex, 2-photon imaging), although these will be carefully planned and not performed at the same time.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most experiments will be performed on genetically modified mouse models of outer retinal degeneration (ORD). The mouse models we plan to use are well recognised for faithfully representing common human ORD disorders and therefore, they will provide important new knowledge about how to rescue or repair retinas with advanced ORD.

The protocols have been designed to keep suffering to a minimum. Where subretinal transplants, tracer injections and recording chamber installation will be carried out, appropriate anaesthetics and analgesics will be administered pre- and post-operatively. Any loss of condition will indicate removal from the procedure and killing by a Schedule 1 method. To define loss of conditions, we will use a score sheet (supplied within each protocol), which considers several features including piloerection, decreased activity, abnormal posture, weight loss, movement impairment, and eye grooming.

All the team members involved in subretinal injections will be trained appropriately by the Vet team and existing team members/collaborators with expertise in this technique. This will ensure competency demonstration which will feed into good animal welfare and consistent animal experience. We will work closely with the Vet team to ensure we are up to date with refinements and improvements in the surgery and anaesthetic protocols.

During the surgery, we will monitor temperature and keep mice close to the oxygen mask until they recover and start to move. Once the surgery is completed, we will monitor animals closely using the animal facility anaesthetic monitoring sheet.

Transplants will be performed using cells that have been differentiated at least for 60 days ensuring that virtually all stem cells have differentiated into retinal cells. To date, we have not observed any tumour formation, but if this occurs, we will work closely with the vet team and report these animals under condition 18.

Why can't you use animals that are less sentient?

Retinal degeneration occurs over many years in humans; hence, less sentient animals cannot be used as they do not mimic the retina of an adult person. Behavioural tests require in vivo interaction with the environmental stimuli, hence terminally anaesthetised animals are not suitable.

We considered use of alternative animal models, for example zebrafish. Zebrafish models are inappropriate for several reasons: 1) the zebrafish eyes are much smaller compared to mice (radius of retina 1 mm by 13 weeks), hindering subretinal cell injections; 2) although zebrafish models of retinal degeneration exist, all retinal layers are compromised, which prevents studies of photoreceptor integration with host cells that is critical for our studies; 3) zebrafish models of retinal degeneration are very fast and do not mimic the mammalian stagewise differentiation of retinal degeneration observed in mouse models and human patients that underpin the success of donor photoreceptor cell engraftment.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will apply immunosuppression to avoid rejection of transplanted human cells. The immunosuppressant will be administered orally instead of multiple daily injections or inserting mini pumps. We will keep mice in barriered facilities to reduce the likelihood of infections and use anaesthesia during surgical procedures. We are generating in the lab photoreceptor cells that are less "visible" to the host's immune system, thus some animals will be transplanted in the absence of immunosuppression, which has beneficial effects for long term welfare. Best analgesic regime will be optimised in consultation with the vet team and applied before and after the surgical procedure, to reduce pain and suffering. We will use heated pads during anaesthesia and heated cabinets to help with the animal recovery and soft bedding in all cages. Furthermore, to reduce trauma related to surgery, we will use habituation jelly a few days before the surgery. Following the surgery, buprenorphine jelly will be given with the food to avoid additional injections. We have established end points for all adverse effects to reduce animal suffering (please refer to the score sheet supplied with each Protocol).

To minimise infections, we will maintain sterile conditions in our cell preparation methods. Sterility of cultures is checked monthly using established methods. The injection needle is used for one animal and then washed thoroughly in ethanol and PBS before being reused on the next animal.

All animals are expected to make a rapid and unremarkable recovery from the anaesthetic within three-four hours. Uncommonly animals that fail to do so or exhibit signs of pain, distress or of significant ill health will be assessed by the researcher and the NVS and will be humanely killed by a Schedule 1 method unless a programme of enhanced monitoring and care is instituted until the animal

fully recovers. Any animal not fully recovered from the surgical procedure within 24 hrs (eating, drinking and return to normal behaviour) should be humanely killed. Post- surgical assessment will involve waiting the animal to fully recover after the surgery and daily checks for the first week post-surgery. Afterwards the animals will be regularly assessed by experienced competent animal staff members to monitor for signs of reduced welfare, and if these arise, we will consult the NACWO and NVS for potential treatment and determination of potential endpoints.

For 2-photon imaging animals tunnel handling already established under the AWERB standards will be introduced.

For all models and optional procedures good practice guides will be used to help refine the model as described in the ARRIVE guidelines and Laboratory animal's special article. LASA Working Party guidelines on assessment and control of severity will be used throughout the project to determine if any animal is suffering distress. Should distress occur, immediate actions as described in the individual protocols would be taken to reduce an animal suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all models and optional procedures good practice guides will be used to help refine the model as described in the ARRIVE guidelines and Laboratory animal's special article. LASA Working Party guidelines on assessment and control of severity will be used throughout the project to determine if any animal is suffering distress. Should distress occur, immediate actions as described in the individual protocols would be taken to reduce an animal suffering.

We will follow our statistical design and submit study plans of experiments. We will collaborate closely with NAWCO, NVS and the animal facility staff to ensure best practice. All data will be kept in lab books and university secure servers. Analysed data will be included in our open access publications. We will keep a close eye on emerging publications to avoid duplication of work.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have received funding for our work from NC3Rs and thus obtain regular communications by email about new advances in the 3Rs. We also participate and present in NC3Rs conferences and take part in the regular events (webinars, lunch time seminars etc) organised by our animal facility. We maintain regular contacts with the veterinary team and thus are in a good position to implement advances effectively during the project. We will follow closely work in this field through publication readings, meeting with collaborators and conference participations to ensure we are up to date with refined methods on subretinal cell injections and animal welfare.

7. Aquatic toxicity assessment of chemicals with no or low water solubility

Project duration

2 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

dietary exposure, acute and chronic toxicity, maternal tranfer, pre-regulatory, chemical hazard assessment

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to address two key challenges in environmental hazard assessment

The development of a fish test for assessing the aquatic toxicity of chemicals with very low solubility in water (via application of dietary exposures in a series of international OECD test guidelines relevant to regulatory fish toxicity assessment)

A comprehensive toxicity assessment of Dechlorane Plus (one of the chemicals that present very low water solubility) in two generations of fish.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The current regulatory tests for environmental chemical hazard assessment in fish are based on waterborne exposures (e.g. TG203, TG210, TG229, TG230, TG234, TG236). However, many potentially toxic chemicals are highly hydrophobic/lipophilic and therefore present a practical challenge for conducting aquatic animal exposures. In such cases, high volumes of solvents need to be used to achieve solubility or the test fails to meet the acceptance criteria relevant to maintenance of chemical dosing. Solvents present a challenge for discriminating toxicity between the substance in question and the solvent used and in addition, compromise animal welfare. Test failure is resulting is animal wastage. It is therefore important that we address two of the 3Rs (namely reduction and refinement) whilst allowing a sound assessment of chemical toxicity.

Global (including UK) regulatory authorities require chemical toxicity data from vertebrate test systems, including fish, to identify, mitigate and manage any adverse environmental effects arising from their use. The current regulatory tests for environmental chemical hazard assessment in fish are based on waterborne exposures (e.g. TG203, TG210, TG229, TG230, TG234, TG236). However, many potentially toxic chemicals are highly hydrophobic/lipophilic and present a practical challenge for conducting aquatic animal exposures. In such cases, high volumes of solvents need to be used to achieve solubility or the test fails to meet the acceptance criteria for maintaining chemical dose.
Solvents present a challenge for discriminating toxicity of the test substance from the solvent used and may additionally compromise animal welfare. Test failure is resulting in animal wastage. It is therefore important that we address the 3Rs (in this case Reduction and Refinement) whilst allowing a sound assessment of chemical toxicity.

To date, the practical difficulties of conducting aquatic risk assessment for chemicals with no or low solubility in water are acknowledged in only one regulatory test guideline, the fish bioaccumulation test (OECD TG305). Here, for chemicals with a water-octanol coefficient (Kow) >6, a dietary route of exposure is recommended in lieu of aqueous; The Kow is an excellent proxy for hydrophobicity (or lipophilicity). TG305 however, is designed to provide information on chemical bioaccumulation potential alone and does not allow toxicity assessment. In all other acute or chronic regulatory toxicity tests, the dietary exposure option is not present. This creates an issue for regulators considering information from the public domain which often suggests toxicity levels are well above the solubility limit of the chemical.

We intend to develop and subsequently validate a new test method for these substances, which combines the principles of dietary exposure as described in TG305 but also allows toxicity assessment as required by relevant regulatory tests. The model is based on the likely transfer of lipophilic chemicals to the developing embryos via the fish gametes (sperm and eggs). In this way, exposure of the second generation during critical developmental windows, can be achieved via natural transfer rather than the problematic, high solvent-based, aqueous route. This approach would allow toxicity assessment at early life stages, which are critical for environmental risk assessment, as well as chronic toxicity to juvenile and sub-adult stages. For the purposes of test development, it is critical that comparative data between dietary and waterborne exposures are generated. This is because all environmental quality standards are currently based on water (rather than biota) concentrations.
The project aims to combine the principles of existing regulatory guidelines to address two key challenges in environmental hazard assessment: 1) the application of an environmentally relevant route of exposure for highly hydrophobic/lipophilic chemicals (via

dietary exposure of pre-adult fish) and 2) the comprehensive assessment of toxicity of Dechlorane PlusTM (DP) in two generations of fish.

DP is very strongly hydrophobic (Kow above 6) and thus an extremely poorly water-soluble compound. Screening models indicate that DP has a long environmental half-life in water or soil and therefore meets the Persistence criterion of the Stockholm Convention and REACH legislation. As lipophilic compound with a molecular weight below 700, it furthermore has a potential to accumulate in the food web and magnify through trophic levels, thereby are also meeting the Bioaccumulation criterion of the Stockholm Convention.

The third and final criterion for listing a substance as a Persistent Organic Pollutant (POP) under the Stockholm Convention is Toxicity. There is a lack of acute, chronic and sublethal toxicity results for dechloranes, particularly for aquatic organisms. Data on DP toxicity are also scarce; the few available data suggest a low acute toxicity for wildlife or humans. In 2019, Norway submitted a proposal to the Stockholm Convention to list DP as a POP, however, given the lack of evidence on DP toxicity, further evidence is required on which to base a decision.

This project application therefore addresses a long term need to assess aquatic toxicity of chemicals with low solubility on water (aiming at creating an OECD international test guideline following future validation) and a short term need to obtain evidence of chronic toxicity of DP.

What outputs do you think you will see at the end of this project?

The main output of this project will be the development of a comprehensive method to assess the aquatic (fish) toxicity of chemicals that are practically insoluble in water (yet require regulatory aquatic risk assessment), thereby protecting animal health and improving environmental quality. More specifically and additionally the project will result in:

- A comprehensive assessment of chronic toxicity of Dechlorane Plus (DP), a chemical that is practically insoluble in water but currently under consideration for classification as a POP (Stockholm Convention).

- A UK-led request to the OECD seeking to update a number of fish toxicity regulatory tests for chemicals of no or low water solubility. The dietary route of exposure is both environmentally relevant and will allow sound assessment of all chemicals of no or low solubility, improving test animal welfare (via reduction of solvents) and reducing test animals used (by avoiding failures to meet dosing criteria).
- A thorough investigation of biomarkers in fish embryos (unregulated life stage) that could be used, following the principles of Adverse Outcome Pathways, as early markers of chronic apical endpoints as required for regulatory decisions.

Who or what will benefit from these outputs, and how?

The immediate primary beneficiaries will be the global Environment Agencies.

If the results of this project provide a solid basis for updating a number of test guidelines, then additional beneficiaries will include global regulators and industry who are required to submit the studies.

Ultimately the project looks to improve future hazard and risk assessment of toxic

chemicals in the environment, aiming to protect both human and wildlife health.

How will you look to maximise the outputs of this work?

The applicant is a member the OECD's Validation and Management Group for Ecotoxicity (VMG-Eco), thereby working with the relevant international force that oversees regulatory test guideline development. Following review of the projects' data, a decision will be made on recommending and implementing guideline updates which will benefit regulators and laboratories generating toxicology data in the UK and across the world. In addition, the test design and information on practicalities and benefits will be published in the peer review literature.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Given the properties of chemicals with low water solubility, exemplified by DP, the main route of exposure to fish can only be via the diet; hence we need to use fish that are capable of independent feeding and employ a dietary route of exposure as suggested for chemicals with high Kow in TG305 (the fish bioaccumulation test).

Data on bioaccumulation and toxicity can be produced for the F0 adult fish (sexually mature) and their offspring (F1), up until they reach sexual maturation. It is important to address toxicity in all these life stages as bioaccumulation (and thus toxicity) is likely affected by the dynamic transport of lipophilic chemicals to the developing gametes; hence a lower toxicity is anticipated in sexually mature fish that can shed the chemical via spawning and a higher in pre-adult life stages.

Typically, what will be done to an animal used in your project?

The project involves feeding fish with contaminated diet or exposing fish to the test substance via the water, at a series of concentrations to establish a dose response curve. The duration of exposure will largely follow existing regulatory test guidelines. Following exposure of the F0 generation (adults), the duration of the dietary and waterborne exposure of their offspring (F1 generation), will vary depending on toxicity outcomes. Exposure of F1 generation will continue until sexual differentiation can be assessed with animals briefly anaesthetised at 30dph and/or 60dph to collect weight and length information. We do not expect any adversity at this step other than the stress induced by brief general anaesthesia and recovery. The maximum exposure duration of both the F0 and the F1 generations will be 90 days. At any point of either dietary or waterborne exposures if mortalities/moribundities exceed 20% of what is accepted in the controls as prescribed in the test guidelines these treatments will be terminated. All fish sampled will be killed.

What are the expected impacts and/or adverse effects for the animals during your

project?

On the basis of the available literature, we expect the adverse effects to be mild as chemicals with low solubility in water are typically eliciting chronic, not acute, toxicity. In addition, we intend to use primarily environmentally relevant concentrations, rather than pharmacological doses.

However, given the bio-accumulative nature of hydrophobic/lipophilic chemicals, which is the focus of this project application, we may encounter moderate toxicity as the exposures continue. The clinical signs are difficult to anticipate without any pre-existing information on toxicity and will vary depending on the chemical and/or life stage. For example, we anticipate that accumulation may be higher in juvenile fish towards the end of planned exposures as they don't have the capacity to shed the chemical via spawning. We anticipate additional observations at these later stages and according to the clinical signs detected.

Weight loss, lethargy, abnormal behaviour, altered fecundity and tumours are potentially expected. Death is neither indicated as an endpoint nor anticipated, although there may be cases where high bioaccumulation may result in high internal exposures and potentially death. This is expected to happen only in a small number of fish used as most concentrations employed will be within environmentally relevant levels.

To ensure impact and adversity are kept low/moderate, if mortality/moribundity is >20% of controls at any treatment group, the exposure at this level will be terminated.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity is anticipated to be mild for over 50% of the fish used and moderate for up to 50% of the fish used.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The information this project application is seeking is relevant to fish toxicity; therefore, replacement options are limited to methods that are relevant to fish, excluding for example invertebrate models. It is important to note that the currently available data for DP is for fish, and it is this that really provides the potential concern being put forward by Norway. Therefore, to investigate that we need to use the same taxa, and ideally same species (which we are). The need to use animals stems also from the physico- chemical properties of the chemicals in question, high hydrophobicity and lipophilicity, which suggest that a)

the route of exposure is long term, most likely via the diet and b) potential toxicity is chronic. To date, there are no alternative methods to assess chronic toxicity in fish only acute toxicity.

The planned work includes a comprehensive list of investigative endpoints at the embryo stage (TG236), which if validated as predictive of apical endpoints, can remove the need for using fish beyond this stage, ultimately reducing substantially the numbers of fish needed for toxicity assessment. This includes next generation sequencing and full metabolite profiling of embryos, along with behavioural assessment and apical points (hatching, survival, heartbeat, developmental abnormalities). This powerful approach will advance New Approach Methodologies (NAM's), providing evidence replace downstream chronic toxicity regulatory endpoints, with early, predictive makers of exposure and adversity.

Which non-animal alternatives did you consider for use in this project?

We considered TG236 (fish embryo toxicity test) and TG249 (Fish Cell Line Acute Toxicity - The RTgill- W1 cell line assay)

A key project aim is to investigate early and predictive markers in the embryos (we will heavily employ the design of TG236 in our investigations) that can ultimately be used for chronic toxicity assessment replacing fish in the future.

Why were they not suitable?

Non-animal alternatives are not suitable for two reasons:

they are designed to assess acute, not chronic toxicity, which this programme intends to achieve.

low water solubility requires unrealistically high solvent levels, which present toxicity issues for both embryos and cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This project is looking at test design that is suitable for regulatory purposes. The factors that were considered in deciding how many fish will be used included:

- The range of concentrations required for establishing a dose response curve (typically 5 although we will consider 3 as a proof of principle)

- Satisfying the numbers of fish used in current TGs for chronic toxicity (including endocrine disruption) to allow future regulatory acceptance

- The variability in assimilation of the chemical into food and subsequent vitellogenin to allow maternal transfer to the embryos

- The fecundity of the species used

- The analytical capability to measure internal concentrations of the chemical in fish tissues (including pools of embryos)

- The current inability to predict chronic toxicity and as such the duration of exposure for the second generation (as required by the current regulatory tests)

The need to generate comparative data between dietary and water exposures as means of anchoring toxicity outcomes using internal concentrations and informing risk assessment which is based on water concentrations.

The potential need to employ additional chemical exposures including positive and negative control chemicals or chemicals that can be diagnostic of mode of action (i.e. co-exposure with antioxidants if oxidative stress is evident from biomarkers of exposure).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental design is limited by the prescriptive nature of regulatory OECD test guidelines that allow chronic toxicity assessment. It is key that we provide data that are comparable with these tests as their primary use involves the UK regulatory authority whilst the overall aim is to update TGs (via development of a dietary route of exposure) that will be acceptable by all global regulatory authorities. This can only be achieved if the experiments are robust enough within the current regulatory framework.

A significant reduction of animals is achieved by the addition of a small diversion from the regulatory test guidelines. To obtain length and weight data compliant with a full set of regulatory endpoints; rather than adding additional fish numbers to experiments to enable lethal sub sampling, at critical timepoints fish will be lightly anaesthetised measured and then returned to the experiment until the subsequent timepoint or the end of the experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
Maximising information from the exposures including clinical signs and -omics data (transcriptomics via next generation sequencing and metabolomics) that can be used subsequently to generate information for an Adverse Outcome Pathway (AOP).

The use of zebrafish, a highly accepted regulatory species and a combination of regulatory tests to avoid extensive needs for further validation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We propose to use a fish species that is a recognised model for regulatory tests for chemical hazard assessment. Zebrafish are recommended and validated for almost all regulatory tests and in addition, most of the available data thus far on DP toxicity are on zebrafish.

Zebrafish are easy to handle, are highly fecund, reach sexual maturity withing 4 months and highly amendable to laboratory culture. In addition, they enjoy many existing resources (full genome sequencing and annotation), facilitating the development of adverse outcome pathways.

The methods will be a combination of existing regulatory tests to allow easy interpretation of data and avoid the need for excessive further validation.

Why can't you use animals that are less sentient?

Because fish are a key phylogenetic group in chemical risk assessment and can also provide information that is relevant to human health, given the highly conserved toxicity pathways amongst vertebrates. This project requires the use of each development stage from embryo to adult and the long term dietary route of exposure negates the use of terminally anesthetised animals.

Besides, fish are often considered less sentient in comparison to "higher vertebrate" species, so the optimum choice within protected vertebrates.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures employed (dietary and/or aqueous exposures to chemicals) are mild in nature and so are the anticipated harms. Toxicity is the only harm that is anticipated but can't be currently predicted as we have little information on the mode of action for most chemicals. The following steps are in place to ensure refinement:
Daily observations (a minimum of two but if signs of toxicity are evident this will increase to a minimum of three) of fish appearance, behaviour and clinical signs via a comprehensive list as developed by the applicant's team for TG203 (see OECD TG203, 2019, Annex).

Application of moribundity in lieu of mortality as an endpoint of chronic toxicity. This is defined by the number and severity of clinical signs.

Termination of exposures in treatments where mortality (moribundity) exceeds acceptable levels by 20% at any point during exposures.

Application of dietary exposure as the **primary exposure route** to avoid the use of high solvent levels, as the latter present potential welfare issues.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The applicants team aspires to apply fully the 3Rs principles in their scientific use of

animals. Some key literature that is relevant to the programme and is guiding our experimental approaches is listed below:

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This body of work is improving current test methods and developing the next steps to meet future regulatory needs and minimise animal use. Engagement with the regulator and up to date good practice on animal welfare, chemical toxicity and regulatory needs will be maintained over the project through close links with the NC3Rs and the OECD Extended Advisory Group for Molecular Screening and Toxicogenomics (EAGMST), a key force that is providing modern tools for the 21st century toxicology needs. In this context a successful outcome would both refine the testing required and reduce the number of fish used by predicting chronic toxicity outcomes via early molecular initiating events.

8. Surgical Models for Supply in Rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Surgery, Rat, Mice

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to supply high quality surgical models in rodents for use within our orginisation's UK sites. In addition, we aim to bring existing surgical models 'in house' to allow for refinement of these models for use on regulatory and discovery studies. Having a central site for this work will mean that we can refine and improve these models efficiently and produce high quality surgically prepared animals for use on our UK sites.

These surgical models will only be supplied to other projects, within our UK orginisation with authority to use them.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will allow a centralised surgical service to provide many of the research models required to carry out the regulatory and efficacy work undertaken at our UK sites. A lot of the models we will produce are required for studies that regulatory authorities need to prove a drug is safe to take, or a chemical is safe for use by humans.

What outputs do you think you will see at the end of this project?

The outputs will be high quality surgical models for use on studies required by regulators, and other studies supporting this aim. This will help our customers progress their drugs into clinical trials, or prove the chemicals they produce are safe to be used by the public. It is possible that any surgical model refinements that come out of this project may be published and shared with the wider scientific community, to enable better surgical techniques/aftercare to be performed and thus better animal welfare.

Who or what will benefit from these outputs, and how?

Centralising small animal surgery at one site will enable us to get a better overview of our small animal surgical services in terms of quality, monitor any issues, apply refinements and improvements in the overall quality of the models, which benefits animal welfare. Customers will ultimately benefit from these outputs as the surgical models will enable them to develop their drugs, prove they are safe for clinical trials, and show that chemicals do not have harmful effects to the public, thus enabling them to sell their products.

How will you look to maximise the outputs of this work?

These models will be used in studies that will inform customers who will, in turn, use it to determine their future strategy, or for submission in documents required by regulatory authorities. These models will be used by our customers in studies to support drugs progressing to clinical trials, or to show that a certain chemical is safe for human exposure, for example. We have previously collaborated with customers and shared data we have produced in the form of scientific publications that are in the public domain. We will follow NC3R's guidelines throughout (National Centre for Replacement, Refinement and Reduction of Animals in Research).

Species and numbers of animals expected to be used

- Mice: 1900
- Rats: 8000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Adult animals will be used in this project, as the testing these animals are being prepared for requires adult species. Rodents are considered to be of the lowest neurophysiological

sensitivity that will allow us to achieve the study aims while being considered suitable for the prediction of effects in humans.

Typically, what will be done to an animal used in your project?

Typically an animal will be surgically prepared under a general anaesthetic for use in another project. These surgical preparations will differ depending on the specifics of the study the animal will be subsequently used in. These surgeries include removal of the reproductive organs, the implantation of a cannula to allow administration of test materials, the implantation of a device to allow measurement of blood pressure and heart rate, and cannulation of the bile duct.

Before surgery, the animals will be administered pain relief and possible antibiotics prior to being anaesthetised. After the surgery, the animals will also be given pain relief and maybe antibiotics. They will be initially kept in a warm environment, and may be given special food and water to help their recovery. They will be closely monitored until they show they have recovered. Veterinary guidance will be sought when planning the drugs required for pain relief. After the animals have recovered from the surgery, and a vet is happy with their condition, they may be transferred to other UK projects. Some animals may need to be transported by road to do this. This transfer will be undertaken in appropriate vehicles and under any applicable government regulations. Animals will be transported securely, with food and water provided, in a temperature controlled vehicle. The duration of transport will be the minimum required to deliver the animals safely.

What are the expected impacts and/or adverse effects for the animals during your project?

Surgical procedures in rodents can result in some adverse effects such as bleeding/blood loss, post- operative pain and weight loss. Most animals have recovered their pre surgical bodyweight fully or partly within 72h of surgery ending. Bleeding is minimised with good surgical technique by an experienced surgeon. Post-operative pain is negated by administration of pre and post-surgical pain relief. If transport is required we will make sure that the animals have recovered sufficiently from their surgical procedures, and have enough food water and bedding for the journey. We will also ensure we transport the animals via the most appropriate direct route, resulting in the shortest possible journey time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals will experience moderate severity. All animals who undergo a surgical procedure are deemed to have undergone moderate severity by the government.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Surgically altered animals have physical transformations (e.g. implants of catheters/devices or removal of tissues) which can currently not be achieved by chemical or other means. The need to use surgically altered animals will be established as part of the justification process before each internal request is accepted. The internal customer will be requested to provide the required information and relevant sections of their Project Licence prior to surgery being started.

We will be providing animals for projects where replacement has already been considered through the ethical review process of the receiving project licence to which the animals will be transferred.

Which non-animal alternatives did you consider for use in this project?

There are no non-animal alternatives to these surgical models. Surgical models cannot be modelled in a test tube or other non-animal model.

Why were they not suitable?

Some of these surgical models are required by regulators after non animal alternatives have identified issues with drugs or chemicals which mean they need to be tested in an animal model. Some of these animals will also be required to test drugs to prove they are safe prior to testing in clinical trials. These types of studies require this testing by law.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers we have used are based on figures of previous usage from previous projects, or a projection thereof (based on estimated incidence) based on requests received from customers in the past. It is, however, impossible to accurately predict the number of studies that may be performed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Surgically altered animals will only be supplied to specific numbers and orders.

As animals surgically altered under this licence are supplied to a specific request, the principles of experimental design will have already been addressed by the receiving AWERB (local ethical review process).

The numbers of animals produced to fulfil the order and to achieve the scientific aims will be kept to a minimum. Success rates of each model will be under periodic review to ensure that only the minimum number of animals will be implanted. The number of animals surgically prepared will aim to ensure that the study can be completed, allowing for patency issues (i.e. blocked catheters) and other issues that might prevent dosing or sampling. By monitoring closely the success rates of each surgical model we can reduce the number of animals implanted while still ensuring study completion, without the need to repeat a whole experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

High levels of surgical skill, aseptic techniques and pre and post-operative care will minimise any losses during surgery procedures.

Animal welfare is of utmost importance and Good Surgical Practice will be observed for any animal undergoing surgical procedures. Surgery will be conducted using aseptic techniques (to prevent infection) which meet at least the standards set out in the Home Office Minimum Standards for Aseptic Surgery.

Before we start surgery, we agree with a Veterinary surgeon what pain relief or antibiotics are appropriate, both before and after the surgery. When recovering from surgery, we give the animals extra heat and monitor them closely until they display normal behaviours. We then check them at least twice daily before they go on study.

In addition, care is taken to provide as much environmental enrichment as possible . This might include plastic shelters in their cages, blocks to gnaw on, extra bedding for warmth and if they need it, food supplements after surgery.

Surgical procedures will be carried out in accordance with the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017). All surgeons will be trained and designated competent by another surgeon who is already competent to assess a specific technique. This will be reflected in their training records.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species and animal model used under this project licence is research demand driven and authorised in the receiving project licence. Materials and methods will be chosen which allow the animals to be as mobile as possible, high standards of enrichments will be provided and the animals will be group housed wherever possible.

The choice of surgical technique or method will always be aligned with best surgical practice. As a minimum this will be in line with published Home Office guidelines.

In order to minimise animal suffering we will administer appropriate pain relief before and after surgery, combined with the most suitable balanced anaesthesia and a high standard of pre and post-operative care, including close supervision by the technicians under the guidance of Veterinary surgeons.

As the Project Licence Holder is part of the Veterinary team, peer review of any major changes/refinements to surgical technique or pain relief/anaesthesia protocols will be carried out by Veterinary colleagues and AWERB when applicable. As always the people caring for these animals are in regular discussion. This group discussion ensures there is no issue from perceived conflict of interest with the Project Licence holder being part of the Veterinary team.

Only the most refined surgical model that meets customer requirements will be prepared.

Why can’t you use animals that are less sentient?

Rodents (rats and mice) will be used in all of the studies conducted under this licence. Rodents are considered to be the species of the lowest neurophysiological sensitivity (have a brain and the physiology similar to humans) that will allow us to achieve the study aims and are considered suitable for the predicting what's likely to happen in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is of utmost importance and Good Surgical Practice will be observed for any animal undergoing surgical procedures. Surgery will be conducted using aseptic techniques (to prevent infection) which meet at least the standards set out in the Home Office Minimum Standards for Aseptic Surgery, and largely to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

Before we start any procedures, we also ensure that the requested surgical intervention is required and scientifically justified. We will agree with a Vet what pain relief or antibiotics the animals need both before and after the surgery. When recovering from surgery, we will give the animals extra heat/bedding, and monitor them closely until they recover and start behaving normally again. We then check them at least twice daily before they go on study.

In addition, care is taken to provide as much environmental enrichment as possible . This might include plastic shelters in their cages, blocks to gnaw on, extra bedding for warmth and if they need it, food supplements after surgery.
If we have to transport animals to other sites, this will be done following appropriate government guidelines, ensuring the animals are transported in secure, temperature controlled vans. The animals will be provided with food, water and bedding as appropriate for their journey. The duration of transport will be the minimum required to deliver the animals safely.

Animals will be closely monitored for signs of pain and discomfort after surgery using a clinically appropriate method, for example, The Grimace Scale. Technicians observing animals both before and after surgery are familiar with adverse clinical signs that may indicate pain and discomfort. Animals will be group housed after surgery where possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. A report by the LASA Education, Training and Ethics section. (E Lilley and M. Berdoy eds.).

Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Procedures. (2014) London: Her Majesty's Stationary Office.

Home Office Minimum Standards for Aseptic Surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This will be achieved by regular discussions with our Named Information Officer, colleagues in Animal Technology, and by attending appropriate training courses and conferences, or getting feedback from such events.

The choice of surgical model is justified in the Surgical Request form. Any advances in knowledge or refinement surgical techniques will be implemented throughout the lifespan of the Licence.

9. Physiology and pathophysiology of cortical network oscillations

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain, Oscillations, Interneuron, Plasticity, Epilepsy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how network oscillations are generated in the brain, how they influence neuronal communication and learning, and what leads to too much synchronisation of neuronal activity in epileptic seizures.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The human brain is the most complex thing in the known universe, and we still do not understand how this mass of cells gives rise to our thoughts, perceptions and memories. Our work focuses on understanding how the brain works at the level of individual neurons, the connections between these cells, and activity patterns generated in small neuronal networks. We perform these experiments in mice, which have similar cell types and

circuits as observed in the human brain. Importantly, this allows us to use powerful and invasive techniques to interrogate neuronal function, which would not be possible in humans. This is important for generating fundamental insights into brain function, which also supports our understanding of the pathology and treatment of brain disorders. We are particularly interested in what goes wrong in the brain to cause seizure activity observed in epilepsy. This disorder remains resistant to drug treatment in approximately 20 % of patients, and studying the mechanisms underlying such seizure activity in mice will provide the opportunity to identify new targets for treatment.

What outputs do you think you will see at the end of this project?

New insights into fundamental neurobiology
Presentations and publications
Insights into the mechanisms and treatment of inherited childhood epilepsy

Who or what will benefit from these outputs, and how?

In the short-term, new insights into the mechanisms and function of neuronal network oscillations will be shared with the neuroscience community through seminars and conference presentations.

In the short- and medium-term, the results will be shared with the wider neuroscience community through publications in journals.

In the longer-term, the results may benefit patients with drug resistant epilepsy. We will focus particularly on mice with epilepsy mutations, for which the results would most directly benefit patients harbouring the same or similar mutations. However, there is the potential for wider benefit to patients with other types of epilepsy syndromes.

How will you look to maximise the outputs of this work?

Collaboration - our work focuses on cells and circuits, and we will collaborate with other groups to understand the relevance to behaviour, which will maximise the impact of these studies.

Dissemination of new knowledge - we will publish our results in open access journals and/or deposit the final submitted manuscript in research archives, in order to maximise access. When allowed by the journal, submitted manuscripts will be deposited in preprint repositories to speed up dissemination.

Publication of unsuccessful approaches - graduate students will deposit digital copies of their theses on research archives, providing access to successful and unsuccessful experimental data. Postdoctoral researchers who find negative results will publish these results on an Open Research publishing platform, if this would inform the field.

Species and numbers of animals expected to be used

- Mice: 4800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to understand the mechanisms and function of brain rhythms, we use mice that have similar cell types and circuits as observed in the human brain. Some of these mice are genetically altered to control the expression of proteins - this allows us to identify, manipulate and/or record neuronal activity in specific cell types. We study the mechanisms and function of brain rhythms during postnatal development, as well as in the adult brain.

In order to understand the causes of childhood epilepsy, we use genetically altered mice that have mutations similar to those observed in patients with inherited neurological conditions associated with childhood seizures. Mice expected to show clinical symptoms are killed before the expected onset of seizures. We thus study the changes in late postnatal development that lead to seizure generation, which is relevant to the pathological progression in inherited forms of childhood epilepsy.

Typically, what will be done to an animal used in your project?

The recording of neuronal activity will be performed in mice under terminal anaesthesia, or in tissue harvested from mice that have been killed humanely.

Mice without disease mutations - some of these mice will undergo one surgery for the injection of viruses into the brain, and maintained for periods up to several months to enable viral expression. The mice will then be killed.

Mice with disease mutations - mice will be killed before the expected onset of seizures.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice without disease mutations are not expected to show any inherent clinical signs. Those undergoing brain surgery are expected show lack of grooming, reduced movement, and redness and swelling around the wound in the 2 days following surgery. Minor weight loss (<10 %) may occur in the week following surgery.

Mice with disease mutations may show deficits in co-ordination and balance during late postnatal development, but this will not affect their ability to eat or drink. Mice will be killed before the expected onset of seizures

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold: 15 %

Mild: 70 %

Moderate: 15 %

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project addresses fundamental neurobiological principles, which can only be resolved in living brain tissue. The invasive recordings and manipulations of neuronal activity cannot be performed in humans. Neuronal cultures can be produced from immortalised cell lines or induced pluripotent stem cells derived from animals or humans, however these cultures develop under artificial conditions that are not able to replicate the intrinsic and extrinsic inputs that occur naturally during development in situ, and thus display differences in circuit anatomy and physiology.

Which non-animal alternatives did you consider for use in this project?

Computational modelling can provide a powerful approach to understand the mechanisms and function of brain rhythms. We complement our studies with computer simulations, but experiments in living brain tissue are required to design and validate these in silico models.

Brain slices can be prepared from human tissue resected during surgery. We are now attempting to complement our animal studies with experiments in human brain slices, but there is limited tissue availability, it is obtained under pathological conditions, and it does not afford the powerful genetic toolbox that can be used to understand circuit physiology in mice.

Neuronal cultures are appropriate for studying the effects of genetic mutations on the molecular biology of neurons, but cannot be used to determine the circuit deficits that develop in situ.

Why were they not suitable?

Non-animal alternatives are not suitable alone to understand physiological and pathological network oscillations, but we use them to complement our studies:

Computational modelling helps in interpreting our data, establishing sufficiency of hypothesised mechanisms/functions, and exploring the parameter space to guide further experimentation.

Experiments in human brain slices will enable us to test whether mechanisms of circuit physiology are conserved between mice and humans.

Results from neuronal cultures will be used to generate hypotheses about the effects of disease mutations at the circuit level.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice required are estimated based previous experience.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Each part of the brain contains many different types of neuron, which vary in their anatomical structure and gene expression. These properties cannot be visualised reliably in live brain tissue, and we have previously had to use filling and staining techniques to resolve cell identity after the experiment. The use of transgenic mouse lines enables us to target fluorescent tags to genetically-specified populations of neurons, as well as specifically manipulating their activity, which is a more efficient process in dissecting cellular and circuit function.

The majority of experiments will be performed in ex vivo brain slices, which enables several experiments to be performed in tissue from one animal.

The application of multielectrode recordings and/or population imaging techniques increases the amount of data that can be gathered from each animal.

The majority of our experiments involve acute modulation of neuronal activity, for which we have internal controls. For experiments in which there is chronic manipulation of neuronal activity or expression of disease-related mutations, we will conduct our experiments so that they comply with the ARRIVE guidelines on publication.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding - Several groups across our institute use the same genetically altered mice, and we share mice for experiments and breeding to reduce the number of animals used. We reduce the number of breeding pairs to the minimum we can, striking a balance between the numbers required to assure continued genetic integrity and reduction.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice without disease mutations, including genetically altered animals for expressing fluorescent proteins, ion channels and/or receptors in specific cell types, are not expected to show any inherent clinical signs. Some of these mice will undergo one surgery for the injection of viruses into the brain - this is required to target manipulations to specific regions of the brain, and is not expected to induce chronic pain, suffering, distress or lasting harm.

Mice with disease mutations to model childhood epilepsy will be killed before the expected onset of seizures. Some of these mice may display deficits in balance and co-ordination, but it is necessary to maintain these mice to the latest possible point prior to seizure onset in order to determine the underlying brain circuit deficits, while limiting the possibility of the mice suffering pain and distress during seizures.

Why can’t you use animals that are less sentient?

While cortical architecture and electroencephalogram (EEG) patterns are well conserved across mammalian species, this is not the case for fish, amphibians and reptiles, and the EEG of non-mammalian vertebrates has proved to have limited use for even distinguishing sleep versus wakefulness. Non-regulated animal species, such as flies and worms, lack cortical structures altogether. The mouse represents one of the least sentient species that can be used study mammalian cortical network oscillations, and is the most refined choice due to its genetic tractability.

The patterns of cortical network activity change during development, and we need to study their mechanisms in both postnatal and adult mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The protocols we use are well established and scrutinised by the veterinary and research communities, but we shall ensure that we further improve these protocols in the light of any new developments in anaesthesia and surgery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines provided by the NC3R (https://nc3rs.org.uk) and Lasa (https://www.lasa.co.uk) on best practice, and follow additional advice provided by the NVS, NACWO and/or Named Information Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project license holders in the department meet every term, and these meetings are attended by the regional NC3R manager who provides updates on any advances in the 3Rs. Further information is provided on the NC3R website (www.nc3rs.org.uk).

10. Breeding livestock for traits derived from new technologies

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

CT scanning, phenotypes, genotypes, environmental impact, breeding

Animal types	Life stages
Sheep	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to produce new knowledge and tools to measure traits of importance in breeding programmes for farm animals to increase overall productivity and welfare, whilst minimising environmental impact.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the long term it is expected that the programme of work will deliver mechanisms to breed sheep for higher production efficiency and welfare, whilst minimising environmental impact. In particular, it will provide in the short-medium term:

novel knowledge on the genetic basis of new traits that could be included in livestock breeding programmes

harmonised and robust methods to measure these traits across large numbers of animals

capability to employ genetic or genomic (DNA-based) selection for traits that have previously proven difficult or expensive to measure, including meat and carcass quality, welfare indicators, feed efficiency, methane emissions.

What outputs do you think you will see at the end of this project?

Outputs from the project include:

novel knowledge on the genetic basis of new traits that could be included in livestock breeding programmes. This will include estimation of genetic parameters and genetic correlations to enable recommendations and strategies for inclusion of novel traits into breeding programmes in the most appropriate and effective ways. These results will be published in peer-reviewed journals and presented at academic conferences, as well as forming the basis of articles and presentations aimed at industry end-users.

harmonised and robust methods to measure these traits across large numbers of animals. Protocols and standard operating procedures for phenotyping UK sheep for novel traits will be produced to enable future use of these technologies and methods.

capability to employ genetic or genomic (DNA-based) selection for traits that have previously proven difficult or expensive to measure, such as meat and carcass quality, spine characteristics, health and welfare indicators, feed efficiency and methane emissions. Outputs will include databases, parameters and pipelines to produce routine genetic and genomic breeding values for these novel traits in future.

Who or what will benefit from these outputs, and how?

In the medium-long term (5-10 years) it is expected that the programme of work will deliver sheep with genetic potential for higher production efficiency and welfare, but reduced environmental impact. This will provide public-good benefits of producing high quality animal protein, to help meet global food security targets, whilst minimising GHG emissions per kg of product, to help meet net-zero targets.

In the short-medium term it will provide:

novel knowledge on the genetic basis of new traits that could be included in livestock breeding programmes. In the short term, this will benefit the research community and the industry and policy bodies that they inform - to help develop policies and strategies to incorporate novel traits into sheep breeding programmes. In the medium term, this will benefit sheep breeders, who can select for new sustainability traits in their stock, making them more valuable in the market. It will also benefit commercial sheep producers who buy the improved breeding stock to produce lambs that better meet market specifications and government targets for reduced methane emissions (potentially linked to future subsidy payments).

harmonised and robust methods to measure these traits in large numbers of animals. In the short term, this will benefit the research community and industry bodies - to help develop

robust and reliable mechanisms to routinely measure novel traits in UK sheep breeding programmes. In the medium term, this will benefit sheep breeders and commercial sheep producers, as detailed above.

capability to employ genetic or genomic (DNA-based) selection for traits that have previously proven difficult or expensive to measure, such as meat and carcass quality, spine characteristics, health and welfare indicators, feed efficiency and methane emissions. In the short term, this will benefit the research community, potentially across a number of disciplines, and industry bodies - to help develop strategies to incorporate novel traits into sheep breeding programmes. In the medium term, this will benefit sheep breeders, allowing more efficient (and cost-effective) selection of breeding stock of improved genetic merit across a number of important economic and environmental traits, with reduced need for extensive phenotyping of animals. In the medium term, this will also benefit commercial sheep producers, who will be able to buy breeding stock of known genetic merit (with genetic / genomic breeding values) for numerous novel sustainability traits, as detailed above.

How will you look to maximise the outputs of this work?

The research organisation works closely with farmers, industry representatives, funding bodies etc., through its research, education and consultancy activities, and delivers knowledge exchange to different UK and international audiences. They have an excellent track record in applied livestock breeding research and dissemination. Results from previous sheep breeding research projects have been successfully applied in the UK and beyond. For example, breeding values for novel product quality traits measured by imaging techniques, developed under a previous version of this licence, are now provided to all terminal sire sheep breeders that record as part of the AHDB Signet Sheepbreeder scheme across the UK, as a direct result of that research. Therefore, breeding values for these traits are available to the industry on tens of thousands of performance recorded sheep per year. Applied research carried out under this licence will have a similar direct route to end-users within the livestock industry, ensuring maximum impact.

Collaboration with other research groups working in similar areas, particularly within relevant international projects, will result in joint peer-reviewed publications within this field, international harmonisation of data collection protocols and increased impact from combining knowledge and experimental results. These collaborations will also reduce duplication of research efforts, with beneficial effects on total research spend and number of animals used across research trials.

Research results (both positive and negative) will be presented at academic conferences and in peer- reviewed journals, as well as in trade journal articles and at knowledge transfer events aimed at end- users.

Species and numbers of animals expected to be used

- Sheep: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Since we need to measure these traits in the target species to enable genetic selection, and look for biological and genetic markers in the relevant species, the work needs to be done on animals and the proposed goals cannot be achieved by using any alternatives. Wherever possible we use our extensive databases containing historical data of archived material from previous studies (e.g. images captured for body composition analysis procedures) or use alternatives such as meat joints, but there are limited opportunities for replacement of animals with alternative models for most elements of the work.

It is anticipated that sheep from a variety of breeds and production systems will be used within the studies, to ensure relevance of research results in different populations of UK sheep. The majority of the trials will focus on growing lambs under 1 year old. However, some studies may also measure mature animals, in order to fully understand the repeatability of results across different life stages, which can have different impacts on the sustainability of sheep systems.

Typically, what will be done to an animal used in your project?

Central to the achievement of the project objectives are five experimental procedures: advanced, non- invasive imaging of live sheep for genetic or genomic selection, or to understand interactions with management regime; DNA sampling (e.g. nasal or saliva swabbing, blood sampling, or ear punch) for DNA extraction or to look for biomarkers; individual faecal sampling to look for faecal markers; measurement of greenhouse gas emissions from individual sheep; and sampling of rumen fluid from individual sheep to analyse the gut microbiome. Most animals will only undergo one or two of these procedures once in their lifetime, although some may get multiple procedures over time to look for physiological changes or relationships between measurements. In the vast majority of animals, allprocedures will take place within a period of less than 3 months. Otherwise animals will be managed as in commercial sheep flocks.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected from these procedures and it is anticipated that animals will be returned to their home flock, and will be fit to be slaughtered or sold for breeding, if appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All procedures are categorised as mild in their severity level and no animals are expected to suffer anything but short-term mild discomfort or behaviour restriction.

What will happen to animals at the end of this project?

- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Since we need to measure these traits in the target species to enable genetic selection, and look for biological and genetic markers in the relevant species, the work needs to be done on animals and the proposed goals cannot be achieved by using any alternatives. Wherever possible we use our extensive databases containing historical data of archived material from previous studies (e.g. images captured for body composition analysis procedures) or use alternatives such as meat joints, but as we are now extending studies into other technologies and traits, there are limited opportunities for replacement for most elements of the work.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we use our extensive databases containing historical data of archived material from previous studies (e.g. images captured for body composition analysis procedures) or use alternatives such as meat joints.

Why were they not suitable?

We are now extending studies into other novel technologies and traits, and as such there are limited opportunities to use previously-collected data for replacement for most elements of the work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The maximum number of animals used has been estimated for the projects that have been funded, or that we hope to receive funding for, within the lifetime of this work programme. The exact numbers of animals required will vary with particular experimental designs and will be based on previous experience and the scientific literature.

For each experiment, an experimental protocol is submitted to the organisational Animal Welfare Ethical Review Body, which includes statisticians in its membership. The protocol includes: a statement of the objective(s) and a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group), and the experimental material. Furthermore, protocols for each experiment including the above information and other matters such as methods of analysis are produced to conform to Institutional Research Quality Assurance requirements.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Consultation with statisticians ensures that the minimum number of animals are used to enable robust scientific conclusions to be drawn. Where possible, on both ethical and economic grounds, our research is based on re-analysis of existing data, or data sharing with other institutes. We maintain well-organised, comprehensive computer-based databases for the type of experiments described here. This means that: (i) historical data is readily available for re-analysis, where this is relevant (thus reducing or replacing the need for animals in some cases), and (ii) we have good procedures for checking whether animals which have been subjected to particular experimental protocols have performed in a different way from others (allowing refinement of procedures if necessary).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where required, pilot studies will be used to provide the baseline data to inform on larger trial work, and to refine sampling procedures and techniques for data capture. We will also use the opportunity to share data and samples with collaborators (internally and externally) to achieve maximum value from minimum resource. In particular, close collaboration with partners in international projects who are using the techniques that are new to our research group (Portable Accumulation Chamber (PAC) measurements and rumen sampling) will inform optimal sample sizes and experimental design. Where possible, results or data will be combined across research groups to maximise impact and avoid duplication of research effort.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Highly trained staff and good animal housing, handling and recovery facilities, have enabled us to refine advanced imaging techniques and tissue / blood /faecal sampling procedures, so that suffering is minimised. We have experienced very few problems in applying protocols very similar to those described here, under our previous licences. Sedation of animals minimises stress. Use of mobile imaging equipment reduces the need for excessive animal transport and means that we can take the equipment to farms with appropriate handling systems. The imaging equipment has been replaced in recent years with a higher specification instrument which gathers data more quickly, reducing the data acquisition time, so that the procedure for each animal is faster and more reliable.

We are constantly looking for minimally invasive ways of collecting samples or data. For example, the use of saliva / or nasal swabbing to replace faecal and blood sampling are used where possible.

For the procedures new to our research group, training will be received from experienced personnel in other countries (Ireland, Norway and New Zealand) or research groups (beef unit technicians within the same organisation) and detailed protocols and SOPs will be shared by those groups, to ensure that methods are employed to minimise suffering. The groups in those countries have recorded thousands of sheep through Portable Accumulation Chamber (PAC) equipment and have rumen sampled hundreds of animals, resulting in highly refined protocols.

Why can't you use animals that are less sentient?

It is not possible to use immature, less sentient or terminally anaesthetised animals. The study aims to develop phenotyping tools and methods of optimising efficiency and minimising environmental impact that are commercially applicable to farming environments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures described here are already refined as a consequence of our work over the last 24 years and are regularly in use by our team. These include measurements taken by advanced imaging technologies and sampling procedures for blood and faeces. Where we are using new methods - i.e.
methane measurements using portable accumulation chambers or rumen sampling - we will implement pilot testing where appropriate and follow detailed training and instruction protocols from experienced research groups in these techniques.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where appropriate, we will use methods that conform to International Committee for Animal Recording (ICAR) guidelines for recording traits to be used for animal breeding programmes.

The research group has well-established, previously-published, methodology and guidelines for collecting and analysing similar images from live animals using these advanced imaging techniques, and measuring numerous phenotypes from these images. Our group is considered one of the world- leaders in this area of research in sheep.

Published studies, guidelines, SOPs and protocols from highly-regarded research groups, that are leaders in the field, will be followed to ensure best practice for procedures that are new to our research group (portable accumulation chambers and rumen sampling).

When publishing our research we will use the ARRIVE guidelines to ensure that we make all the relevant information known to others and help refine further studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continually review our procedures throughout our work and seek less harmful alternatives whenever these are available. We will regularly visit the NC3Rs website to check for any new developments.

11. Development, homeostasis and disease of the peritoneum and the intestinal tract.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

peritoneum, post-surgical adhesions, enteric nervous system, aganglionosis, therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to improve our understanding of

the development and role of the peritoneum, especially the mesothelium covering the intestine and the peritoneal wall, during homeostasis and in response to external challenges during (adhesion) scar formation;

the cellular and molecular processes involved in Hirschsprung's disease (HSCR), which is a congenital abnormality of the enteric nervous system (ENS).

We seek to test therapeutic approaches in order to prevent scarring in response to injury (peritoneum), and aganglionosis (Hirschsprung's disease).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The peritoneum is generally well-protected from external injuries. However, a range of clinical symptoms can arise including peritonitis, endometriosis, peritoneal scarring due to dialysis, peritoneal disease (metastasis) and post-surgical adhesions. In all these phenotypes, the mesothelium the outermost layer of the peritoneum, is involved and affected. Post-surgical adhesions arise in response to damage to the peritoneal layers of the intestine and can involve the abdominal wall. Adhesions can arise in up 93% of patients after intra-abdominal or pelvic surgery, leading to considerable morbidity since they can be a major cause of infertility in women, or lead to small bowel obstruction, with a 3-13% mortality rate. Post-surgical adhesions can be a frequent cause of chronic abdominal pain. The only effective treatment is adhesiolysis, which involves further surgical intervention, resulting in a huge economic burden ($2.3Billion / year in the USA). While therapies against adhesion formation include physical barrier consisting of membranes, gels or liquids, none have provided success in randomised clinical trials. Therefore, there is an urgent need to improve our understanding of the cellular and molecular mechanisms that lead to adhesion formation in order to develop successful therapeutic strategies, for example by targeting specific molecular pathways.

Hirschsprung's disease (HSCR) is a congenital disease in 1:5000 live births. HSCR is associated with an absence of enteric ganglia in the hindgut, based on the lack of parasympathetic intrinsic ganglion cells in both submucosal and myenteric plexi of the hindgut. It is thought that HSCR arises as a consequence of premature arrest of the migration of vagal neural crest cells into the hindgut. The internal anal sphincter is invariably affected, however, the absence of enteric ganglia can affect varying length of the intestine. The lack of innervation leads to a distention of the colon (megacolon), resulting in no or very slow gastrointestinal passage. Current treatment involves surgical intervention, with a large number of patients suffering postoperative gastrointestinal dysfunction. However, recent research promises the prospect of cell therapies to regenerate the aganglionic hindgut, however, there are large gaps in our understanding of how therapies using cells or molecules could work successfully.

Therefore, the overarching goal of this project is to establish an advanced understanding of biological mechanisms and to develop translational approaches in preclinical mouse models that replicate the clinical symptoms, for the treatment of peritoneal abnormalities including post-surgical adhesions, and of Hirschsprung’s disease. In order to facilitate these advances in knowledge and understanding, we need to include detailed analyses of the cellular and physiological processes giving rise to mesothelial tissues and their maintenance, as well as communication with neighbouring tissues, and to the ENS.

What outputs do you think you will see at the end of this project?

This project will provide a number of outputs, including:
A deeper understanding of external stressors like surgery on the peritoneum. This involves a more detailed insight of peritoneal development and homeostasis, and the effects of ageing on homeostasis and response to injury. In includes defining mesothelial cell heterogeneity and differential molecular responses to injury. These outcomes will provide

novel insight into molecular and cellular processes that could be clinically exploited for therapeutics.

An in-depth analysis of the abnormalities of the ENS in the hindgut/colon of mouse models of HSCR. This will provide us with an improved understanding of the abnormal interactions of cells and the modified underlying molecular pathways in this congenital disease. We will be able to use these insights to determine routes to therapeutic interventions.

Multiple research publications in peer reviewed journals. We have several manuscripts that are going to be published within the coming months and we strive to generate more publications from our funded studies, not only for the benefit of the young researchers involved, but also to improve understanding and knowledge in the field.

Scientists with unique training and expertise in various techniques including surgery, colony maintenance of wildtype and genetically altered animals, approaches to testing possible therapies, data analysis. These skills will be invaluable for the research careers of the staff and students involved in this programme of work.

The long-term aim of this programme is to establish a solid foundation of knowledge of molecular and cellular processes that enable the testing of therapeutic interventions with potential for translation to the clinic.

Who or what will benefit from these outputs, and how?

Short term beneficiaries:

The research community seeking to develop treatment for HSCR and post-surgical adhesions, developmental and cell biologists, as well as the regenerative medicine research field. Our research findings will be communicated to these communities via workshops and conference presentations, which will lead to exchange of ideas and cross-fertilisation of outcomes, ideas and concepts. The research communities will also benefit from research publications generated from our findings, with the potential to stimulate further research.

The young researchers working on these projects, as it will equip them with unique expertise in mouse models of injury and disease, mouse genetics, surgery and ex vivo methods arising from these.

Medium to long term beneficiaries:

This will include the research team as short-term outcomes will build further expertise of the entire team, leading to continuity and consolidation as well as refinement of techniques.

The research community (research-interested paediatric surgeons and clinicians and basic researchers, including those interested in HSCR, post-surgical adhesion, developmental and cell biology, regenerative medicine) will be beneficiaries as our findings will increase knowledge. In addition, accumulation and consistency in outcomes will consolidate the reliability and reproducibility of our work, leading to an improvement in standards.

Clinicians (paediatric and adult surgeons, clinicians, HSCR, post-surgical adhesions) will benefit from improved understanding of the mechanisms that lead to the disease outcome, including cellular and molecular processes. We expect that our findings will be important

contributors to the development of clinically relevant therapeutics for treatments in HD or post-surgical adhesion patients that can be tested in clinical trials.

HSCR patients suffering from aganglionosis and blocked gastrointestinal passage, as well as patients suffering from post-surgical adhesions with the associated intestinal obstructions.

The public will benefit from increase in knowledge, dissemination, and treatment options for patients.

How will you look to maximise the outputs of this work?

Our outputs are maximised by interactions with colleagues from preclinical and clinical research fields, as well as interactions with patient representatives. We have ongoing international and national collaborations which strengthen our outputs.

We are strongly engaged with local clinicians treating patients with HSCR and post-surgical adhesions and understand their clinical needs. Through these interactions, we can reach a wide audience of specialist preclinical and clinical researchers and practitioners as well as lay people.

We maximise our outputs through attendance at workshops and conferences, and most importantly through publication of our findings in open access journals, including the use of pre-print serves (e.g. bioRxiv). We are keen to publish unsuccessful approaches, and datasets are made available after publication.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our overarching aim is to develop treatments to prevent peritoneal scarring after abdominal surgery, and to prevent HSCR to cause megacolon and colonic constrictions and associated surgery and morbidities that could in the future be used in patients. We will test cells or cell-derived substances as treatment, and use animals in order to find out which are the most successful cells or substances to reduce the scar in the peritoneum/colonic constrictions. We use mice because their peritoneum and colon have very similar tissue structure and functionality to humans, and show similar response to injury or lack of ENS as in patients. Mice are the simplest animal model with this level of similarity to humans. Therefore, mice are the most appropriate animal to achieve our aims. Peritoneal scarring can occur throughout the life course, often years after surgical intervention. Therefore, we will use adult mice, but also aged mice.

Typically, what will be done to an animal used in your project?

Animals in this project may be part of studies that

analyse normal developmental or homeostatic processes, in some cases combined with genetic lineage tracing,

induce injury to the peritoneum after surgery combined with genetic lineage tracing, and/or

test and determine the success of administration of cells or cell-derived substances or molecules.

With these studies, we also wish to understand how the successful treatment works, and where the cells that we use as treatment, go in the body.

During these studies, animals will be administered substances, most frequently tamoxifen or other recombination-inducing agents, to which they may respond with mild weight loss within the 7 days after start of dosing.

Some of the mice will become unwell because they lack gene function. We have specific humane endpoints in place which will allow us to determine when to kill the mice in order to prevent them from undergoing unnecessary suffering.

Mice which undergo surgery, will be under general anaesthesia, but will recover uneventfully from this intervention. They will be given peri- and post-surgical treatment of pain relief. This intervention may be associated with a mild version of weight loss, from which the mice will recover.

Some of these mice will undergo in vivo imaging, which may involve the injection of small volumes of contrast substances that can be detected by the imaging instruments. These steps are typically performed under general anaesthesia. These measurements can take place repeatedly over the study period but at the most appropriate times to reduce harm to the mice.

Some of the mice will receive cells or cell-derived substances or molecules as test treatment. We will monitor and measure clinical signs of progression of the injury or disease with and without treatment.
Mice after lineage tracing induction, surgery and/or therapy treatment may be monitored for up to 6 months.

Some of the mice will be aged when treatment of resumes in order to determine the effect of ageing on injury progression and efficacy of therapies. We have specific scoring documents in place in order to determine the humane endpoint for the mice that are aged and undergo steps of the protocols under this licence, considering age-related frailties.

What are the expected impacts and/or adverse effects for the animals during your project?

The experimental conditions may lead to loss of weight in mice that

have been given tamoxifen or other recombination-inducing agents,

have undergone surgery,

have undergone in vivo imaging steps.

In B) and C), anaesthesia contributes to the weight loss. Weight loss is only temporary, and animals generally recover uneventfully.

Because of the need for clinical signs of peritoneal injury or colon constrictions in order to assess the effect of the treatments, these adverse effects are necessary.

Aged mice may be more frail than healthy adult mice and their treatment regime during the steps of protocols will be adjusted so that they are milder without preventing us from obtaining relevant information on the same question of peritoneal injury and effectiveness of treatments with cells or cell- derived substances.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the six protocols in this licence, four have a severity band of moderate, while two have a severity band of mild.

In moderate Protocol 2, we may breed genetically modified mice which may show signs of moderate health problems, at about 50% of the animals under this protocol. Ageing mice will be generated under

Protocol 3, which can lead to moderate severity in their clinical signs. Overall, we expect that about 70% of the mice under this protocol show signs of moderate severity.

In moderate Protocol 4, we may perform genetic lineage tracing, which may be combined with surgical induction of peritoneal injury, and administration of therapies to explore their efficacy, and in vivo imaging. We expect that overall, up to 80% of mice under this protocol show signs of moderate severity.

In moderate Protocol 5, we may administer therapies to animals with Hirschsprung's disease and combine this with in vivo imaging. We expect that about 25% of the mice under this protocol show signs of moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The conditions that contribute to the development of peritoneal scar formation or Hirschsprung's disease, and possible treatments, cannot currently be reproduced in the non-animal setting since due to the in vivo complexity of the diseases, including by intestinal wall cells, immune cells and other physiological factors beyond the interactions of

cells inside the intestine or peritoneum. Mammalian physiology and anatomy are complex and other organs may also contribute to the injury / disease and any beneficial treatment response. Any beneficial treatment response observed in a non-animals condition may have to be validated using animals models before treatments can be trialled in patients.

Which non-animal alternatives did you consider for use in this project?

In vitro systems (cell culture of mesothelial explants or primary mesothelial cells, bowel-derived neurospheres) offer some opportunities to replace the use of mice. Cell culture work is being performed to study effects of therapeutic agents on peritoneal mesothelial or ENS progenitor cells, but only deliver limited information due to the isolated setting. These approaches are currently being used, however, they are based on the isolation of cells or tissues from animals. The in vitro system will be complementary rather than full replacements of animal studies.

Why were they not suitable?

In vitro approaches cannot reproduce the entire disease setting and physiological condition of the animal. These are important aspects that contribute to the injury or disease, and treatment response. This includes interactions with other organ systems and cells as well as physiological parameters including intestinal and peritoneal function. Although cell-based studies produce important information in their limited format on the response of isolated cells to specific conditions, a whole range of these conditions are not being assessed because they still lack the intricate interaction between cells within organs, and between organs and systems in the animal.

In vitro or ex vivo experiments cannot completely replicate the animal model since disease or injury processes in the patient take place in a complex environment. This needs to be considered when working towards achieving the aims of our work, which are to determine the efficacy and mechanisms of action of cells or cell-derived substances or molecules within the animal to peritoneal injury and scarring or colonic constriction based on aganglionosis.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

My experience in this area of research over the last 10 years allows me to estimate with confidence the mouse numbers needed for this programme of work. Animal numbers are determined based on currently funded studies and the experience with previous project licences. These are based on effect sizes (including variances) from previous work or published studies, and also considering adverse effects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The studies funded for this programme of work will have undergone peer review which includes providing detailed statistical analysis and power calculations. We have made use of the NC3Rs experimental design assistant but also other online power calculation tools (G star power etc) to design our studies and power our experiments so that we can achieve sound primary outcome measures. We base calculations on group sizes on estimates of effect sizes from our previous work, including preliminary data, and on published studies.

We have performed longitudinal studies including the use of in vivo imaging, which allow for a reduction of animal numbers since it reduces end point analysis at these different time points.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have established efficient breeding of the compound mutant lines. Out of four genotypes that arise, two genotypes can be used for breeders to maintain the line. One of these can also be used for gene ablation studies. One additional genotype can be used for normal lineage tracing experiments and in combination with surgery to induce peritoneal injury; males of this genotype are mostly used for matings to generate embryos. The fourth genotype is also of value for studies involving only the ubiquitous dTomato reporter expression.

Generally, we attempt to make use of all mice by utilising their tissue post-mortem in ex vivo/in vitro cultures that complement the in vivo work. We have stored tissue blocks which will be of use to students being introduced to techniques of histological analysis including immunostaining.

Image data sets are stored digitally and can be re-analysed at later stages.

We perform pilot studies where required when new external compounds or treatments are being introduced to mice, restricting original pilots to small group sizes (~3 animals).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this programme of work, we use two different mouse models:

mouse models of surgically induced peritoneal injury and scarring which very closely replicate the clinical phenotypes and symptoms of patients having undergone abdominal surgery. These injuries are required to achieve our overarching aim of developing therapies for treatment of peritoneal scarring and fibrosis, using cell or cell-based or molecular treatments. Our injury models are widely accepted as standard for mouse experiments that

replicate symptoms of peritoneal injury in patients.

These models induce only temporary pain due to the surgery, which will be mitigated with analgesics. In order to analyse contributing cells to scar formation and fibrosis, we include genetic lineage tracing strategies. For this purpose, the mice will be administered a drug/compound (i.e. tamoxifen) that induced recombination to activate lineage tracing of specific cells of the peritoneum. The mice may undergo minor weight loss from which they recover.

Overall, we have not experienced any suffering or distress or lasting harm that in animals of the surgical/lineage tracing model.

mouse models that replicate closely the clinical symptoms of congenital Hirschsprung's Disease. The model is caused by loss of gene function and leads to onset of disease shortly after birth. We have established the humane endpoint as day 7 and until then newborn mice are monitored carefully for any signs of suffering and distress.

Some of the mice in experimental treatment groups will receive versions of cells or cell-derived substances or molecules with the aim to reach a reduction of the level of disease, which should correlate with the level of suffering and distress.

In loss of gene function studies mice will generally be carefully monitored before they reach well established humane endpoints in order for the mice to progress to the clinical signs required to reach the research objectives while undergoing the least distress, suffering and pain.

Why can't you use animals that are less sentient?

In this programme of work, we study effects of cells or cell-based substances or molecules as therapeutic treatment in mouse models of peritoneal injury and scarring, and Hirschsprung's disease, mimicking variances of the disease found in patients. The mouse is the simplest model organism that can replicate these disease scenarios because it has a very similar anatomy and physiology to the human.

Adult or even aged mice are needed to perform these studies because post-surgical adhesion patients can fall within this bracket. It is necessary to have fully functional organ systems available in the animal for the studies to yield relevant information, and early embryonic stages would not be providing the required data. It is not possible to perform the studies in terminal anaesthetised animals as various outcome measures wouldn't be able to be assessed, making this an impractical approach.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I have worked with mouse models of kidney injury for over 10 years, and have experience with mouse models of peritoneal injury for over 5 years.

We started the Hirschsprung's mouse model 2 years ago.

We have also established multi-modal imaging in healthy and injured mice under previous licences.

I have >20 years of experience in mouse models of various diseases, and have used

genetic lineage tracing and ablation models. Based on these experiences, I have established an excellent strategy for monitoring and care of mice by assessing and scoring animal well-being in different disease situations, which could present stages of disease progression and injury.

In order to implement the mouse models of injury and disease, and other procedures within this programme of work, mice are closely monitored during the critical phases after injury induction in order to maintain the severity levels and determine when humane end points are reached.

One of the main predictors of animal distress and suffering is animal weight, and so animals are weighed regularly and their overall appearance monitored every few hours on the day of surgery or other induction of injury, and daily afterwards. This may involve close monitoring of well-being during critical phases of injury response by night visits in order to avoid unnecessary suffering of the mice.

We constantly strive to refine procedures to minimise suffering and improve welfare of the animals. This includes regular reflection of steps that could be improved.

For example, the Hirschsprung's mouse model (Ednrb mutant line) was published as more robust than we have experienced in our animal facility. The clinical signs of lack of an enteric nervous system and subsequent distention of the colon in the Ednrb mutant mouse strain, can lead to severe and life- threatening inflammation of the bowel in the young mice, which had been described as occurring from day 21 onwards. Because Ednrb homozygous mice showed these clinical signs much earlier, between days 7 and 10, we refined our strategy and set day 7 as the humane endpoint for these mice.

In another example, we have optimised the experimental design for surgical induction of acute and chronic kidney injury, since we recognised that animal groups undergo larger variability in response unless certain surgical parameters were more tightly controlled. These observations and refinements have been published on the bioRxiv preprint server and are currently in revision at one of the leading renal physiology journals. This refinement subsequently leads to a reduction in animal number as the experimental design calculations will include adjusted effect sizes, since variability in response doesn't need to be addressed in larger group sizes.

In addition, we have previously established the use of the ultrasound imaging instrument to refine the administration of cells into the left ventricle in order to avoid misinjections and unnecessary suffering.

We plan to incorporate expertise by BSU staff and grimace scoring into an overall strategy that allows us to monitor closely the wellbeing of the mice in an unbiased way.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow LASA guidelines on dosing and administration of agents, and withdrawal of blood.

For the scoring of ageing mice, we follow the guidance by Wilkinson and colleagues (Wilkinson et al., 2020, Lab Anim. 54(3), 225-238. DOI: 10.1177/0023677219865291), and also the score sheet that has been set up in collaboration with colleagues who have longstanding expertise in research using ageing mice.

We are in regular contact with colleagues on best practice of the surgical adhesion model as we collaborate and aim to ensure reproducibility between both sites.

We follow the ARRIVE guidelines for which an update (2.0) was published this year (Percie du Sert et al., 2020, PLoS Biol 18(7), e3000410. doi: 10.1371/journal.pbio.3000410).

We have sent researchers to other laboratories nationally and internationally to learn and improve on techniques that are relevant for this programme of work, for example with regards best practice in using in vivo imaging instruments.

As part of a EU Marie Curie training network, that is contributing funding to our work, we are in constant exchange with other researchers in the partner countries to discuss and improve general and specific experimental designs and approaches.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Biomedical Services team is very active in announcing and organising NC3Rs meetings, workshops and conferences. I have attended several local NC3R workshops, and have presented at an international NC3R conference on severe suffering. I encourage members of the team to use the NC3Rs website, communicate information that becomes available, and attend conferences.

The animal unit at our establishment is proactive in displaying important publications, posters and other information leaflets that are important for work in the NC3Rs area. The NC3Rs regional manager for the establishment is actively engaging with the animal researchers, and happy to provide support where required.

In our work, we constantly aim to apply the 3Rs principles; this includes continuous reflection on studies and subsequent optimisation so that refinements can be introduced to limit suffering, and also to reduce animal numbers. We are also keen to explore alternative model systems (in vitro, organoids, gastruloids, ex vivo etc.) in the laboratory.

12. Development of Vaccines

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

vaccines, infectious diseases, immunology

Animal types	Life stages
Mice	adult, juvenile, aged, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This work aims to develop new and improved vaccines and vaccination regimens for prevention and treatment of infectious diseases (eg malaria, Influenza, HBV, SARS-CoV2) that can be rapidly translated to the clinic. We aim to increase our knowledge of the immune response induced by vaccination and required for protection against infection so that we can further improve our vaccine platforms and rapidly respond to new disease outbreaks.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines are one of the most cost-effective health tools available. It is estimated that over 3 million lives per year are saved through vaccination, with vaccination campaigns leading to the complete eradication and control of some infectious diseases. Despite these successes, infectious diseases continue to cause significant morbidity and mortality world-

wide because there is no licensed vaccines (eg malaria, Nipah, CCHF, MERs), current vaccines require annual changes (eg Influenza) or the disease is caused by a newly identified pathogen (eg SARs COV2). While historically vaccines were developed for prevention of infectious diseases, the ability of vaccines to stimulate the immune response is leading to development of vaccines to prevent non-communicable disease (eg cancer) but also as treatment tools once disease has developed (eg chronic viral infections). By continuing to develop and optimise different vaccine platforms we are able to apply our technology to a variety of diseases and rapidly respond to new disease outbreaks.

What outputs do you think you will see at the end of this project?

Development of new and improved vaccines and vaccination regimens against malaria, influenza and emerging pathogens (eg SARS COV1, SARS COV2, Nipah, MERs, CCHF) that can be rapidly translated to the clinic.

Develop vaccination regimens for treatment of chronic infections (eg HBV, HCV, HTLV-1). Increased understanding of the immune response induced by different vaccine platforms. Increased understanding of the immune response required for protection against different infectious organisms.

Who or what will benefit from these outputs, and how?

Short-term impact of this work will be an increase in knowledge and understanding of the immune response following vaccination for the scientific community. Insight into how the immune response is induced and type of immune response required for protection against specific infectious disease will also lead to improvements and alternative approaches to vaccine design.

Medium-term impact of this work will include translation of new/optimised vaccines or vaccination regimens to small scale clinical trials, with long term impact (15 years later or more, typically) includes approval and licensing of a vaccine.

How will you look to maximise the outputs of this work?

Scientific knowledge and results will be disseminated through presentations at scientific meetings (local, national and international) and publication of results in peer-reviewed journals. In addition, we actively participate in local 3Rs meeting and local ethical review committees, sharing and gaining insight into protocol refinement methods. We have strong collaborations with vaccine (human and veterinary) researchers in the UK and international collaborations enabling the sharing of results, resources and techniques.

Species and numbers of animals expected to be used

- Mice: 20500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have chosen mice for these studies as they are the lowest sentient animal, with a complete immune system that closely mimics the human immune system. Performing these studies in mice ensures selection of the most immunogenic and protective vaccines/vaccination regimens that can then be progressed to GMP manufacturing and human clinical trials.

We use juvenile and adult mice as they have a fully developed immune system.

Typically, what will be done to an animal used in your project?

The majority of mice will be immunised with a vaccine preparation on up to 2 occasions and killed at a defined timepoint post-vaccination for in depth *ex vivo* characterisation of the immune response. For some infectious diseases, there are established models which mimic human disease, therefore we can test the efficacy of our vaccine. In these instances, mice will be vaccinated with a vaccine preparation and infected with the relevant pathogen (eg malaria or Influenza virus) at set-timepoints post vaccination and monitored for development/clearance of disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Most animals experience only mild adverse effects following vaccination, in line with the experience of humans (eg mild-flu like symptoms for up to 24 hours after vaccination). In studies testing the efficacy of vaccines against respiratory pathogens (eg Influenza and SARs), the predominant indicator of disease is weight loss, which peaks around 5 days after challenge before mice start to recover. When testing the efficacy of malaria vaccines, we monitor mice for parasites present in the blood, with animals displaying mild systemic signs of disease (piloerection), but for most challenge studies we are able to reach the scientific endpoint of the study before showing systemic signs of disease.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild - 60%

Moderate - 40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune response to vaccination involves multiple, complex systems interacting in a

physiological environment often involving the antibodies, T cells and cells of the innate system and therefore at present cannot be fully replicated in tissue culture. As our work aims to identify vaccines/vaccination regimens for use in humans, vaccines need to be tested in a system which closely mimics the human body. In addition, mice are the most immunologically characterised species of animal, they have proved to be excellent indicators of immunogenicity enabling the clear assessment of novel vaccines and vaccination regimens. Therefore mice have become the standard species used for testing immunogenicity of vaccines, prior to progression into higher order species if required.

Which non-animal alternatives did you consider for use in this project?

Where appropriate we use *in vitro* neutralisation assays (typically lenti-viral assays) as a first step efficacy assessment. This can be used as a surrogate of protection for some diseases (Ebola), typically when there is not an appropriate animal model to robustly test efficacy.

We use an *in vitro* sporozoite inhibition assay that is used to show antibody mediated protection against malaria parasites with mouse, NHP and human serum samples, replacing the need for *in vivo* studies as performed by other groups around the world.

We would also like to explore organoid cultures in our development of an *in vitro* T cell killing assays for malaria.

Why were they not suitable?

These *in vitro* models can only replicate or test one component of the immune system and currently the models are not in place (or sufficient) to fully replicate the immune system, although we continue to explore potential alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

The number of animals is based on:

- the number of projects we currently have running
- the number of projects for which we are planning to apply for funding
- our experience of how many animals are used within each of our past projects

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We follow the ARRIVE guidelines and use statistical power calculations to inform and adjust our experimental design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Combining studies: When new vaccines require comparison to standard vaccines, we maximise the number of groups in an experiment, but to the limit of having a manageable experiment where scientific integrity will not be compromised.

Sequential sampling: we are able to monitor the immune response in the same animal over time by either sampling small amounts of blood, or through non-invasive imaging studies. This reduces the total number of animals required for a single study.

Collaborations: Challenge experiments are performed through collaborations with groups that have established challenge models (eg Ebola, Lassa, MERs), therefore we don't need to use additional animals to optimise the challenge models.

Sharing tissue: we collect multiple organs from single experiments and share samples between groups/collaborators when possible.

Efficient Breeding: Breeding will be optimised, wherever possible, to produce only the genotype required e.g. Homozygous breeding pairs, and breeding colonies monitored closely to avoid inefficient and non-productive crosses. Samples for genotyping will be taken in timely manner so that the incorrect genotypes are not kept within the colony.

Using excess mice from breeding: maintenance of our mosquito colony requires feeding mosquitoes with the blood of a naive mouse, where possible we use excess mice from breeding (eg animals that can't be used in experiments) instead of purchasing animals for this purpose.

Pilot studies: when establishing new models, we perform small scale pilot studies to provide important information on reactogenicity of the vaccine, or reproducibility of the assays. This data is then used in power calculations to determine optimal groups sizes required in future experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen mice are they are one of the most immunologically well characterised animal species and therefore the standard species to for immunogenicity testing of vaccines.

We predominately use non-genetically altered strains of mice, in which the immune response is well defined. When testing the vaccine efficacy, we use strains of mice and species of malaria parasites or viral strains in which the disease course is well defined,

therefore the scientific readout can be reached are earlier timepoints in the disease course.

We use genetically altered mice (GAA) to study the role of specific immune cell-types and genes in the immune response. Alternatively, we use mice expressing a human protein that enabling mimicking aspect of human immune response or is required for infection of mice with human pathogens. We will only use established GAAs of known phenotypes to ensure appropriate care and monitoring protocols are in place.

Why can't you use animals that are less sentient?

Mice are the least sentient animal with a well-defined immune system that closely mimics the human body, enabling us to test the immunogenicity of our vaccines.

There are extensive sets of reagents available for analysing immune responses in mice and they have proved to be excellent indicators of immunogenicity, enabling the clear assessment of novel vaccines and vaccination regimens for improvements. With the numerous different immunological tools available, mice can be used for detailed characterisation which is not possible in higher organisms. Using genetically modified mice with defined gene modifications provides the unique opportunity to study the role of particular genes in the induction of an immune response and required for protection.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will constantly look for more refined alternative approaches. As the primary aim is clinical translation, we will use adjuvants (or bioequivalent) that have been approved for use in humans. We use the most appropriate route of administration for each vaccine formulation, with routes and maximum volumes following published guidelines.

Our extensive experience with these vaccination studies enables the selection of most informative timepoints.

We use short term anaesthesia when the route of injection can be painful, eg intramuscular injection.

Our typical route of vaccine administration is in-line with standard administration of vaccines in humans (eg intramuscular, intradermal, sub-cutaneous) and only use alternative routes of vaccine administration when targeting the response to specific sites.

Where possible we use less virulent strains of the pathogen and/or modify the challenge dose or route of administration to reduce disease severity.

When studying the role of specific cells requires removal of these cells, generation of chimeric mice (mice that have received a bone marrow transplant) is only used if there is no alternative method that can achieve this scientific aim (eg depletion of cells with drugs or antibodies or the use of GAA mice).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The Handbook of Laboratory Animal Management and Welfare, Sarah Wolfensohn and Maggie Lloyd, Blackwell publishing, Third Edition (2003) in addition to following NC3Rs,

LASA and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Members of our team are active members of local ethical review committees, therefore regularly exposed to improvements and alternative approaches by researchers using similar models. We receive regulars NC3Rs and University 3Rs newsletters, we attend and participate in local 3Rs meetings. We keep up to date with the literature in both the vaccine and infectious disease field, ensuring we are aware of new or improved models that could be implemented in our research.

13. Tissue response following synovial joint injury and potential for therapies to restore joint structure

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cartilage, Bone, Osteoarthritis, Cellular therapy, Biomaterials

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to study the biological mechanisms that contribute to the repair response after joint surface injury. This data will provide a better understanding of the role that drugs, biological molecules, biomaterials and regenerative cell therapies can play in restoration of joint tissues.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Arthritis is the biggest cause of pain and disability in the UK. The most common form of arthritis, osteoarthritis (OA) is believed to affect an estimated 8 million people in the UK, and worldwide this figure rises to 343 million. Any joint in the body can be affected by OA

but it is more frequently observed in joints that support the most weight, such as hips and knee. A joint is formed in the body where bones meet and to ensure that they can move against each other, their surface is covered with a smooth, slippery but tough tissue, called cartilage. In OA the cartilage begins to thin and its surface becomes rougher meaning that the frictionless movement of the healthy joint is lost. These changes, together with others in the surrounding bone and lining tissue of the joint can cause pain and loss of mobility. OA is associated with age but younger people are also affected, often impacting on their ability to work, exercise and socialise. Whilst total joint replacement surgery is an option for end stage disease there are no widely available treatments that can be used to halt or ease the progression of OA. Microfracture is a procedure where the surgeon creates a controlled joint surface injury at the site of localised cartilage damage to induce a limited repair response. This approach is currently used as a treatment in a restricted number of patients but produces cartilage which does not completely recreate the original tissue. The goal of our research is to understand how this surgical approach can be refined to benefit a much wider group of patients and produce repair tissue that restores joint function and halts further disease progression.

What outputs do you think you will see at the end of this project?

This project will provide greater insight into the healing of bone and cartilage within a joint following injury and how the addition of drugs, cells or materials suitable for introduction to living tissue can improve the healing process. These new discoveries will be shared with others at local, national and international scientific meetings and in widely available publications. The data from this work will form the basis of future funding applications and where appropriate will support patent filings to protect intellectual property. In more detail, it is our expectation that our research will produce one new therapy that can be advanced to a point where it can be investigated further in a large animal model. Over the longer term (5-7 years) we aim to develop at least one human clinical trial to determine the safety and success of the therapies developed in this project.

Who or what will benefit from these outputs, and how?

In the early stages of this project (years 1-3), researchers who focus on understanding tissue damage in the joint and the potential to improve the healing response will be the major beneficiaries of this work.
These findings could also have broader significance to those researchers studying mechanisms of disease in the joint and also the wider research community investigating tissue repair following injury. In the medium term (years 3-5), the findings from this work will benefit clinical groups and industrial companies interested in the development of new treatment approaches for the restoration of cartilage and bone in the joint. In the longer term (5-7 years), this work will benefit patients with localised cartilage loss that have been recruited to clinical trials. Ultimately (7-10 years) we hope that larger numbers of patients will benefit from the therapies developed from these studies once they have been shown to be safe and effective.

How will you look to maximise the outputs of this work?

The discoveries from this work, which may include unsuccessful findings, will be shared in the first instance with our research networks. These groups meet regularly and include researchers from broad academic disciplines including life sciences, medicine and engineering as well as complementary areas of biological research. Our results will be disseminated more widely through presentation at national and international research conferences, through publication in peer-reviewed journals and where appropriate

submission to "publish, then review" journals such as eLife or bioRxiv, an open access preprint repository.

Species and numbers of animals expected to be used

- Mice: Mice: 3700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use adult mice only. Mice are the lowest experimental species to humans with comparable organ systems and folding limbs that support body weight. This means that our studies on joint surface injury and healing will be performed in a tissue and mechanical environment that provides useful information directly relevant to humans. In addition, mice strains with specific genetic alterations could be used in our work to help identify the detailed mechanisms that are responsible for the healing of bone and cartilage in the joint.

Typically, what will be done to an animal used in your project?

In a typical experiment, the mouse will undergo a single surgical procedure to create a joint surface injury in the knee of the animal. This surgical procedure will be completed under general anaesthesia so that the animal will remain in a state of sleep/unconsciousness throughout. The mouse will then be kept alive for up to eight weeks before being humanely killed and tissues harvested for further study. In approximately 30% of the animals a modified material that can be safely introduced into the body will be included at the site of injury to assess its impact on repair. In a further 30% of the animals, a drug or therapy will be administered (orally or by injection, either into a vein, into the body cavity or directly into the joint space of the knee) to determine its potential to modify joint repair following injury. Cells as a therapy will be administered on a single occasion into the joint space whilst drugs may be used on multiple occasions before (for example to target the function of a particular cell type) and/or after the surgical procedure (to directly impact on the healing response). Approximately 15% of animals will have imaging (like x-ray analysis) performed at single or multiple time points whilst the injury is healing. This may include specialist imaging such as magnetic resonance imaging (MRI) to identify cells that have been labelled to allow their visualisation. Detailed analysis of the MRI data will detect altered signal from the labelled cells revealing their specific location within the joint structure. In some experiments, the surgical procedure will expose the mouse knee but not include making a joint surface injury. These so-called, sham-operated mice will allow us to understand the impact of the surgery alone on the biology of the knee joint.

What are the expected impacts and/or adverse effects for the animals during your project?

The procedure to induce a joint surface injury is generally (in 95% of animals) well tolerated. We anticipate that 100% of the animals that undergo this procedure will have pain, lameness and joint swelling but this will rapidly improve over 48 hours after which

the animals will not show any clinical signs. During this initial 48 hour period animals will receive pain relief. In some cases though, animals may continue to show or develop during the experimental period reduced movement, weight loss, reduced food intake or an abnormal coat. If after interventions, such as treatment with antibiotics or high energy soft food, these clinical signs persist then the animals will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse: Mild 10%

Mouse: Moderate 90%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Prior to performing experiments in animals we conduct detailed laboratory studies of the human cells that we judge important in the healing of joint surface injuries, identifying their characteristics and response to factors likely found in the wound environment. However, it is not currently possible using laboratory based approaches to reproduce both the mechanical environment and the complex organisation of tissues and cell types that occur through time in response to injury in the joint. Several of the cell types that are implicated in the repair response only have access to the damaged tissues via blood vessels and so we need a functioning heart and circulatory system to investigate these responses in a way that is clinically relevant and meaningful. Our earlier experience with the experimental approach described here has provided us with a good overview of the healing events after osteochondral injury in the mouse. It has also illustrated the robustness and quality of the data from our studies providing insight into the activity of some cells and the molecules that they may respond to or produce during osteochondral repair. However, further detailed questions remain concerning the function of key cell types following synovial joint injury and the efficacy of therapies. It is these questions that drive the breadth of our planned studies.

Which non-animal alternatives did you consider for use in this project?

Approximately 80% of our research is conducted in the laboratory to study individual human cell types both alone and in simple model systems of two or three different cell types. This work includes using the latest cell printing and other manufactured cell culture environments. These studies directly contribute to the replacement of animal studies by identifying the cell types, treatments and time points after injury which should be the focus

of our investigations.

Why were they not suitable?

Even the most advanced laboratory cell culture environment cannot reproduce the mechanical forces and complex tissue and cell interactions that occur within a sophisticated anatomical structure such as the joint. For this reason it remains necessary to address the unanswered questions surrounding the healing response in the joint using animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals has been estimated based on our experience of using these and similar experimental approaches over the last five years. For each of the studies that we wish to perform we are able to predict the number of animals that will be needed to give us reproducible and reliable information. We also understand the lengths of time that our studies need to be performed over to give clear answers to our research questions. This enables us to predict how many experiments can be accomplished over the time given to our studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our previous studies have provided us with a clear understanding of the magnitude of effect that is biologically meaningful and its variation within the experimental data. This means that in the experiments that we perform, each experimental group will contain the minimum number of animals to provide biologically meaningful data. When a new treatment, method of imaging or adaptation of the surgically created injury is introduced, it is first investigated in pilot experiments that contain fewer animals. This approach allows us to understand the effectiveness of the intervention and quality of the data to decide if the group sizes in these experiments should be recalculated. We will use the NC3Rs Experimental Design Assistant and other online tools to help us in confirming that our experimental approach is reliable and likely to provide reproducible data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use a number of complimentary approaches to reduce the number of animals needed in our work:

Pilot experiments will be performed with fewer animals when a new drug, method of analysis or modification of surgical practice is introduced. This will ensure that subsequent larger studies can be designed to be as accurate as possible.

In studies where the effects of a new treatment or sham surgery versus injury are evaluated, the mice will be randomly allocated to control and treatment groups. In addition, where possible, any treatment will be administered to the animals in such a way that the person delivering it is not aware of whether it is the active treatment or inactive control substance. When the assessment of healing is based on microscopy, "blinded" observers will score the specimens and in experiments analysing large datasets bioinformaticians will analyse the data with no prior knowledge of the experimental groups. The data will then be matched back to the original experimental groups at the end of the analysis, so avoiding bias.

Where appropriate we will share excess breeding animals with other researchers and use any animals culled as tissue donors for use by our group or by other researchers.

In studies that use human cells as a therapy, multiple studies using the same human cells will be performed. This approach minimises variation introduced by using different human donors and reduces the number of animals used.

In some studies, non-invasive imaging techniques will be used to follow aspects of the experimental outcomes of our work through time in individual mice. These approaches mean that fewer animals will be required as it removes the need to cull animals at distinct timepoints.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The principal experimental approach that will be used in these studies is a surgically created joint surface injury model. This approach has been refined such that it causes the least pain and suffering to the animals. The surgical procedure itself is expected to result in lameness which will improve within 48 hours. The recovery from surgery will be rapid and progressive with no deterioration in lameness expected to occur. This model is not expected to result in persistent clinical signs that fail to respond to treatment (such as pain relief medication or antibiotics). If however, clinical signs do not resolve animals will be humanely killed and no animal will experience lasting harm.

Why can’t you use animals that are less sentient?

Our work focuses on the joint, a complex part of the anatomy which undergoes significant change throughout development and into adulthood. Adult mice are the least sentient animal that allows us to perform these investigations. The response to injury and the repair processes that follow take days and weeks to develop and for this reason it is impossible to perform these studies under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs

(harms) for the animals?

All animals used in our studies will have a minimum period of 7 days acclimatisation to their environment, including social group, prior to undergoing a surgical procedure. In these experiments each mouse receives a single tissue defect in one knee only which minimises initial pain, discomfort and lameness that the animal might experience. Immediately following the procedure the animals will be housed with access to warmth, post-operative bedding and other nesting materials and wet mash food on the floor to minimise the need for movement. Working with the staff at our animal facilities there are thorough procedures for the post-operative monitoring of all experimental animals, including the use of score sheets to record animal health status, discomfort, lameness and weight. The major clinical impact of our surgical procedure is initial lameness which can be clearly identified by observation but the close monitoring of bodyweight will also help ensure that humane endpoints are adhered to. Oral pain relief medication, that is flavoured to make it more pleasant-tasting, will be given to the mice for several days following surgery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidelines including those published by the Laboratory Animal Science Association (LASA), e.g. record keeping, performing surgery, education and training, and reporting of experimental results will be followed in our work. Specific guidance on the principles of surgery will be followed from LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery - A report by the LASA Education, Training and Ethics section (E Lilley and M. Berdoy eds.). The health status of all animals will be supported by guidance on body condition scoring e.g. Ullman-Culleré MH, Foltz CJ. Lab Anim Sci. 1999 Jun;49(3):319-23. In our studies we will also follow the Animal Research: Reporting of *In Vivo* Experiments (ARRIVE) guidelines on experimental conduct, including study design, avoiding bias and statistical analysis of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will continue to review relevant publications, guidelines and best-practice information. This will include resources from The National Centre for the 3Rs (NC3Rs) and practical guidance from the Laboratory Animal Science Association (LASA), Institute of Animal Technology (IAT), and the Royal Society for the Prevention of Cruelty to Animals (RSPCA).

14. Developmental control and cell to cell interactions of African trypanosomes

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

African trypanosomes, Sleeping sickness, Quorum sensing, Nagana, Development

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how trypanosomes communicate with one another in their mammalian host in order to prepare for their transmission to tsetse flies, the disease vector for African trypanosomiasis (a disease of humans and livestock), and how this is lost in some trypanosomes in the field. We further want to understand how the simultaneous presence of more than one strain or species of trypanosome in a host might influence their virulence or capacity for transmission.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The ability of trypanosomes to use environmental signals via cell-to-cell communication (a process called quorum sensing (QS)) to regulate their development in mammalian hosts controls their ability to prepare for uptake by their vector, the tsetse fly, and so is an important component of disease spread.

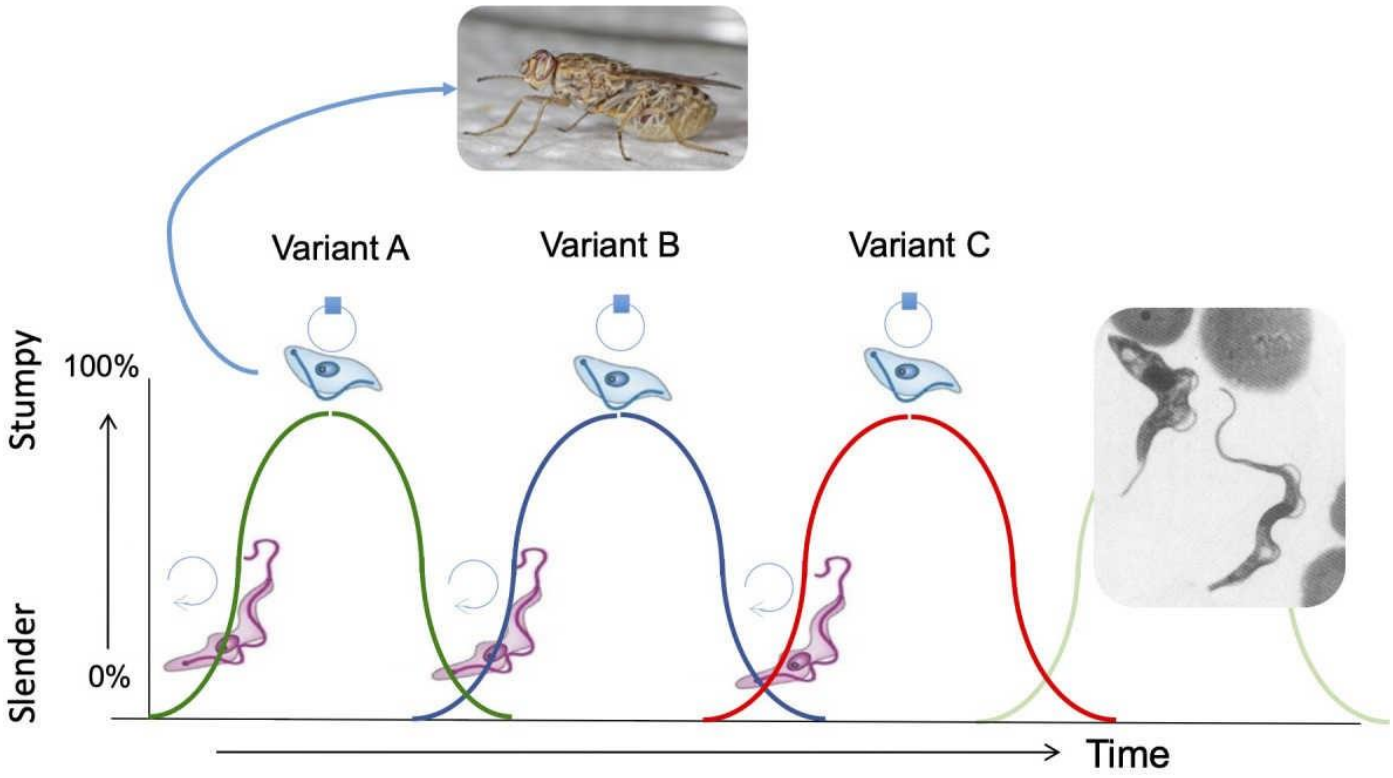

Figure: The life cycle of *Trypanosoma brucei*, showing waves of parasites in the mammal host (caused by waves of antigenic variants in the population), and- within each wave- the development from slender to stumpy forms, ready for transmission. The stumpy forms are taken up by tsetse flies to continue the life cycle.

When the cell-cell communication system is lost naturally in the field, some trypanosome species (Trypanosoma brucei evansi, Trypanosoma brucei equiperdum) have developed alternative routes of transmission using non-tsetse biting flies or venereal transmission, for example. Furthermore, since trypanosomes frequently co-exist with other trypanosome strains and species in disease-endemic regions there is the potential to select for reduced or enhanced transmission and also altered disease virulence generated by interactions between the parasites. By understanding the molecules the parasite uses to monitor and respond to its environment, how these processes are disrupted in some naturally occurring or selected parasite lines or species, and the presence of other trypanosomes, we aim to understand the basic biology of parasite virulence and transmissibility. This also offers the potential to identify routes to block or accelerate development in order to kill the parasites or reduce their transmission and to predict the emergence of more virulent strains. Analysing and perturbing the interactions between trypanosomes also provides the potential to predict the consequences of, for example, drug resistance in the field, or altered host and vector access, for parasite virulence and transmission when in single or mixed infections.

What outputs do you think you will see at the end of this project?

We expect to gain new information on the biology of how trypanosomes might perceive environmental information and the presence of other, related, parasites and the

consequences of this as they undergo development as an adaptation for transmission to their tsetse fly vector. Because trypanosomes are evolutionarily divergent organisms, molecular understanding of their mechanisms for perceiving their environment can highlight unusual eukaryotic processes or identify novel mechanisms that differ from those of other eukaryotic organisms including their hosts (humans and animals). This has the potential to provide new knowledge as well as new potential therapeutic approaches, for example through identifying new targets for drugs. The interactions between different infectious agents in a host also has relevance in many disease contexts and our studies will provide new understanding of the consequences of these interactions for disease virulence and spread. The work will generate research publications for the scientific community but will also be disseminated to the public through appropriate channels (e.g., newspapers, radio and television).

Who or what will benefit from these outputs, and how?

The discovery of the mechanisms by which trypanosome parasites respond to their environment provides novel routes to controlling the parasite. For example, manipulating the signals that normally drive their cell division arrest could reduce the virulence of the parasite, as could perturbing the activity of molecules that transmit this signal within the cell and between cells. The gene expression profile of some of the molecules linked to arrest as stumpy forms, or proliferation, might also provide molecular markers that permit the prediction of the virulence of the parasite or their likelihood for transmission.

The interactions of different trypanosome species could also be informative in predicting the threat of virulence of parasites that have been selected in coinfected hosts, since they may exhibit particular virulence profiles in the absence of coinfecting competitors. Trypanosomes are amongst the most evolutionarily ancient nucleated cells (eukaryotes). Hence, as well as discovering potential vulnerabilities in their life cycle that can be exploited for therapy, the understanding of their molecular pathways involved in development may provide fundamental knowledge helpful to understand how all cells undergo specialisation, including our own cells.

How will you look to maximise the outputs of this work?

Our laboratory collaborates widely with researchers in the UK, Europe, USA, South America and Africa. These activities generate knowledge sharing and joint publications, personnel exchange, etc. In addition to publication in high impact journals, we have (and will continue) to publish less impactful or negative outcomes in specialist research journals as well as general open access avenues such as BioRxv, Wellcome Open Research, etc. We have also put considerable effort into communicating our research through Schools' outreach, participation and engagement days as well as at a very well attended (at least 37,000 attendees) public museum exhibition.

Species and numbers of animals expected to be used

- Mice: 3500
- Rats: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will predominantly use adult mice. Murine infections allow comparison with previous analyses of routine infections in our laboratory; infections in these animals are very reproducible and predictable over the first wave of parasitaemia, which will be the focus of most of our studies. However, some studies will use longer term infections to explore the consequences of long-term interactions between trypanosomes or to compare early and chronic stages of infection. Some experiments will use particular mouse strains where this is necessary for comparison with results from other labs that use that model. Our lab has many years of experience of monitoring trypanosome infections in mice and so are able to identify the likely progression of parasitaemia and associated clinical signs. By accurate projection of the course of infection, monitoring can be increased as necessary during critical phases of infection. The predictability of infections will also aid the selection of appropriate time points to capture parasites at different stages of differentiation. It also minimises the possibility of unanticipated infection pathology ensuring that experiments derive maximum outputs from the minimal number of animals used.

Rats are used when larger numbers of trypanosomes are required- approximately 10 times as many parasites can be harvested from adult rats as from adult mice.

Although in vitro culture of parasites can be used for many experiments, analyses are required where the context of infections in vivo are being explored, for example in the presence of the host immune system or where interactions with host molecules are being studied (for example, degraded host proteins can contribute to the generation of the parasite's quorum sensing signal). Furthermore, the number of trypanosomes that can be isolated for molecular studies from infections is much higher than from culture, such that in vitro methods are not possible for some analyses and become unfeasible where large amounts of parasite material are required for study. Hence, infection-derived material can provide sufficient material to make feasible some molecular purifications that are impossible using culture methods and this is necessary to achieve the scientific objectives of the work.

Typically, what will be done to an animal used in your project?

Typically, animals will be inoculated IP or IV with trypanosome parasites, optionally after their immunosuppression with cyclophosphamide. The infections will then be monitored by sampling the tail vein by scab removal after around 3 days until the developmental progression of the parasites occurs in wild type parasites (typically after 6-9 days). Where molecules potentially important in development are identified, mutant parasite lines will be created and their virulence and developmental progression to transmissible stumpy forms will be monitored after ectopic expression, gene deletion or gene silencing, this being carried out with appropriate group sizes and in comparison to wild type parasites.

Most infections will be terminated after 6-9 days when stumpy forms develop, or prior to this if the loss of stumpy formation enhances virulence of the infections. For some experiments longer term infections will be analysed using either single trypanosome species or strains or using a mix of more than one trypanosome species or strain. These infections will be monitored for the relative proportion and developmental status of the component trypanosome species/strains.

The distribution of parasites within the mouse host may also be monitored using red-shifted luminescence imaging under anaesthesia. This involves the inoculation of parasites

IP, and then the monitoring of infections at time points after infection under anaesthesia by the inoculation of a luminescent substrate to allow the compartment or distribution of the parasites to be visualised using recording equipment.

Where pharmacological agents are identified that may alter the development or viability of the parasite, these will be investigated for their effects on parasite viability, development or growth in vivo. This will be preceded by range-finding experiments where appropriate pharmacological doses are determined. In each case, parasite numbers and developmental form will be assessed by isolation of a blood drop from the tail vein and then analysis of parasite numbers or morphology microscopically or using molecular markers (e.g. immunofluorescence microscopy, qRT-PCR).

The transmission capacity of parasites may also be monitored by assessing the ability of tsetse flies to become infected after feeding on anaesthetised infected mice.

In all cases, at the end of experiments, animals will be terminally anaesthetised and, optionally, parasites harvested by cardiac puncture and blood collection. Organs might also be isolated post mortem to determine the distribution of parasites according to the luminescence of tissues infected with parasites expressing red-shifted luciferase.

What are the expected impacts and/or adverse effects for the animals during your project?

Trypanosome infections can be fatal in rodents, death being preceded by progression through a predictable series of symptoms on a relatively predictable timescale. Our experience of working with these parasites in mice (over 20 years) means that we have become expert at monitoring and predicting the progression of infections, so that experimental outcomes can achieved without the infection leading to severe illness or death, which is a rare occurrence (less than 0.5% of infections). Mice and rats are monitored for their disease progression based on a numerical scoring system and undue suffering prevented by humane killing should the infection progress to a level where death is anticipated within a few hours or might occur if animals were left unmonitored overnight. As a consequence, the overall severity for our experiments is classed as moderate. At the end of experiments animals are euthanized and parasites are harvested.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice- expected severity based on values from 2020 Mild- 32%
Moderate- 68%

Severe- less than 0.5%

Rats- expected severity (no experiments with rats were carried out in 2020, values are estimates based on historical values)

Mild- 50%

Moderate- 50%

Severe- less than 0.5%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We routinely grow trypanosomes in cell culture. However, their life cycle development does not progress normally in cell culture, such that the production of the transmission stage (stumpy forms) is best achieved in parasites grown in mice. Furthermore, the evaluation of the effects of disrupting particular parasite molecules and processes can only be accurately determined by studying parasites growing in the natural context of a bloodstream infection in a mammalian host where the host physiology and immune response may contribute. For the isolation of large numbers of parasites, the ability to harvest tens of millions of parasites from a single infection makes some experimental approaches feasible that would not be possible using cultured parasites that are in an un-natural growth medium and isolated from the host (and thereby in the absence of an immune response and where molecular signals are not at natural levels due to their non-physiological accumulation or turnover in culture). Furthermore, parasites grown in culture do not generate synchronous populations of stumpy forms that are required to analyse molecular events in the population that reflect molecular events going on in each individual parasite. Coinfections also require to be studied in the context of a functional immune system. Whilst interactions between parasites in culture can be informative, ultimate validation of any effects observed needs to carried out using parasites growing in a mammalian host where the combination of immunity, signal production and turnover can contribute to the infection dynamic. Where parasites occupy particular host body compartments, this must also be assayed in vivo.

Which non-animal alternatives did you consider for use in this project?

We have developed non-animal based protocols for growing parasites and generating stumpy forms in vitro using brain heart infusion broth and, more recently, basement membrane extract. These are effective at generating populations of stumpy forms that accurately reflect those generated in vivo. This allows genetic perturbations of parasite lines to be evaluated in pilot experiments and the onward developmental capacity of trypanosomes to tsetse midgut forms to be explored. Small molecules driving or inhibiting differentiation can also be tested in these in vitro assays. However, these cannot fully recapitulate growth in vivo, and so experiments must also be validated in vivo or extended to assay the contribution of the host physiological environment.

Why were they not suitable?

In vitro culture cannot accurately reflect the complexity of in vivo signals, parasite interactions with host molecules or the immune system, or the kinetics of small molecule accumulation or turnover in vivo. In addition, the contribution of physiological compartmentation (e.g. in the adipose tissue or skin) cannot be studied in vitro. For these

reasons assays finally must be carried out in vivo to assess the environment in which parasites establish and differentiate accurately.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on current laboratory usage and reflect the number of animals needed to generate molecular material or maintain parasite blood stocks, or the number of animals required for statistical validity when assessing parasite phenotypes after gene knockout, knockdown or overexpression studies. Likewise, experimental design considerations for the analysis of coinfection experiments dictate the numbers of animals used in experimental groups. In all cases, pilot assays are also used to establish the dose of trypanosomes for infections, their likely progression of growth and differentiation and dosages for particular pharmacological regimens. These small pilot studies help to optimise the experimental studies where larger groups of animals are used for statistical analysis.
Maintenance of parasite blood stocks (which can be cryopreserved) can also use small animal numbers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Trypanosome growth in mice progresses on a relatively predictable course, such that it is straightforward to generate reproducible and statistically valid datasets that satisfy external scientific scrutiny (i.e. where the probability of the observed outcome being incorrect is less than 5%). We are experienced in analysing and predicting parasite virulence in mice and so can minimise distress whilst deriving the necessary scientific information from infections. Genetic manipulations of trypanosomes often involve use of gene silencing or gene overexpression techniques, which are controllable using chemicals supplied in the rodent drinking water (e.g. doxycycline). This provides well controlled analyses because phenotypic comparisons between treated and untreated populations provide a robust experimental outcome using the same parasite material. We have used the assistance of an Experimental study design and statistical support officer to help plan appropriate group sizes for studies where there is variance in the effect size. This support provides advice on the planning and interpretation of experiments to achieve statistically meaningful outputs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot assays are used to establish the dose of trypanosomes for infections, their likely progression of growth and differentiation and dosages for particular pharmacological or experimental regimens. These pilot studies help to optimise the experimental studies where groups of animals are used for statistical analysis.

In vitro assays using basement membrane culture media also optimise our studies by identifying those cell lines that exhibit the appropriate gene perturbation or best regulation using inducible systems such as tetracycline/doxycycline controlled overexpression or gene silencing.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are used to monitor trypanosome infections in laboratories worldwide. This allows comparisons of the infection profile and kinetics of proliferation and differentiation between studies and between laboratories. The symptoms linked to trypanosome infection in mice are also predictable allowing us to track the progression of infections with a scoring system allowing defined humane end-points. A staged approach will be adopted when novel drugs are used. Mice do not exhibit overt signs of distress or discomfort from infection except in the critical phases when infections are closely monitored.

Rats are required occasionally where it is important to isolate very large amounts of parasite material- beyond that achievable either in vitro or in mouse infections.

Why can’t you use animals that are less sentient?

Trypanosomes can only infect mammalian hosts as their disease relevant bloodstream form. Infections must be sustained over a period of days to allow for parasite development, or longer to explore aspects of the parasite's interactions with the host or other parasite strains or species. Adult animals are required to explore the parasites' biology in a manner relevant for livestock or human infections in Africa.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
We carry out ongoing review of procedures, in consultation with the relevant services at the Institute, to assess where animal welfare can be ensured and enhanced. Examples of procedure adaptations include improved environmental enrichment, avoiding single housing where possible and exploring the potential for the introduction of refined local anaesthesia for the harvesting of small parasite samples from the tail vein etc.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experimental procedures have been developed in house but also adapted or adopted as new approaches are described or detailed in the literature. For example, we have published methodology for parasite development in vitro using Basement membrane extract. Other methodologies follow those of colleagues in other laboratories.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Ongoing training and education will be provided through the Institute, with updated information provided via their regular community meetings and information updates. Training guidance will be disseminated through local animal unit personnel and at our own laboratory meetings, held weekly.

15. Neural circuits: neuron-glia-immune interactions in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neuroscience, Inflammation, Psychiatric illness, Memory, Dementia

Animal types	Life stages
Mice	neonate, juvenile, adult, embryo, pregnant, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to study brain function in normal, healthy conditions and how this changes due to disease. We will also study how life-style 'risk factors' such as obesity interact with the **immune** system to increase the severity of conditions such as dementia. Our focus is on different cell types in the brain: **neurons**, which are nerve cells that communicate via electrical signalling, and **glia**, which form the majority of cells in the brain but were previously viewed as 'care-takers' and mostly ignored by researchers. Recent advances show that glia actually play a profound role in sculpting brain structure and function, and may be responsible for mediating many healthy and disease-related processes in the brain. Additionally, we aim to test the idea that disruptions in **neuron-glia-immune** interactions are a common feature that underlie many neurological and psychiatric illness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding **neuron-glia-immune** interactions is likely to be the key to unravelling the neurobiology of many diseases. The emerging field of **neuroimmunology** has demonstrated that there is a life-long, continuous interaction between brain and immune systems that begins to affect brain function even at the earliest stages of pregnancy. Molecules that the immune system uses to signal throughout the body are also involved in determining how the brain develops, from embryo to adulthood. The aim of our project is therefore to study electrical communication in the brain to determine how different regions interact to support brain functions such as memory and decision-making, and how interactions with the immune system change this.

Immune molecules are produced to excess in conditions such as obesity, smoking and lack of exercise; these conditions appear to greatly increase the risk of late-life disorders such as Alzheimer's disease and other dementias, by creating an excessive amount of immune molecules in the body, causing inflammation. These inflammatory molecules from the blood then enter the brain and are known to activate certain glial cells, called **microglia**, and affect how microglia can clear toxic proteins and repair damage in the brain.

Much neuroscience research is focused on neurons. However, it is important to understand how these neurons are changing in the wider context of the other cells in the brain. By learning how neuronal function is shaped by glial cells and influenced by the immune system, we believe that we will gain important insights into the mechanisms through which an individual's lived experience and lifestyle factors can interact with their genetic background, making them either more or less susceptible to disease. This should uncover novel potential therapeutic targets for prophylactic or disease-modifying therapies.

What outputs do you think you will see at the end of this project?

By the end of this project, we believe that we will have learned a great deal of information about how immune system activation at different points in life (pregnancy, adolescence, adulthood) interact with genetic risk factors to manifest as neurological or psychiatric disorders, with mechanisms including changes in the brain's electrical activity, and how the brain's immune cells can shape connections between different neurons throughout life. We also expect to gain important insights into how these systems interact in normal, healthy conditions. Beyond new knowledge, the outputs from these projects will mainly be in the form of scientific publications, and lectures to academics and the public.

Who or what will benefit from these outputs, and how?

In the short-term, the benefits from these outputs will be increased understanding of how the immune and brain systems interact in healthy and diseased states. In the longer term, this could provide novel therapeutic targets for the treatment of psychiatric or neurological conditions, from schizophrenia, through depression to Alzheimer's disease and Lewy Body dementia. Mental illness such as depression affects 1 in 6 people at some point in their lifetime, with 1% of the global population being affected by schizophrenia. As humans live longer, dementia is becoming an increasing burden on society: there are 900,000 people in the UK living with dementia (out of 55 million worldwide) at a cost of almost £35bn per year. By 2040, it is estimated that 1.4 million individuals in the UK will be living with

dementia, at a predicted cost of over £94bn per year. If our research can provide new therapeutic targets for treatment of these conditions, the potential impact is significant. By studying how the immune system interacts with the brain, which is implicated in many distinct brain disorders, our research will have relevance to all of these conditions.

Furthermore, our plans to replace immune cells in mice with those derived from patients could provide key information in predicting which patients are more likely to show improved response to medications, using preclinical research as a stepping-stone to precision, individualised medicine.

How will you look to maximise the outputs of this work?

In order to maximise the benefits of our work, I have established collaborations with clinical colleagues working in the field of rheumatology; rheumatology patients are at an increased risk of developing conditions such as depression and dementia, so by working collaboratively in projects that incorporate both human clinical, and our preclinical mechanistic studies, we hope to maximise the potential of our work to play a role in improving human life. We have also established collaborations with neuropathologists, where we have been using insights from human post mortem studies to better improve our approach to developing animal models of dementia, particularly in the field of Lewy Body Dementia. Additionally, we are currently actively exploring opportunities for collaborations with pharmaceutical companies in the field of neuroinflammation. Whenever not commercially-sensitive, we will publish our findings as widely as possible, including depositing our results on preprint servers upon submission to academic journals.

Species and numbers of animals expected to be used

- Mice: 10500
- Rats: 350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will primarily use mice because a number of advanced tools for studying brain function have been developed in genetically-altered mice, and because well-established models of both Alzheimer's disease and schizophrenia have been developed in genetically-altered mice. Our choice of life stages are dictated by experimental need: to study how environmental factors during pregnancy can influence brain function over time, it is necessary to work with pregnant mice. Similarly, dementia is a late-life disease, so it is necessary to study this disorder in older animals. Most of our work will be carried out in young, adult animals. Rats are more intelligent than mice and are larger, so we may carry out a small number of experiments in rats when these attributes make them more likely to be able to successfully complete an experiment.

Typically, what will be done to an animal used in your project?

Many of our experiments will require surgery where we can use viruses to insert genes into various parts of the animal brain to allow us to change the way that they function, or to

better study how different parts of the brain are connected. In these cases, animals will undergo surgery lasting around an hour, where we make a very small hole in the skull to insert a small needle to inject the virus into the brain.
We will then seal up the skull and allow the animals to recover. Typically, animals experience some pain after the surgery, but this can be easily controlled with medication, under the guidance of a vet. Animals typically recover within a few days, and are housed normally for several weeks until they are killed under deep anaesthesia so that the brain can then be removed for further study.

In a smaller group of experiments, we will also implant devices into the animals' brain to allow us to record electrical activity while they carry out behaviours such as exploring a maze. During these surgeries (typically lasting 2 hours), animals will be deeply anaesthetised and small devices (typically weighing around 2 grams, which is about 10% of a mouse's body weight) will be implanted into their brains and secured in place using dental cement. At least a week after surgery, animals will undergo behavioural experiments, during which they will be connected to recording apparatus via a wire, which can cause some initial distress. Animals quickly get used to this type of experiment, and become comfortable enough to fall asleep during the experiments. Before each behavioural experiment, animals may receive an injection of a drug designed to increase or decrease activity in a specific part of the brain to allow us to better understand how that part of the brain is needed to carry out the task. At the end of these experiments, animals will be killed under deep anaesthesia to allow us to remove the brain and study anatomical changes. Alternatively, instead of using electrical recordings of brain activity, animals will have a small glass window implanted in their brain to allow us to use microscopes to directly observe activity in the brain. When connected to the microscope, the heads of the animals will be fixed in place, but they will be able to move by running on a treadmill or floating ball, which minimises stress from the procedure.

Some of our experiments require us to examine how lifestyle factors affect the development of brain diseases. In these case, mice will be fed a high-fat diet to mimic lifestyle factors known to increase the risk of brain disorders in humans.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that have been genetically modified to model diseases such as dementia or schizophrenia show only subtle changes in behaviour or memory that require special tests to be able to observe. The most common adverse effect for our animals will be pain immediately after undergoing surgery to have viruses injected into the brain to deliver genetic tools and / or devices implanted for recording brain activity. Animals typically require painkillers for 1 to 2 days after surgery, under guidance from our vets, and fully recover within 7 days. Animals with head implants typically experience some distress when first connected to recording equipment, but get used to these after 2 to 3 recording sessions. When not connected to recording equipment, animals typically show no signs of distress or discomfort due to the presence of head implants.
In a smaller number of animals, we will inject them with substances designed to mimic viral or bacterial infections, to study the effect of the immune response on the brain. In these cases, animals will typically feel unwell for a few days after the injection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category

(per animal type)?

Most (around 60%) animals will be genetically-modified animals that are bred for the sole purpose of creating more mice (some of our experiments require two different types of mouse to be crossed to generate those useful for experiments). These mice will experience only mild severity, although there will be no aversive phenotype beyond subtle changes in behaviour in some of the transgenic disease models that require sensitive tests in order to observe these behavioural changes.

The remaining 40% of mice will experience moderate suffering due to the experiments described above, as will 100% of rats. The majority of experiments will be carried out using mice, with rats comprising less than 5% of all animals used. Of these animals The remaining 20% of mice will undergo a viral injection as well as a brain::

- Approximately 75% of mice (and 60% of rats) will experience only a viral injection into the brain and will recover fully within 4 - 7 days. After several weeks or months to allow genes delivered via viruses to be fully expressed, these mice will be made unconscious (using an anaesthetic) and their brains collected for further study without additional suffering.

- Approximately 15% mice (and 40% of rats) will receive a head implant and / or a viral injection.

- Approximately 10% of mice in total will receive a manipulation to activate the immune system (either a high fat diet, genetic expression of immune molecules, or injection with substances to mimic viral or bacterial infection), with or without viral injection and / or head implants.

- more than 80% will experience only a viral injection into the brain, and will recover fully within 4 - 7 days. After several weeks or months to allow genes delivered via viruses to be fully expressed, these mice will be made unconscious (using an anaesthetic) and their brains collected for further study without additional suffering.

- Of the remaining 20% of mice, fewer than half will undergo a viral injection as well as receive a head implant as described above.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our research aims to discover how different regions of the brain are *functionally* connected in both health and disease, and how different types of brain cell are influenced by the immune system. While we can learn which brain regions are anatomically connected using histological studies in dead tissue, these studies cannot tell us how these anatomical studies influence electrical activity in the brain, nor how this electrical activity can generate

complex behaviours such as learning and memory. Only by studying live animals can we discover how activity from different types of brain or immune cell can influence behaviour. Additionally, our focus is on how long-term increases in immune activity, through lifestyle factors such as poor diet, can change activity in the brain and interact with the progression of diseases such as dementia both at the level of brain circuits and behaviour. As a late-life disease, we can only study these interactions in organisms that live sufficiently long, have an immune system analogous to humans, and have a nervous system sufficiently complex to support experimental studies of decision-making and memory.

We are interested in the complex connections linking different parts of the brain, so need to study an animal that has analogous regions to those in humans. As such, mammalian models are essential for this work as non-protected animals such as fruit flies and nematode worms do not possess sufficiently complex brains. Much of our work will be carried out in rodents: qualitatively, rodents have the same brain regions as humans, but quantitatively, the brain is smaller and simpler. However, the brain regions that subserve memory and decision-making in humans (hippocampus, prefrontal cortex, etc) carry out the same role in rodents and no substantial differences between humans and rodents in terms of connectivity or basic circuit physiology have yet been discovered. Furthermore, numerous genetic tools for studying the function of brain circuitry exist in genetically-altered mice, so using mice will enable us to take advantage of these tools.

Which non-animal alternatives did you consider for use in this project?

The only non-animal systems that could potentially be useful in this project are computational modelling or *in vitro* systems such as cell culture or the use of brain organoids (small 'brains-in-a-dish' that have recently been described).

Why were they not suitable?

Computational (*in silico*) approaches are not suitable because computational models rely on having a well-defined system to model. The nature of long-range connectivity of mostly unknown and systems that try to model biologically-realistic models of the specific brain regions require huge supercomputers and several weeks to run, whilst still not being at a level suitable for testing the hypotheses of our project.

Cell culture systems can be useful to determining how one neuron communicates with another, but these systems cannot reproduce the architecture of brain circuits, nor can they incorporate any meaningful model of long-range communication nor interactions with immune systems. Similarly, while brain organoids show some promise in replicating the 3D structure of the brain, they do not yet provide a robust model of brain circuit function and, like cell culture, cannot address our questions relating to rhythmic network activity, long range connections, immune function or cognition. As such, the only suitable model for our research is *in vivo* or *ex vivo* animal research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were based on two factors. The first is our extensive experience carrying out this kind of research, which informs our planning process when designing new experiments. We are able to keep animal numbers to a minimum by using cutting edge methods, such as optical recordings of many hundreds of identified brain cells at a time, that yield large amounts of data, and experimental designs that allow multiple measurements to be made from each animal. The second factor was the use of statistical tests that are widely used in both animal and clinical research to allow estimation of the number of animals required to be confident that the results of tests are indeed correct.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We estimate effect sizes and adjust required numbers of animals to the minimum required to test our working hypotheses. Furthermore, we employ "within-subject" experimental designs (we measure the same animal before and after a treatment) wherever possible to reduce the number of animals required. Additionally, we maintain ongoing discussions with colleagues about best practice for designing animal experiments and minimising numbers. We take account of ARRIVE (Animal Research: Reporting of In Vivo Experiments) reporting guidelines when designing experiments, which is aided in places via use of the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Beyond good experimental design, we will use a number of other measures to optimise the number of animals used. The majority of the mice used in our project will be for breeding to produce genetically- modified animals for other protocols. We will use best practices, as guided by our animal facility staff, to breed our colonies as efficiently as possible to minimise the number of mice bred, and offer any excess mice to other researchers, when the experimental design allows. We will carry out pilot experiments for new studies to allow an accurate estimation of sample sizes to be made, ensuring that we use sufficient numbers of animals to answer the research question but no more. Finally, when carrying out histological studies, we will retain any unused brain tissue for future use by ourselves or other researchers, ensuring that maximum use is made of the tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The aim of our research is to make inferences about human brain physiology through use of animal models. Mice are one of most commonly used mammalian models in research, and genetically- modified mice allow us to target specific types of brain cell, so mice are the

most appropriate mode for our research as they allow us to gain the largest amount of information from the smallest possible number of mice. Genetically-altered animals will be used wherever possible to model dementia or schizophrenia. The models that we will use are well-validated and are known to faithfully recapitulate specific aspects of human disease, so represent the most refined way of studying these disorders.

The majority (75%) of our experiments will be to study electrical activity in the brain using *ex vivo* brain tissue. These experiments typically involve a surgical procedure to use viruses to insert genes into the brain to allow specific cell types or brain pathways to be studied. By using *ex vivo* preparations, we will minimise pain and suffering to only the days immediately following surgery, after which animals will be deeply anaesthetised before killing for tissue collection. Animals will be housed to the highest welfare standards possible, and all surgical procedures will be carried out using appropriate aseptic technique and post-operative analgesia and care to minimise the suffering and stress.

The remaining experiments will involve immune activation and / or head implants, with or without subsequent behavioural testing. When implanting devices into the brain, we carry these out during the same surgery as any viral injections to minimise the suffering an individual animal undergoes. The immune activation experiments will involve either dietary manipulations, genetic expression of immune molecules, or administration of substances to mimic viral or bacterial infection. In the latter case, we will use well-validated models with the minimum treatment duration required to produce an immune response. We expect that genetic expression of immune molecules or dietary manipulations will provide a more refined and less aversive way of activating the immune system, but these will need to be compared with the models that mimic infection to validate these approaches.

All behavioural tests will be carried out with as little stress to the animals as possible; indeed, many of the behavioural tests promote behaviours that rodents would display in the wild so could be considered a form of environmental enrichment. Some behavioural tests require animals to work for food rewards so in these cases, they will have access to food restricted for a maximum of 16 hours per day. This degree of food restriction is considered mild and animals that undergo this type of restriction have been shown to live longer and be healthier than mice allowed to eat whenever they want.

Why can’t you use animals that are less sentient?
The majority of our experiments (at least 75%) will be gathered from animal tissue or animals under terminal anaesthesia. However, some types of brain activity are linked to different behaviours (such as exploring a maze or sleeping), and understanding how this activity changes in disease is essential for determining which strategies may be effective treatments in human. As such, it is necessary to carry out some experiments in awake, behaving animals.

In terms of life stage, brain circuits begin to form during pregnancy and, in rodents, mature in the first 3 weeks after birth. Molecules used by the immune system also provide important signals for the developing brain. To learn how these systems function in humans, it is necessary to study the interaction between immune and brain systems in these early (neonatal and juvenile) stages. We also need to study the adult stage of development, which is when these systems are fully matured and animals are capable of displaying complex behaviours (such as memory and decision-making) that are directly analogous to those seen in humans. Mice present the ‘simplest’ mammalian organism that have similar nervous and immune systems to humans, so are the least sentient that can be used for our experiments. As such, our project will primarily use mice, and we will only use rats when we need to study neural circuitry or behaviour in an animal with higher

levels of cognitive flexibility than mice are capable of demonstrating (this is particularly relevant for experiments that involve the prefrontal cortex, a brain region important for decision-making and executive function). Finally, dementia is a late-life disease in humans, where progressive memory loss develops after lifetime accumulations of proteins associated with neurodegeneration. It is necessary to used aged mice to reproduce these dementia pathologies in a physiologically-relevant manner.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will monitor new strains of mice very carefully to assess their health and physiology. Post-operative care will include close monitoring of pain and weight, and the use of pain-killers. Animals undergoing procedures that may cause stress will be trained such that they gradually get used to the experimental set-up, spending increasing amounts of time each day with the equipment until it is no longer stressful.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE guidelines throughout.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to the NC3Rs newsletter and attend their virtual symposia whenever possible. We maintain open dialogue with colleagues in our own institution and beyond to ensure that best practice in animal welfare and experimental designs are maintained.

16. Novel delivery methods for cancer immunotherapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Immunotherapy, Therapeutics, Vaccines, Oncolytic virus

Animal types	Life stages
Mice	adult, juvenile, neonate, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop novel immunotherapy drugs and delivery mechanisms for these drugs which facilitate an improved anti-cancer immune response when compared to currently available treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

50% of people in the UK (367,000/ year in UK and 17 million worldwide) will suffer from cancer at some point in their lifetime and it will cause 28% of all deaths (166,800/ year in the UK and 10 million/ year worldwide). Immunotherapies have shown that the immune system has the inherent potential to cure metastatic disease even when prior

chemotherapy, radiotherapy and surgery have failed. Currently only a minority, approx. 20% of patients, benefit from immunotherapy due to multiple tumour resistance mechanisms. Research has shown many of the ways in which tumours prevent immune cell attack and there is a great need to develop treatments that can overcome these barriers to improve cancer survival statistics. Prior to human clinical studies only in vivo models can provide the entire immune system in all its complexity for the testing of immunotherapy. During this project the delivery of immunotherapeutic agents to tumours, the magnitude of immune stimulation and anti-tumour efficacy will be investigated as these are all limiting factors for currently used and developing immunotherapies in the clinic.

What outputs do you think you will see at the end of this project?

Information for development of therapeutic products and publications including:

treatment regimens to improve delivery of immunotherapy to tumours

efficacy of novel immunotherapy molecules and vectors

Who or what will benefit from these outputs, and how?

Information to inform new treatment regimens that will improve delivery of immunotherapy to tumours enabling the most efficacious dosing regimen for all of our immunotherapy projects to be taken forward.

The benefits in the short-term, 2-3 years from first use in the project, will be to shorten the drug discovery process and improve chances of success in formal preclinical studies of new drug candidates by showing their potential efficacy and safety. The information will also be used to guide the design of first in human clinical studies in the medium term, 3-5 years, and eventually as treatment for patients in the long-term, 7-10 years. Delivery of sufficient levels of immunotherapy molecules to tumours has been a limiting factor for efficacy against all carcinomas to date. Publishing peer reviewed articles detailing the efficacy of these treatment regimens will facilitate obtaining further funding to progress towards clinical studies and ultimately to a final therapeutic product in 10 to 15 years time, as well as inform other researchers on the level of efficacy shown in animal models.

Information regarding the efficacy of novel immunotherapy molecules and delivery vectors will lead in the short-term (1-3 years) to go/no-go decisions on each molecule and vector tested. Each molecule has already passed in vitro testing using human cells but is untested in a whole body system similar to that of a cancer patient. These data driven decisions ensure efficient use of time and funding which also reduces the harm to animals and humans by preventing progression to formal preclinical and first in human studies of molecules or vectors that are unlikely to show sufficient efficacy, this is a benefit seen in the medium to long term (4-10 years). The information will also feedback into the in vitro development of our future products ensuring prior to testing in animals only strategies most likely to succeed are taken forward such as immunotherapies targeting particular immune cell subsets (i.e. macrophages, T cells, innate receptors), tumour targets (i.e. particular cell surface targets) and delivery vectors (i.e. RNA, protein or virus delivery vectors). Information may be used to strengthen patent applications that will enable fund raising for products to enter clinical studies. Publishing peer reviewed articles will also assist in fund raising and bring an awareness to the field of effective drug targets.

The longest term benefit (10-20 years) would be to provide information regarding drug interaction with the whole body. Improving the design of immunotherapy molecules and

treatment regimens making it more likely that new drugs developed show efficacy in phase III clinical studies and be medically approved for use improving cancer survival.

How will you look to maximise the outputs of this work?

Outputs will be first maximized by the use of statistical tests and rigorous experimental design to obtain the maximal information for the number of animals used.

The data from the outputs will allow for patent protection and comparison to approved and developing immunotherapy treatments to maximise the chances of obtaining funding to progress to testing in human patients. The publication of data allows for peer review validation of the data assisting fund raising and bringing an awareness to the field of new immunotherapy approaches. During these projects we will be collaborating with academic groups and commercial companies further disseminating knowledge and informing immunotherapy development activities.

Species and numbers of animals expected to be used

- Mice: 3300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using adult mice from age 8 weeks up to a maximum of 12 months of age. The majority (>80%) of these mice will be wild-type, but in some instances, they may be genetically modified without a harmful phenotype. Mice are appropriate models as they can be reasonably housed within animal facilities with environmental stimulation and space to socialise and exercise. For our work on the immune system, mice are the least complex animal which still possess a complete set of immune cells with comparable human equivalents. Additionally, cancer and immunotherapy mouse models are the most widely used in the field with a wealth of peer reviewed literature to inform the experiments and limit harm to the animals. Where genetically modified mice are required only already established strains with known phenotypes will be used. These mice will have modifications to components of the immune system or to proteins often expressed in human cancers, to allow growth of implanted murine tumours expressing human proteins and then to test our novel therapeutics i.e., antibodies or viruses.

Typically, what will be done to an animal used in your project?

At 8-12 weeks of age, the mice will be administered cancer cells under the skin on the side of the mouse. These cancer cells are derived from common types of cancer such as breast and colon cancer and are routinely used in cancer research. They will be left to grow into palpable size tumours approximately $15mm^3$ in volume. Some groups of mice will then be treated by injection or via oral administration of proteins or chemicals that temporarily inhibit the immune system to help maximise the amount of subsequent immunotherapy that could escape clearance by the immune system and reach tumours. The mice will then be injected intravenously, into the abdomen, or directly into the tumours, immunotherapy in the form of proteins, attenuated virus or RNA. At fixed time

points a blood sample will be taken, for example at day 1 and day 3 after administration of immunotherapy, to measure concentrations of immunotherapy drug in the body. The growth of the tumours will be monitored using callipers or imaging under general anaesthesia at regularly spaced timepoints dependent on the growth rate of the tumours, typically every 1 to 3 days, until they reach a maximum size of 1200mm^3 volume, up to 6 weeks after cancer cell administration. The mice will then be humanely killed and tumours, organs and blood collected for analysis.

In an alternative immunisation protocol where the immune response to a model protein is measured, mice 8-12 weeks old will be administered RNA into the muscle of the leg and the production of a protein measured under anaesthesia using imaging every 1-3 days. The RNA administration will be repeated 1-4 weeks later and at a total of 5-8 weeks the mice will be humanely killed with blood and organs harvested for analysis of immune responses to a model protein.

What are the expected impacts and/or adverse effects for the animals during your project?

In mice administered tumour cells there should be no measurable effect on the ability to move, eat or drink and therefore no reduction in body weights. If tumours ulcerate and do not heal within 48hrs of developing the mice will be humanely killed. We define ulceration as a full thickness break in the skin and expect this to be a rare event happening in less than 5% of animals. Drug treatments with proteins, chemicals, viruses or RNA may induce a transient reduction of body weight with an acceptable limit of up to 15%. The reduction in body weight is likely to indicate the mouse is in some discomfort and has a loss of appetite similar to a mild infection in humans, it is expected this will not last longer than 48 hours. The use of injections or anaesthesia are only expected to induce low level transient distress like that in humans undergoing vaccination or anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90% mild, 10% moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Prior to carrying out animal experiments we have tested all the immunotherapy treatments in vitro using human immune cells and human cancer cells and only those showing an effect are taken forward to test in animal experiments. To measure the effect of different treatment regimens to improve delivery of immunotherapy to tumours an intact circulatory

system, organ pathology and immune system are required. In vitro models such as 2D and 3D co-culture systems which involve mixing a few specific cellular subsets and cancer cells with immunotherapy are used prior to animal experiments, but they cannot completely replace live animal experiments as they do not recapitulate the complexity of the whole body. The whole body modulates the efficacy of immunotherapy through the effects on pharmacokinetics and immunogenicity that cannot be replicated in vitro. Replacement of mice with non-mammalian live animals (e.g. fruit flies) is not possible as the part of the immune system targeted by immunotherapy (the adaptive immune system) is different to that of mammals.

Which non-animal alternatives did you consider for use in this project?

In silico methods are used to design our immunotherapy treatments reducing the number of immunotherapy molecules that need to be tested. The literature and databases of immunotherapy molecules that have reported efficacy in previous animal or clinical studies are redesigned to ensure only molecules that are likely to produce results are taken forward to testing, first in vitro, then ex vivo and finally in animals.

Genetically modified reporter cell lines and purified proteins are used in vitro to determine the binding and functional effects of immunotherapy molecules prior to testing in ex vivo models.

Ex vivo models using human peripheral immune cells cultured with human cancer cell lines are already used in our laboratory to pre-screen immunotherapeutic treatments before testing in animals. Those showing no efficacy ex vivo are excluded from further study.

Why were they not suitable?

The immunotherapy treatments to be tested have undergone all the in silico, in vitro and ex vivo testing it is possible to do. Information regarding dosing regimens, pharmacokinetics and immunogenicity can only be obtained in a live animal over a period of weeks after treatment. Stem cells, organoids, ex vivo collected clinical samples cannot replicate the complexity of the whole body required for testing prior to human studies. These non-animal systems compliment and reduce the numbers of animal experiments but cannot currently replace them entirely.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have set a threshold for improvement that is required to show an immunotherapy treatment is sufficiently efficacious based on the literature and 20 years of experience in the field. Statistical significance based on the size of the minimum expected improvement in efficacy and variance is set to be a medium sized biological effect. This shows that groups of 10 mice per treatment are required to be statistically robust.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Mice of the same strain and sex will be used for each experiment reducing genetic or physiological differences between animals. Where possible and in the majority of experiments multiple immunotherapy treatments will be simultaneously compared to a single mock treatment group reducing the number of separate experiments required and therefore control groups used.

Randomisation of which animals are assigned to each treatment group will be carried out to ensure an unbiased distribution of animals across groups. Blinding where possible will be used when administering drugs and measuring tumour size to prevent user bias. These techniques decrease variation between groups and prevent the need to repeat experiments due to erroneous results based on user bias.

The use of pilot or dose escalation experiments using a reduced number of animals to determine a maximum tolerated dose or maximal effective dose will be carried out where appropriate. This will allow for fewer treatment groups in the definitive experiment where there are more animals per group as only the effective dose will be tested.

Additionally, where the therapeutics to be tested do not cross-react to murine targets, murine tumours expressing human proteins will be used. In some instances, wild-type mice would reject these tumours reducing statistical power, therefore the use of genetically modified mice or partially immunodeficient mice will ensure successful tumour engraftment and reduce the total number of mice required.
Breeding genetically modified mice is an inherently wasteful process and therefore where possible mice will be bought in from external suppliers as they are required for experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout the project, in vitro work testing potential therapeutic treatments and small in vivo pilot experiments will be utilised to reduce the overall number of animals used.

When progressing to in vivo work, the purpose of pilot experiments (typically ~3 animals per group) will be used to identify adverse effects of the protocol and to determine the approximate effect size and effective dose of our treatment. A thorough inspection of the published literature in combination with our past experience will sometimes allow us to accurately estimate dose, effect size, variability and therefore group size, without pilot work. Where this is not the case, data gained from pilot experiments will allow for power calculations to estimate the required number of animals for future work and prevent experiments from having to be repeated because they do not reach statistical significance or use of excessive numbers of animals per group.

Wherever possible when humanely killing animals, we will co-ordinate with other researchers in our facility to share tissues and make any excess material from our mice available to others, thus maximising the scientific output from our work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Drug treatments: Wherever possible, we will deliver drugs dissolved in the drinking water of the mice. This delivery route avoids restraining the mice and the stress of an injection or a gavage. If this is not possible due to the mechanism of action of the drug, the least harmful appropriate delivery route will be chosen.

Tumour development: The injectable mouse tumour (syngeneic) models that we plan to use have reliable and well characterised disease course, avoiding unexpected increases in severity. When injected subcutaneously or intraperitoneally these tumours rarely metastasize and can therefore be closely monitored. Where murine tumours expressing human proteins or fully human tumours are needed but may be rejected by wild-type mice, genetically modified mice will be used to ensure successful tumour engraftment. Only already available genetically modified mice with known non- harmful phenotypes will be used avoiding immune rejection of implanted cells.

Virus therapy: We will genetically engineer the virus which we use to deliver our therapies to ensure that the virus is attenuated in comparison to wild-type and causes very little harm. This approach has been performed extensively before and is well tolerated by mice.

Why can’t you use animals that are less sentient?

Given that our aim involves utilising the host immune system to target the tumour, we require an animal which possesses a complete set of immune cells comparable to humans. In this context, mice are the least complex animal which still allow us to develop therapies which may translate to humans. While invertebrate organisms such as fruit flies share some components of the human innate immune system, they do not make antibodies or immune memory responses which are a key component of how our therapies will work in cancer. In addition, the vectors which we will use to deliver our therapeutic transgenes virus, protein and RNA have proven abilities to be effective in mice and are well tolerated.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have developed a scoring system for our cancer experiments which implements increased monitoring of the animals as they begin to develop clinical symptoms, ensuring that any welfare issues are detected quickly. This will include implementation of the NC3Rs Mouse Grimace Scale as a sensitive early indicator of distress. Wherever possible, we will deliver drugs dissolved in the drinking water of the mice. This delivery route avoids restraining the mice and the stress of an injection or a gavage.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For cancer experiments, we will follow the guidelines set by the National Cancer Research Institute and outlined in Workman et al., British Journal of Cancer (2010) 102, pp 1555–1577. For general administration of drugs, we will follow the LASA Guidelines on Administration of Substances.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to regularly monitor the NC3Rs website for updates relevant to the project and disseminate these updates to all PIL holders. In addition, PIL holders on this licence will be offered the opportunity to attend NC3Rs courses as appropriate.

17. Characterization of novel diagnostic and therapeutic targets in obesity and its associated comorbidities

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
Metabolism, Cancer, RNA therapeutics, Fatty liver disease

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We intend to describe how some of the smallest components of cells of the body are involved in obesity and other conditions which exist with it (known as comorbidities) such as type 2 diabetes or fatty liver disease/cancer, with the aim of identifying new potential targets for future treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The rising frequency of obesity and its associated comorbidities such as type 2 diabetes (T2D), cardiovascular disease or fatty liver disease constitutes a major health problem. It is estimated that almost 500 million people will suffer from type 2 diabetes worldwide in 2030. In addition, fatty liver disease is becoming an important contributor to liver cancer, mainly hepatocellular carcinoma. Several factors including physical inactivity, aging and poor diet (i.e high calorie diets) are critical contributors to the rising numbers of these

diseases. We need to know more about how the mechanisms linking obesity with liver disease in order to develop new and more effective therapeutic approaches.

What outputs do you think you will see at the end of this project?

This project will generate relevant information about how our metabolism in regulated. The results will be published in international journals and diseminated in scientific and general audiences. We will generate a number of new models and research tools.

Who or what will benefit from these outputs, and how?

The predicted benefits and beneficiaries are summarized below:

Short term: Metabolism and physiology research. Understanding at the microscopic level how our body copes with daily fluctuations in energy supplies has relevance to how our bodies respond, and to nutrition. The reagents and research data generated in these studies will be a useful resource for the scientific community because it will lay the foundations for future works on metabolism and will allow other scientists to investigate the effect of drugs targeting these mechanisms.

Medium term: Translational research. Our work will use a new therapeutic approach known as RNA therapeutics, what is an emerging area of research. Our studies will evaluate the therapeutic potential of specific substances called 'RNAoligonucleotides'.

Long term: Clinical beneficiaries. The proposed work will develop and test the effect of drugs for the treatment of metabolic disorders such as obesity, fatty liver disease or atherosclerosis (where fatty deposits are laid down on artery walls). Furthermore, the reagents generated could be used to investigate other diseases such as hepatocellular carcinoma (cancer).

How will you look to maximise the outputs of this work?

Research data and reagents generated as a result of the experiments outlined in this document will be made available to the public as quickly as we can. We will disseminate our findings in local, national and international meetings, as well as on our websites, which will be frequently updated and finally we will publish our findings in an open-access fashion.

Species and numbers of animals expected to be used

- Mice: 13910

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the lowest vertebrates amenable to genetic manipulations and thus represent an ideal model to study how genes work. For this reason, mice are frequently used to model human metabolic disorders resulting from mutations (changes caused by a range of factors) in specific genes. They also share similar substance-secreting systems to humans

and are susceptible to develop diet-induced diseases such as obesity, which can be equated to humans and thus represent a very useful model to investigate specific metabolic processes. Our experimental models will try to recapitulate the effect of lifestyle factors such as diet in the development of obesity and associated pathologies. For this reason, the experimental models will use adult or juvenile animals.

Typically, what will be done to an animal used in your project?

Once we have identified a gene of interest, we will develop methods to modify this gene. Some of these methods consist in the use of viruses or the use specific substances called 'RNA oligonucleotides' to activate or inactivate this gene. Such viruses or substances will be administered to the mice to measure their effects on disease.

Typically, mice with or without a modification in a particular gene will be randomly selected to receive a particular diet or treatment to bring about disease (e.g diet-induced obesity). Initially, we will use a model that recapitulates the initial stages of metabolic pathology such as diet with a high calorie content to promote obesity and mild accumulation of fat in the liver. The diet will be administered for the shortest period to establish the expected symptoms of disease, typically ranging from 4 to 16 weeks. The role of the gene of interest will be investigated by comparison of the development of obesity and other associated diseases in different groups of animals. For this comparison we will monitor changes in body weight, analyse blood samples to check how well the animals process glucose. Typically this is done by simple assays called 'tolerance tests' where we inject (intraperitoneally) a substance such as glucose and monitor how mice are able to process it over a period of 120 minutes. Usually, we perform 1 to 3 tolerance tests over the lifetime of a mouse, and we let them rest at least 1 week between two tests.

Depending on the results, we will use a similar strategy to interrogate the effect of this particular gene in alternative experimental models. In this case we will provide alternative diets or substances to mimic a more advanced stage of metabolic disease such as liver inflammation or fibrosis, but the experimental protocols are similar as described above.

In some circumstances, we will investigate the effect of a particular gene in the development of liver cancer. In this case, we will admisiter by intravenous injection a specific DNA designed to promote the development of liver cancer. We will then inject specific substances such as 'RNA oligonucleotides' to activate or inactivate our gene of interest and evaluate its role in the development of liver cancer.
Tipically, the mice are humanely sacrificed before mice develop any overt clinical manifestations, and effect of the intervention are evaluated by pathological and biochemical analysis of the liver and other tissues.

What are the expected impacts and/or adverse effects for the animals during your project?

Procedures cause either mild or moderate harm. Taking samples from animals and giving injections causes only brief stress or discomfort. Transplantation of embryos is carried out under anaesthesia and pain relief given where necessary. When a high-fat diet is administered for more than 16 weeks, obese mice may show reduced activity and grooming behaviour and are occasionally prone to skin diseases as a result. Induction of liver cancer is associated with transient distress caused by the injection. In addition, potential side effects included decreased physical activity and weight loss can be observed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate 15%

Mild 75%

Subthreshold 10%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Until now, no computer or laboratory methods have successfully modelled the complex interactions we are studying which occur between parts of the body. For example, some of the effects of hypercaloric diets on the liver can be recapitulated in isolated hepatocytes or ex vivo systems such as liver-on-a- chip. However, some other components such as the reverse cholesterol transport from peripheral tissues to the liver, or the multi-organ crosstalk must be studied in vivo. Therefore, we need to use whole animals.

Which non-animal alternatives did you consider for use in this project?

Before performing any work with live animals, we make use of publicly available scientific information. Analysis on the computer helps identify genes of interest and reduces the amount of animal work needed for meaningful results. In addition, much of our experimental work is done in the laboratory using non-animal methods. We are also expanding our non-animal studies to include new methods such as the ‘liver-on-a-chip’ to mimic the diseases we study.

Why were they not suitable?

As the complex systems we study involve different organs of the body, we do need to include animal studies in our research, although we use non-animal systems mentioned previously wherever possible. We promote the 3Rs by using these models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated based on power calculations, our previous experience and similar studies published in the literature in order to achieve meaningful results. We estimate 1250 mice for each of the experimental protocols, 10000 animals for breeding purposes and 160 mice in the event of generating novel genetically modified mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental design is made considering the NC3Rs Experimental Design Assistant and taking advice from local biostatisticians where necessary.

At every stage in our experiments, consideration will be given to ways in which we can reduce the number of animals. Several of the protocols that we use are designed in such a way to obtain the maximum possible data from a single animal. For example, various organs are dissected from an experimental mouse or we take multiple samples from a single piece of animal tissue.

The generation and maintenance of genetically modified mice considerably increases the number of mice used in a research project. For this reason, and whenever possible, some of the procedures needed to alter genes will be carried out in the laboratory rather directly on the animals themselves, thereby significantly reducing the number of mice involved.

If this is not possible we will first check if animals with the genetic make-up that we need already exist by sending notices via the ‘mouse locator’ services and searching mouse databases and publications.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding is assured with assistance from experienced staff within our animal research facility. Where possible we will use strategies that maximise the use of offspring when breeding genetically modified mice. In addition, we will ensure that new-born litters are not disturbed to maximise the survival of the offspring.

We will ensure that the use of tissues and samples from each experiment is maximised to obtain maximum information from each mouse. Spare animals will be made available for use to other scientific projects.

When appropriate, we will freeze mouse lines that are not required for extended periods, rather than maintaining stocks.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Where possible, genetic changes to modify the expression of a gene of interest, will be made to specific parts of the mouse rather than to the whole animal to lessen potential adverse effects associated with whole-body genetic changes. This will also improve the quality of our research findings.

To administer specific diets or drug treatments, we will use the lower dose and during the shortest period of time possible to obtain meaningful results. When medium-long term treatment is needed, wherever possible these will be delivered using pellets rather than by giving the animals multiple injections. In addition, to prevent pain whenever is expected pain relief will be provided.

When using a model of liver cancer, we will use the hydrodynamic tail vein injection model, instead of other models (e.g DEN injection, of streptozotocyn plus western diet), as it produces meaninful results in a shorter period of time, reducing unnecesary suffering of the animals.

Why can't you use animals that are less sentient?

Our studies are generally performed in adult mice. Anaesthesia has a strong effect on metabolic rate and it is therefore not usually possible to study metabolism in anesthetised animals, however, when possible, general or terminal anaesthesia will be used (e.g local anesthesia in i.v injections) to minimise stress and suffering of the animals.

Many key metabolic processes are not conserved in lower organisms such as non-protected animals (e.g. invertebrates such as insects, decapods, nematodes) or less sentient animals (eg zebrafish). Then these models cannot be used as alternatives for our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When viral vectors are being used, wherever possible, adenoviruses will be replaced by adeno- associated viruses which trigger a much lower immune response. Animals will be kept warm and monitored regularly during and after anaesthesia. Sterile methods will be used and pain relief will be given as necessary. Any animal experiencing undue distress or which has reached the defined limits pre-agreed in this licence will be humanely killed. We will regularly consult with CBS staff, vets and colleagues about best practice and potential further refinement of our procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will keep following recommendations from the local 3Rs advisory group, Laboratory Animal Science Association (LASA), Animal Research: Reporting of In Vivo Experiments (ARRIVE) and governmental documents such as the Guidance on the Operation of the Animals (Scientific Procedures) Act 1986. In addition, we follow in daily basis scientific publications and will specifically look for improvements in our animal work protocols which could lead to a refinement in our experimental work.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will maintain regular conversations with some members of the local 3Rs advisory group and other colleagues regarding 3Rs and other improvements of our animal work. Databases such as the NC3R's mouse database (http://nc3rs.org.uk/GAmice) will be consulted regularly.

18. Host-pathogen interactions in the immune system and CNS

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

immune system, CNS, infection, prions, ageing

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to determine how infectious microorganisms "hijack" or exploit the body’s immune system to establish infection, and in some cases spread to the brain where they can cause damage to neurons. In addition, the second major aim is to understand how additional factors such as ageing, inflammation and co-infection with other pathogens can affect the function of the immune system, and susceptibility to infections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One of the main pathogens that will be studied in this project is prions which affect humans and animals. Infection with prions causes extensive neurodegeneration in brain ultimately leading to death. Prion diseases are currently untreatable. If we can understand the mechanisms that prions use to establish infection, we may be able to design novel therapeutic strategies to block these currently untreatable diseases. Over 26% of the UK population is >65 years old and this is expected to rise significantly in future decades.

Immunity in the elderly is significantly compromised by ageing and is associated reduced vaccine efficacy and increased incidence of infectious diseases and cancer. A thorough analysis of the factors that underpin the dramatic ageing-related decline in immune function will help identify the ageing-related factors that influence pathogen susceptibility and aid the development novel approaches to improve immunity in the elderly.

What outputs do you think you will see at the end of this project?

Identification of novel cellular and molecular mechanisms that influence disease pathogenesis and susceptibility to prions and other important pathogens, especially gastrointestinal pathogens. The identification of new cellular and molecular mechanisms could identify new therapeutic targets to help to protect against infection.

An improved understanding of how inflammation and ageing affect the development and function of the immune system, and how this can affect the immune system's ability to protect against pathogen infection.

A detailed analysis of how concurrent pathogen infections can influence prion disease pathogenesis and susceptibility to other infections.

Data from this project will be deposited in publicly-accessible databases. Where appropriate, useful publicly available web resources cataloguing the range of genes expressed by important immune cell populations will also be created.

Dissemination of findings and data related to the above outputs through open-access scientific publications, presentations at scientific conferences, seminars to relevant stakeholders, creation of public engagement activities to describe the outputs of this project to the general public and stakeholders, and where appropriate engagement with the media.

Who or what will benefit from these outputs, and how?

In the short term the international immunology, mucosal immunology and neuroimmunology scientific communities and other interest stakeholders will gain information on the role of how specific cells in the immune system are exploited by pathogens to establish infection. They will also gain an understanding of how additional factors such as old age, inflammation etc. can affect the function of these cells, and how this affects susceptibility to pathogen infection.

Scientists and industrial stakeholders (eg: pharma/biotech. companies) may benefit from data on cellular/molecular mechanisms that regulate the immune system and its ability to provide protection to certain infections. In the longer term, this could lead to the development of novel treatments to prevent or treat these infections.
Our collaborators and other interested scientists will also benefit through having access to data and unique biological samples generated from this project. Many other scientists may also benefit from access to these samples or data derived from them.

UK policy makers will have interest in the project's findings on factors that may influence prion disease susceptibility. This may influence their assessments of the risk of prion disease transmission.
How will you look to maximise the outputs of this work?

Data from the experiments described in this report will be disseminated to the international

scientific community through a combination of publication in peer-reviewed journals, data deposition in public databases and presentation at scientific meetings. Studies will be submitted whether the data describe significant/exciting advances, or conversely, show no effect of treatment etc. The latter are equally as important, and by publishing these so-called "negative-results" studies this can help to reduce the number of animals used in future studies by preventing unnecessary experiments being undertaken.

Where possible, opportunities will be taken to communicate the project's findings and implications to the public, through a range of public-engagement activities. The applicant's organisation has a dedicated and very active public-engagement department and helps the scientists to design a range of activities to explain the importance and impact of their research to a range of audiences from schools, to public open days, targeted stakeholder groups, and larger public agricultural events and scientific shows/discussions.

The release of potential news-worthy publications will be discussed with the Institute's press officer and press-releases issued when appropriate. The applicant has much experience of this. Many of the applicant's publications from recent project licences were handled in this manner and attracted much media interest, including The Times newspaper and BBC news. The applicant has also given interviews to organisations such as "Understanding Animal Research" to help explain to lay-audiences the important and useful findings obtained from animal studies undertaken in the lab.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The aims of this study are to determine how pathogens such as prions exploit cells and tissues of the immune system to spread from the site of exposure (eg: intestine), establish host infection and ultimately cause disease in the CNS. We are also interested in how factors such as ageing, inflammation, pathogen co-infection and the presence of the "friendly" commensal microbiota can affect affect development of the mucosal immune and central nervous systems and how these affect susceptibility to infections. These cannot be achieved using species outside the animal kingdom which do not have complex digestive, immune and nervous systems. The complex interactions between these systems is also difficult to study in reduced in vitro systems.

For these reasons it is essential to use mice, and young-adult/adult/aged mice will be used throughout. Among mammalian model organisms, the information and literature on basic anatomy and physiology of the immune and central nervous systems is most extensive for mice which provides the best platform for understanding data produced in this project in the context of previous work. Although differences do clearly exist between species, the major features of the immune system are conserved in mice and humans allowing meaningful extrapolation. Indeed, the findings from this project will be directly relevant to enhancing our understanding of disease pathogenesis and susceptibility in large animal species (sheep, cattle, deer etc.) and of course, humans.

Typically, what will be done to an animal used in your project?

The animals used in this project may undergo one or more of the following procedures, for example: undergo surgery, irradiation followed by reconstitution with haematopoietic cells such as bone marrow, injections of substances, and infections with some pathogens. Some animals will experience only one of these, but in some studies these may be used in combination depending on the nature of the study. Experimental duration will range from acute (hours), to days (less than 1 week), to several weeks to months, depending on the study.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the mice in this study will be infected with prions or other infectious agent and a proportion of these will develop clinical disease: moderate severity. However, to avoid unnecessary suffering these mice will be culled at the onset of definite clinical signs. The duration of oral prion infection in mice is very long ~340 days. However, for approx. 90% of this period the mice are free of clinical signs and appear healthy. In many studies the majority of the mice will be humanely culled during the pre-clinical period before they show signs of clinical disease.

Other mice may also undergo periods of moderate severity, for example after a short exposure to irradiation. A split dose of irradiation is used to reduce the impact of the adverse effects on the mice. However, in this instance the period of severity and weight loss is transient because soon after irradiation the mice are given a bone marrow transplant. Following bone marrow transplant their body condition and weight typically recovers within a few days of treatment.

Where necessary and appropriate analgesia may be given to reduce pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Many of the mice will experience no greater than mild severity after the procedure. However, some animals (approx. 10%), such as those that undergo irradiation followed by reconstitution with haematopoietic cells such as bone marrow may experience a transient period of moderate severity. Similarly, some animals may develop moderate clinical signs of infection. However, not all of the infected animals will be maintained until they do develop clinical signs. The majority (approx. 60+%) will be culled before they develop detectable clinical signs and tissues analysed ex vivo.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aims of this study are to determine how pathogens such as prions exploit cells and tissues of the immune system to spread from the site of exposure (eg: intestine), establish host infection and ultimately cause disease in the CNS. We are also interested in how factors such as ageing and the commensal microbiota affect development of the mucosal immune and central nervous systems.
Experimental systems that allow this are limited and must involve the use of vertebrate animals. Therefore, this cannot be achieved using species outside the animal kingdom which do not have complex digestive, immune and nervous systems. The complex interactions between these systems is also difficult to study in reduced in vitro systems.

Which non-animal alternatives did you consider for use in this project?

Every opportunity will be taken to exploit computational methods during the study these are inadequate on their own because the complexity of interactions between the nervous and immune systems. Where possible we will also use data available in published transcriptomics studies, and have done so in many recent studies. These negate the need to use additional sets of animals to obtain cell/tissue preparations to generate our own samples.

Organoids and/or intestinal enteroid cultures: Wherever possible this project will also in vitro systems of isolated cell populations (some derived from cell lines not requiring the use of animals) to address specific questions or to complement the in vivo studies. Many in vitro studies of pathogen uptake across the gut epithelium have typically used monolayers of apparently differentiated enterocyte cell lines. However, it is questionable whether these systems are accurate representations of the gut mucosa as they lack the complexity of the mixture of cell populations in the gut epithelium. A recently described 3D, physiologically relevant in vitro model of the gut epithelium provides an alternative whereby gut organoids (enteroids) are established in vitro from isolated intestinal crypts in a collagen-based matrix. These undergo multiple crypt fission events, generating many villus-like epithelial domains surrounding a central, closed lumen. These enteroids maintain the cellular diversity that is present in the gut epithelium (enterocytes, goblet cells etc.). They can also be maintained long term enabling the chronological in vitro study of host-parasite interactions. The isolation and propagation of enteroids is well established in the applicant’s lab. Importantly, these have been used in his lab. to study the role of CSF1R-signalling in maintenance of intestinal crypts, and have also been developed from bovine, porcine and avian tissues and have been used to study aspects of host-pathogen interactions. A particular benefit from the use of these enteroids is that they can be maintained for weeks and serially passaged. Thus, many 100’s of enteroids can be obtained from a single tissue sample (~20 cm of intestine) negating the requirement for large numbers of animals. Thus, where possible, enteroids may be used as an in vitro alternative to provide further characterisation of data derived from in vivo studies. Where appropriate these enteroids may also be used to test hypotheses before subsequent development of in vivo studies. This approach was successfully used to study the effects of Salmonella Typhimurium on gut epithelial cells. Alternatively, data obtained on the effects of ageing on intestinal crypts was investigated further using mouse enteroids to identify potential molecular mechanisms.

Detection of prions: At present there are no other reliable methods that enable prion agent infectivity levels in cells or tissues to be accurately estimated other than by recipient

mouse bioassay. The magnitude of prion disease specific PrP^{Sc} protein (a major if not sole component of infectious prion particles) can be used as a reliable surrogate. The relative level of PrP^{Sc}-seeding (converting) activity can also be a useful comparison and will be used where appropriate. A tissue culture-based prion agent infectivity bioassay has been described with potentially promising results. However, there are limitations with such assays, not least sensitivity.

Why were they not suitable?

As mentioned above, some of the listed techniques can be very useful and can be used to replace/reduce the need for live animal studies. However, as described below these do have some limitations.

While every opportunity will be taken to exploit computational methods during the study these are inadequate on their own because the complexity of interactions between the nervous and immune systems. The lack of existing data upon which to construct accurate models in silico introduces too many uncertainties that would compromise data interpretation. However, the applicant regularly exploits publicly available data bases to obtain useful data on the effects of certain treatments, immunodeficiencies etc. on gene expression data.

At present there are no other reliable methods that enable prion agent infectivity levels in a wide range of cells or tissues to be accurately estimated other than by recipient mouse bioassay. Accumulation of the disease-specific isomer of the prion protein, PrP^{Sc}, can provide an estimate of the magnitude of prion infectivity in diseased tissues. However, immunoblot detection of PrP^{Sc} is less sensitive than mouse bioassay of infectivity, and PrP^{Sc} and infectivity can sometimes be separated in vitro and in vitro. The applicant's research has also demonstrated that during the very early stages of a prion infection, detectable levels of PrP^{Sc} in lymphoid tissues can often lag behind that of prion infectivity. PrP^{Sc}-seeding activity assays: This is very sensitive at detecting the ability of PrP^{Sc} in a sample of interest to convert normal cellular PrP^{C} into the prion disease-specific isoform. Although useful, these assays do not directly detect prion agent infectivity.

Cell culture based prion infectivity assays: However, there are limitations to using this assay since its reliability appears to be restricted to a particular prion agent isolate (RML scrapie prions) that is not used at our Institute. The vast majority of the data we have obtained on the pathogenesis of prion disease over the past 25 years has been obtained using the ME7 scrapie agent strain. This mouse- passaged strain was originally derived from a sheep with natural scrapie and our data suggests provides an excellent mouse model to study prion disease pathogenesis in larger species. The pathogenesis appears to be similar to natural sheep scrapie, CWD in cervids (deer, elk etc.) and vCJD in humans. The RML prion isolate, in contrast is not a strain and instead is a mixture of 2 agents which can vary in pathogenesis depending on the host. This obviously questions its use in in vivo pathogenesis studies as it is difficult so separate the prion effects from the host effects, and confidently conclude which are the important factors. Thus although a cellular assay can be used to detect RML prions, we do not consider it appropriate to use in the current project. Furthermore, we have no experience of using the RML prion isolate and would need repeat many of our past experiments to obtain baseline data.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Good principles of experimental design will be applied to ensure the minimum numbers of animals necessary to achieve satisfactory results are used. All experiments are critically reviewed by the named vet, NACWO, NTCO and a statistician prior to commencing. A study request is submitted which includes a description of the objective and hypothesis, experimental groups, treatments, and assessment of effects, methods of data collection and statistical analysis. Formal procedures are in place within our Institute for review and approval of each experimental study prior to their commencement. This review system is intended to ensure that the numbers of animals utilized is at a minimum whilst ensuring that robust and meaningful results are produced for each experiment. No study involving the use of experimental animals can be undertaken in the Institute without having successfully undergone this critical review.

The numbers of animals allocated to each experimental group is reviewed continually for each experiment and judgements made based on previous experience. Professional statistical advice will be sought for complex study designs– this is available through the Institute's scientific and ethical review committee, which includes a qualified statistician. This protocol is designed to ensure that numbers of experimental animals are kept to a minimum, whilst at the same time ensuring enough animals are used to produce statistically significant results. The applicant's experience of >25 years of working with the pathogen infection models described in this project has shown that groups between 6-12 mice are required to give reproducible and statistically significant incubation periods following inoculation by peripheral routes. The minimum statistically useful numbers of animals to use for serial kill time points is 4 animals, and has proved reliable in recent studies. These group sizes will be used unless there is sufficient justification for including a larger number of animals, for example when first analysing the influence of a factor for which we have limited previous experience. Previous experience has shown that groups of 4-6 intracerebrally injected mice are sufficient as controls to eliminate the possibility that prion disease pathogenesis is affected once disease is established within the brain. As the experiments in this project licence progress, further experience will be gained from the use of these experimental systems and group sizes revised accordingly. Indeed, throughout the duration of this licence, group sizes in such studies will continue to be assessed and refined, where considered appropriate.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In addition to the measures described in the above section, the inclusion of the use of these transgenic mice in prion infectivity bioassay experiments has reduced both the number animals required and their duration in experiments.

To attempt to reduce the numbers of animals used in prion agent infectivity bioassay experiments, the use of genetically altered PrP-overexpressing Tga20 mice was explored. As these mice develop prion disease with much shorter incubation periods than wild-type mice, the duration of these experiments is substantially reduced (from typically ~300 d to

~130 d). The savings encountered through use of Tga20 mice include the following (using the ME7 scrapie strain):

-Much smaller group sizes. Use of 4 recipient Tga20 mice is sufficient to provide statistically useful data in bioassay experiments, compared to at least 6 wild-type mice.

-Reduced typical prion disease incubation period from 300 to 120 days.

-Reduction of maximum experiment duration from 500 days to no more than 200 days.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Many of the typical measures used have been described in the above sections. However, we also will implement efficient breeding procedures. We have also found that targeted pilot studies aimed at determining for example, the optimal dosing regimen can provide a significant saving. These have helped to eliminate the need for much larger titration experiments; have identified the optimal duration of dosing or effect; identified treatments/protocols that return a null result. The latter has prevented the unnecessary use of much larger numbers/groups of animals in a large experiment that would have returned a negative result with no additional scientific benefit. This has also helped to identify potential unexpected adverse reactions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The C57Bl/6 mouse strain will be used in many experiments (either as wild-type or as a background strain for the genetically-altered animals, GAA). Our data show that the C57Bl/6 strain develops age- related changes similar to the immune system similar to those observed in large animal species and humans. We will use wild-type mice (Eg: C57Bl/6J) and genetically altered mice without harmful phenotypes as animal models. As a consequence, these animals in their unperturbed states are not expected to experience harmful effects as a consequence of the genetic alteration.

Key approaches in this project include the use of animals with specific immunological modifications to enable the manipulation of the immune system or sub-populations of cells. In mammals, such technologies and associated reagents are currently most widely available for mice. purification of immune cells for ex vivo analysis (gene expression profiling by mRNA-seq) and live imaging of specific cell populations (e.g. mononuclear phagocytes). Each of these can only be achieved by using animals where these cell populations are easily identified. Currently, transgenic mice expressing fluorescent labels such as GFP offer the only practicable means to identify specific cell types for these applications. Mice ideally suited to fulfil the objectives in the project are available within the Institute (e.g. CSF1R- EGFP-tg mice which express GFP selectively in mononuclear

phagocytes).

Why can’t you use animals that are less sentient?

The in vivo experiments will use mice. A mammalian species is necessary since the main aim is to investigate interactions between certain pathogens and host immune cells and tissues, including those in the CNS. As a consequence, it is not possible to examine this in less sentient species.

Data generated from this project will be directly relevant for enhancing our understanding of disease pathogenesis and susceptibility in large animal species (sheep, cattle, cervids etc.) and humans.

Among mammalian model organisms, the information and literature on basic anatomy and physiology of the immune and central nervous systems is most extensive for mice which provides the best platform for understanding data produced in this project in the context of previous work. Although differences do clearly exist between species, the major features of the immune system are conserved in mice and humans allowing meaningful extrapolation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any of studies involving surgical or invasive intervention will adopt appropriate pain management and post-operative care.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE (Animal Research: Reporting of In Vivo Experiments; arriveguideline.org) guidelines will be used to ensure experiments are designed and conducted in the best possible manner to address the principles of the 3Rs, and to also ensure they are reported in sufficient detail enable maximal reliability and reproducibility.

The PREPARE guideline (https://norecopa.no/prepare) cover the three broad areas which determine the quality of the preparation for animal studies: 1, Formulation of the study ; 2, Dialogue between scientists and the animal facility; 3, Methods.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the advances in the 3Rs by attending informational events provided locally, obtaining information from our departmental website and through regular communication from our named information officer (NIO). Information on advances on the 3Rs will be provided by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and through other sources such as the Norecopa newsletter and the PREPARE guidelines.

19. The neural control of movement in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Spinal cord, Brainstem, Motor Neuron Disease, Movement, Spinal cord injury

Animal types	Life stages
Mice	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The first, basic aim of this project is to advance our understanding of the neural networks within the brainstem and spinal cord, which control movements such as breathing and walking (locomotion). The second, more translational aim of this project is to reveal disease mechanisms underlying the devastating, fatal neurodegenerative disease known as Motor Neuron Disease (MND) or Amyotrophic Lateral Sclerosis (ALS).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To treat a range of diseases and injuries that alter normal movements or cause paralysis by damaging parts of nervous system, it is critical that we reach a much better understanding of how these systems work in their normal, healthy state. We must then use

this 'basic' knowledge to guide parallel research that determines what changes occur within these motor control regions during disease or following injury. By performing such complementary strands of basic and translational research, we will be ideally placed to reveal new targets and ultimately develop new treatments for devastating, often fatal, diseases and injuries that prevent normal movements. In the present project we will focus on motor control regions within the brainstem and spinal cord, which control breathing and walking. We will study how neural networks in these regions control movements in their normal, healthy state. We will also investigate how these neural networks change in models of Motor Neuron Disease (MND), and in doing so reveal novel therapeutic targets for this devastating and incurable disease.

What outputs do you think you will see at the end of this project?

We expect to generate a significant amount of new information regarding components of neural circuits that are critical for the control of movements, in particular walking and breathing. In addition, we expect to generate important new knowledge about changes within these neural circuits that contribute to dysfunction and neuronal loss in Motor Neuron Disease. This output will most likely take the form of open access research publications in international, peer-reviewed journals.

Who or what will benefit from these outputs, and how?

The most likely short-term beneficiaries of the outputs from this project will be members of the wider academic community. We expect our findings to be of significant interest to thousands of researchers worldwide, including many involved in research that goes beyond the immediate field of motor control. Our findings are likely to help direct and form the basis for many subsequent studies aiming to advance our fundamental understanding of how neural networks control behaviours and how neural network dysfunction leads to disease. In the longer-term we expect our outputs describing changes to neural networks in Motor Neuron Disease (MND) (MND) models to be utilised by biotech and pharmaceutical companies to inform drug discovery and development programs, which will ultimately benefit patients. Recent evidence of this includes a collaboration we have formed with a biotech company to assess whether drugs that target communication between glial cells and neurons represent viable candidates for novel MND therapeutics. MND is a devastating, uniformly fatal condition, for which the risk of diagnosis is 1 in 300. MND symptoms typically occur at mid-life and the average life expectancy from the point of diagnosis is less than 3 years. There remains no cure for MND and current treatments only extend life by 3-4 months. Thus, there is a desperate need for new knowledge that will lead to novel therapeutic strategies, which aim to treat and eventually cure MND.

How will you look to maximise the outputs of this work?

We will maximise the outputs of our work by sharing our findings rapidly and widely. We will disseminate new knowledge promptly at national and international conferences and subsequently via publication in leading international, peer-reviewed journals. We aim to publish all our work in open access formats, so that it reaches the widest possible audience, including non-specialist stakeholders. Rapid and wide dissemination will facilitate the establishment of new collaborations with research scientists across multiple fields and disciplines, as well as industrial partners. We will also continue to share our findings with the broader public, including people affected by MND, via social media platforms, public outreach events, public lectures and, where applicable, press releases.
Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to investigate and understand the complex neuronal networks of mammals, and how they are affected by disease, it is necessary to study central nervous system tissue obtained from them. We have chosen mice, typically utilised at early postnatal stages, as our animal model because this allows is to perform carefully controlled experiments on isolated (*ex vivo*) spinal cord and brainstem tissue, without the need for whole animal (*in vivo*) experiments. Mice have also been chosen because of the availability of a growing number of genetic techniques, which allow labelling and manipulation of specific cells within the nervous system and the insertion of mutant genes that cause human diseases.

Typically, what will be done to an animal used in your project?

The majority of animals (~75% of an estimated total of up to 12000 over 5 years) will be used as part of a breeding and maintenance programme to generate specific types of genetically altered mice for experiments. As part of this programme, small biopsies will need to be taken from animals to determine what genes they carry. A subset of animals (~25%), which are born with the correct combination of genes will be used for *ex vivo* experiments. Prior to these experiments some animals (~5% of all animals used on project) will be injected with substances to label specific subsets of cells within the nervous system. Injections will be performed by the least invasive method possible. This will either be via injection into the body cavity (intraperitoneal), injection between the chest wall and lungs (intrapleural), or injection directly into specific muscles (intramuscular). Intrapleural and intramuscular injections will be performed under general anaesthesia. Animals will then be killed via the most humane method appropriate and central nervous system tissue removed for use during *ex vivo* experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

The genetic alterations present in most animals are expected to have no impact or adverse effects. A subset of genetically altered animals used to model human disease may develop motor deficits, such as shaking of limbs (tremors), abnormal walking patterns (gait abnormalities) or hyperactivity leading to a reduction in weight gain during adulthood. Animals are also likely to experience brief, mild pain when tissue biopsies are taken for the purposes of determining which genes they carry and when intraperitoneal injections are performed. Some animals may also experience up to moderate pain associated with intrapleural or intramuscular injections following these surgical procedures and therefore require administration of pain killers (analgesics).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on our previous project licences, we expect the severity of the procedures conducted on the majority (~65%) of animals to be classified as sub-threshold. We expect the severity experienced by some animals (~30%) to be classified as mild. Finally, we expect the severity experienced by a smaller subset of animals (≤5%) to reach the classification of moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to study and fully understand the complex neuronal networks of mammals, including how specific components of these networks ensure appropriate output is produced for the control of movement and what goes wrong within these networks during disease states, it is necessary to study central nervous system tissue obtained from them.

Which non-animal alternatives did you consider for use in this project?

We plan to continue to utilise human stem-cell based models, human post-mortem tissue and some computer-based modelling in parallel with mouse tissue.

Why were they not suitable?

Human stem-cell derived cell culture models cannot fully replace the use of animal tissue because cultured cells cannot recreate the complex networks we seek to understand. Post-mortem tissue only provides a ‘snapshot’ of the end of disease and cannot be utilised for functional analyses. There also remain too many unknowns for computer simulations to fully replace the use of animal tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in the proposed project has been estimated from the published reports of other researchers using similar techniques to answer equivalent research questions and from the ~15 years of similar research conducted in my laboratory under my previous project licences.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where statistical analyses are to be utilised we first determine the minimum number of animals required to obtain significant results. Importantly, this takes into account the likely breeding success, predicted number of animals carrying the required genetic alterations and the expected success rate of experiments (e.g. how many cells we typically record from within each piece of isolated tissue). One of the key principles of our experimental design is that the maximum amount of data should be obtained from each animal killed, thus reducing animal numbers. This is facilitated through the use of *ex vivo* preparations, which last up to (and sometimes more than) 6 hours allowing data to be collected from many spinal and brainstem neurons per preparation. Animal numbers will also be reduced due to our planned use of state-of-the-art genetic techniques. It has historically been difficult to define specific subtypes of spinal and brainstem neurons for subsequent study. This has meant that researchers have had to record from a large number of neurons, even though they have been attempting to study a small, specific population of neurons. In the present study we will utilise the most recent genetic techniques available to label and manipulate discrete populations of spinal and brainstem neurons. Since we will be able to identify subtypes of neurons prior to establishing recordings, we will be able to reduce the number of recordings, and hence animals, required to meet our objectives.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continually optimise breeding strategies to produce the maximum number of animals with the required genetic alterations. As a consequence of using genetic techniques in which animals need to carry multiple inserted genes, a number of the offspring generated will be unsuitable for experimental purposes. Some of these animals will, however, be utilised for future breeding or as control animals. Where appropriate, pilot studies will be used to determine the variability in experimental outcomes and therefore the total number of animals needed to provide valid results. We will continue to optimise each set of experiments to maximise the amount of data obtained from each animal. For example, when investigating the properties of specific types of cells, individual cells are the experimental unit, so we will optimise conditions (e.g. tissue viability and duration of recordings) to allow for the greatest number of individual cell recordings possible from each piece of isolated tissue. We will also continue to share tissue (e.g. other organs such as the heart) from animals we have killed with other researchers when appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will utilise mice, because of the availability of genetically altered animals that allow us to address our main aims and objectives. For our fundamental studies, the genetic

alterations used, which will allow specific populations of spinal neurons to be labelled and manipulated, should have no harmful effects on the animals. For our translational work, animals will carry mutant genes that cause Motor Neuron Disease-like symptoms. These symptoms may include tremors, abnormal walking patterns and, eventually, muscle weakness leading to progressive paralysis. However, because we aim to determine early disease mechanisms, we will carefully monitor disease model mice and use them for breeding, experimental purposes, or kill them using humane methods prior to the onset of significant suffering due to disease.

Alongside genetic techniques, we will also utilise retrograde labelling techniques to label specific types of cells in the spinal cord and brainstem. Our default method for retrogradely labelling cells will be via the injection of substances into the body cavity (intraperitoneal). This will reduce the need for more complex surgical procedures. However, for some experiments, such as those examining neural properties that contribute to the selective vulnerability of different subtypes of motoneurons in Motor Neuron Disease, substances will be injected into muscles (intramuscular) or a space between the chest wall and lungs (intrapleural) to label more specific neuronal subtypes than is possible via intraperitoneal injection.

The choice of mice as the animal model in the present study also importantly allows us to perform analyses in isolated (*ex vivo*) spinal cord and brainstem tissue. By using acute *ex vivo* preparations we can investigate complex neuronal networks whilst avoiding the pain and suffering associated with *in vivo* experiments involving whole animals. Following the breeding of genetically altered mice and/or injection of substances to label specific cells, animals will be used in acute anatomical or physiological experiments, providing a clear endpoint and minimising suffering.

Why can’t you use animals that are less sentient?

The use of isolated mouse tissue is necessary to allow us to study the complex networks of mammalian neurons and produce new knowledge that can ultimately be applied to human health and disease. We cannot utilise more immature life stages because the neural networks we wish to investigate are not sufficiently formed until postnatal stages. For one of our protocols where anaesthesia is used a period of recovery will be required before animals are killed and tissue extracted for analyses. This is necessary to allow time for the injected substances to travel into the nervous system and label specific cells.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The majority of animals will experience no harms associated with the genetic alterations they harbour and will be killed via humane methods prior to extraction of tissue. We will minimise the number of animals that require additional procedures (injection of substances) by seeking out and utilising non- harmful genetic approaches where possible. Where surgery is required to inject substances, we will use appropriate peri-operative care measures, as advised by the NVS, and surgeries will be carried out under aseptic conditions. When using genetically altered animals to model disease, we will perform regular and careful monitoring to ensure that animals are killed prior to significant suffering. Such monitoring will be performed more regularly for any new types of genetically altered animals that we do not have previous experience with and for which detailed data may be lacking.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The *ex vivo* experimental techniques we will perform using isolated nervous system tissue have been refined by many laboratories around the world to improve viability and reliability of the preparations. We will continue to follow the latest scientific publications that describe the most relevant experimental methods utilising isolated nervous system tissue to ensure we maximise the likely success of our *ex vivo* anatomical and physiological studies. In addition, we will utilise relevant guidance published the Joint Working Group on Refinement.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to discuss possible improvements to our methods with our excellent team of animal care technicians. I will also benefit from my on-going membership on the University's Animal Welfare and Ethics Committee (AWEC), where advances in the 3Rs are routinely discussed. In addition, I will obtain ideas for improvement via fora associated with organisations such as LASA and the NC3Rs.

20. Dynamics of stress axis physiology in health & disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Stress, Pituitary, glucocorticoid, corticotroph, physiology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how stress is regulated by investigating the dynamic control of anterior pituitary corticotroph physiology and stress axis function in health and disease. Understanding these mechanisms is fundamental to our ability to diagnose and ultimately treat major human stress-related disorders such as obesity, depression and hypertension.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Stress and stress-related illness has a major impact on the UK economy accounting for > 40% of all working days lost with an estimated annual cost of £6billion with additional burden through effects on animal health, welfare and food production. Understanding the mechanisms controlling the stress response is important for our ability to diagnose and ultimately treat stress-related disorders.

What outputs do you think you will see at the end of this project?

This project will generate a number of outputs of benefit to the scientific community, policy makers and general public including:

New information on the physiology of the stress axis disseminated through peer reviewed publications in open access journals as well as through conferences, seminars and other scientific outlets.

New resources ranging from databases of gene expression, new animal models and other novel tools/resources (e.g. antibodies) and predictive computational models that will be made freely available to the scientific community.

New insights and recommendations for clinicians and policy makers for the diagnosis and treatment of stress-related disorders

Materials and resources for wider public understanding of stress and physiology through public engagement and outreach activities

Who or what will benefit from these outputs, and how?

Shorter term benefits (0-5 years)

These are predominantly to the basic science community that will provide a mechanistic framework for understanding three important areas in lifelong wellbeing and disease: i) the mechanisms controlling physiology of anterior pituitary corticotroph cells that control the stress response, ii) how corticotroph cell heterogeneity and network population dynamics control systems level behaviour iii) new insights into the control and recovery of the hypothalamic-pituitary-adrenal (HPA) stress response in health & disease and identification of new diagnostic and therapeutic approaches. Importantly, the fundamental importance of understanding these processes is essential to communicate to policymakers and general public that will be facilitated through outreach, public engagement and policy engagement forums.

Longer term (5 yrs +)

In the longer term the work will inform translational and applied human and animal research as well as providing possible new diagnostic and therapeutic strategies to treat stress-related disorders that could have significant implications for both human and animal wellbeing and welfare and impact on UK economic prosperity. For example, glucocorticoids are one of the most widely prescribed drugs and stress related disorders result in >£6billion burden to the UK economy including through absence from work and our studies include collaboration with clinicians. Thus understanding how the stress response is regulated and can be manipulated holds the promise of modifying both current practice in how stress is managed and glucocorticoid treatment is prescribed as well as identifying new therapeutic pathways to control stress related disorders.

How will you look to maximise the outputs of this work?

The project is multidisciplinary and we collaborate extensively with both basic scientists and clinicians in both the UK and overseas sharing resources, knowledge and expertise. We use multiple platforms to disseminate our work to both the scientific and lay communities ensuring our work is published in open access journals and all data, regardless of outcomes, are made publicly and freely accessible for reuse. This includes

dissemination and sharing of best practice as well as communication of unpublished findings or unsuccessful approaches in appropriate forums including meetings and events that we organise and arrange in the areas of pituitary, endocrine and stress physiology.

Species and numbers of animals expected to be used

- Mice: 6100
- Rats: 650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are well validated models for understanding the physiology of the stress axis and retain key structural, signaling and behavioural responses observed in humans, unlike lower order species. The majority of our studies will use mouse as a model to take advantage of the wealth of literature and existing data resources on HPA axis physiology and behaviour. This includes extensive genomic, transcriptomic, proteomic, metabolomic and functional data combined with a wide variety of genetically modified animals required for gene specific targeting, cell identification and characterisation that we have already established. For some assays mice are not optimal (for example for multiple serial blood sampling for hormones such as ACTH that require a relatively large (several 100 microlitres) volume of blood plasma for assay and thus rats will be used in a limited subset of experiments. In both cases male and female animals will be used (as there are sex specific differences in HPA responsiveness) and our focus is on postnatal and predominantly adult animals to identify responses to a variety of physiological and pharmacological challenges. Indeed, HPA axis activity changes with development including a stress hyporesponsive period in early postnatal life thus the majority of our studies are focussed on stable periods during early/mid adulthood in rodents. This timing also is optimal for use of a number of the longitudinal assays such as our ability to monitor real-time corticotroph cell activity in freely moving animals during and after stress.

Typically, what will be done to an animal used in your project?

The vast majority of animals (>85%) will be accounted for by generating genetically altered animals and used for isolation of cells/tissues for experiments in a dish. However, to understand the stress response and stress-related disorders requires the complex interaction between the brain, pituitary and adrenal glands. Thus some animals will undergo surgery (for example to implant a device to allow remote monitoring of cell activity or blood pressure), and be exposed to mild stress or changes in diet (e.g having a high fat diet) and taking blood samples to monitor stress hormones. Experimental durations will range from acute (1 h) to several weeks.

What are the expected impacts and/or adverse effects for the animals during your project?
Potential adverse effects include short term pain following surgical procedures which will be significantly reduced with analgesia. Animals exposed to chronic stress, long term steroid treatment or fed a high fat diet show progressive changes in body weight over several weeks that rapidly recovers after the challenge is removed. In addition, some of

the genetically modified animals show mild change such as a staggered walk or reduced bodyweight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For both mice and rats the majority (~ 80%) of animals will be exposed to a mild severity or lower. A small proportion (~20%) of animals will be in the moderate category (eg those receiving surgery or some genetically modified animals).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding the control of stress relies on complex and dynamic interactions between different cells, tissues and organs, as well as with effects of changes to both the internal and external environment such as diet, drugs and ageing. While important aspects of this project will use *in vitro* and *ex vivo* approaches (e.g. pituitary, adrenal & brain slices, primary cultures, clonal cell lines and be informed by computational models) ultimately understanding how the stress axis is regulated and the impact on animal behaviour requires animal use. Importantly, the mechanisms we are investigating are conserved in humans and rodents but not in lower organisms such as worms or flies.

Which non-animal alternatives did you consider for use in this project?

Human tissues, transformed cell lines, lower organisms (eg worms/flies) and predictive computational models.

Most experiments (> 80%) will involve tissues and cells collected from animals that will allow us to validate approaches and tools before proceeding to animal work. In addition, we use a variety of approaches to allow full or partial replacement including use of established transformed cell lines, computational tools to both make predictions based on simulations/models as well as bioinformatic approaches to refine our candidate targets. We have thus considered multiple approaches, and will use aspects of them in our studies, including use of established corticotroph cell lines, organ on chip approaches, non vertebrate models as well as predictive computational models of both corticotroph physiology as well as HPA axis function. We will keep updated on replacement approaches through our networks, literature as well as published resources such as the EURL ECVAM search guide and online resources including from NC3Rs and Animal Welfare Centre.

Why were they not suitable?

Each of the above approaches can only be used for limited aspects of our studies and each have their own caveats.

Human pituitary tissue is very difficult to obtain and typically only from patients with severe disease and we cannot manipulate or measure the function of specific cell types in the stress axis of humans

Transformed cell lines such as the ATT20 mouse corticotroph cell line lack specific receptors and signalling pathways critical for normal pituitary function

Key mechanisms we are investigating are human/rodent specific and thus lower organisms such as worms, flies or zebrafish cannot be used

We and our collaborators have developed predictive mathematical models of both pituitary corticotrophs as well as the stress axis. However, while these approaches will allow us to refine working hypotheses, and to make predictions that can be used to guide and optimise the design of animal experiments the models themselves have to be driven by data we generate from studies in animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimates are based on a combination of our own usage statistics from previous work, including undertaking pilot studies where new approaches or methods are being developed, as well as use of appropriate publications, guidelines and experience from researchers in the field as well as regulatory, funding and learned societies and agencies (for example NC3Rs Experimental Design Assistant tool, ARRIVE guidelines, Medical Research Council, Physiological Society). The numbers required for upkeep and desired out-breeding of lines are derived from estimates provided by the animal facility. We seek additional advice and updates from biostatistical experts employed at our institution.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the experimental design stage of the project, we perform pilot studies where possible before planning for large cohorts. Tools such as the NC3Rs Experimental Design Assistant (EDA), ARRIVE guidelines and resources from the Medical Research Council are used to inform and optimize reduction in animal use. In addition, insights through personal communication with investigators in the field, publications or veterinary advice, including discussion with the NVS.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have established multiple measures to optimise the number of animals required. Pilot experiments coupled with our previous work and search of literature have determined fundamental differences in male and female responses to stress allowing us to optimize breeding and colony management. Our work informs the development of predictive computational models of both corticotroph and HPA axis function that allows us to define clearer experimental strategies as well as measurable endpoints. Our work is optimised to make multiple measurements from the same animal – for example cell activity, stress hormones and blood pressure or using multiple assays from in isolated cells/tissues tissues (for example molecular, protein and functional assays). In addition, our approaches have optimised the use of genetically engineered animals including validation of cell specific reporters and promoters to define specific cell types and targeted approaches. Our analysis of all datasets is maximized to extract the maximum information possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodents as an animal model to assess stress axis regulation and the outcomes of manipulating stress axis function on behaviour. We aim to understand corticotroph and stress axis function in healthy animals which will provide a foundation for understand stress axis dysfunction in disease and in response to physiological and phamacological challenges such as stress or steroid drugs. Thus, this approach will reduce the number of animals subject to adverse states.

We also utilize wild-type and transgenic rodents without harmful phenotypes as animal models meaning that rodents in the unperturbed state will experience no harmful effects.

The mouse is the species of choice for most of the experiments as our project includes analysis of signaling mechanisms that are human/rodent specific. In addition, a large body of literature and numerous databases characterizing the properties of physiology and the annotated genome already exists allowing us to refine our approaches, methods and models. We and others have optimised approaches to minimise distress, harm or pain to animals used. For example, our chronic stress paradigm is optimised so animals receive a mild stress each day for up to 2 weeks rather than using more stressful stimuli or longer periods of stress. Our surgical approaches are already well validated with appropriate anaesthesia and pre- and post-operative analgesia as well as close monitoring.

Why can’t you use animals that are less sentient?

A key goal of our work is to understand the real time dynamics of corticotroph and HPA axis physiology before, during and after chronic stress and other physiological challenges in adults. Importantly, many of the key signalling components and mechanisms are mammalian specific thus use of lower organism such as flies, worms and fish do not allow

us to interrogate function of biomedical relevance to humans. Moreover, the structure and dynamics of the HPA axis changes during development and thus immature mouse stages cannot be used. Importantly, understanding the real time dynamics of corticotroph and HPA axis function before during and after stress cannot be assessed in terminally anaesthetised animals and anaesthesia itself can modify the stress response. Several of our humane endpoints require animals to both experience and respond appropriately to normal physiological challenges.

Thus, while some key experiments can use terminally anesthetised animals (e.g. monitoring the response of corticotrophs to a bolus injection of a drug) longitudinal monitoring of corticotroph activity during chronic stress and following recovery requires adult sentient animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Multiple approaches are used to refine procedures to minimize welfare costs.

Studies have been optimised to reduce the duration of exposure to potential harms, for example we use a 2 week exposure to a daily restraint stress minimising both the total duration and types of chronic stressors required.

Regular non-invasive monitoring of animal function such as daily urine to monitor stress hormone levels

Optimised surgical procedures with appropriate pain management and post-operative care (such as using general anaesthesia during, and analgesia following, surgery).

Improved minituarisation of devices and remote recording of multiple physiological functions (e.g simultaneous monitoring of activity, blood pressure and temperature).

Optimised targeted molecular approaches increasing specificity and thus ameliorating potential adverse effects of global genetic manipulations.

Use of ex-vivo tissue/cells for real time physiology (e.g. electrophysiology and imaging) provides clearer mechanistic insight and defined endpoints prior to refinement of approaches to be used to interrogate in vivo.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We constantly review the literature (including from systematic reviews) as well as regular consultation of refinement guidance published as part of the ARRIVE guidelines, LASA guidelines, NC3Rs resources and NoreCOPA PREPARE guidelines and recommendations for excellence.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We use multiple internal and external resources to stay informed about NC3Rs and ensure effective implementation including: i) Regular discussion with our NVS, NACWO and animal technicians in our dedicated facility. Our institute also coordinate a large number of in-person and digital events and regular communications with updates and best practice.

ii) Regular utilisation of the extensive NC3Rs resources at NC3RS.org.uk including webinars, training programmes, tools and workshops and we subscribe to the NC3Rs e-newsletter for regular updates. iii) we also keep updated of the relevant scientific literature for improvements in our own field (e.g. optimisation of chronic stress paradigms) as well as the broader NC3Rs approaches across new technologies, models and approaches through literature searches and discussions with colleagues, learned societies and relevant funding agencies.

21. Mechanisms regulating energy homeostasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Obesity, Central nervous system, Body weight, Food intake, Metabolism

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to define the brain circuits that control metabolism through their effects on both feeding behaviour and the organs involved in energy balance. The ultimate goal is to further understand how body weight is regulated and how defects in this regulation may cause obesity and its associated diseases, such as diabetes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Obesity and its associated conditions, such as type 2 diabetes, are very common causes of disease and death world-wide. Lifestyle interventions such as diet and exercise are often not effective long- term treatments and other therapeutic approaches are needed. However, currently therapeutic options for the treatment of obesity are suboptimal and this in part stems from an incomplete understanding of the mechanisms by which the brain has overall control of metabolism. Given the substantial unmet therapeutic need and the major economic and social burden of obesity and its associated diseases understanding the causes of obesity will help the development of effective treatments and prevention strategies with potentially enormous benefits.

What outputs do you think you will see at the end of this project?

This project will provide new scientific information on the brain circuits that are involved in metabolism, food intake and food seeking behaviour. The aim of this project is to provide a deeper understanding of the mechanisms by which the nervous system, hormonal system and metabolic tissues regulate bodyweight, feeding behaviour, and glucose metabolism.

New information will be published in peer-reviewed scientific journals and will inform scientists and clinicians working on understanding the causes of metabolic disease and on the development of improved approaches for the treatment of patients with obesity and its associated diseases. In addition to publication the data will be presented to the scientific community at both national and international meetings.

Who or what will benefit from these outputs, and how?

The short term benefits will focus on enhanced understanding of brain circuits involved in keeping energy levels stable, food intake and food seeking behaviour

In the medium term the project aims to identify new potential therapeutic targets that will be useful for future research and for other investigators conducting experiments in a similar area. If we can identify new therapeutic targets in the brain to control feeding behaviour and metabolism then we will use these to try to design further studies to test these targets. This information may also be useful for other scientists involved in the discovery of new drugs and other treatment approaches focussed on the brain. Furthermore, data will be used to design experiments and investigations that will move the field forwards in future work. In the long term, if therapies based on this work can be developed doctors will benefit from the development of improved treatment of patients with obesity and its related diseases. Furthermore, patients may benefit through the development of treatment strategies for obesity which may be drug or behaviourally based.

How will you look to maximise the outputs of this work?

We will collaborate with research groups within our establishment, the UK and worldwide if necessary in order to gain access to the best technologies and expertise. Furthermore, we will share our mouse models and viruses with the wider scientific community.

We will present at both national and international conferences to disseminate our research. We will also publish our work in peer-reviewed scientific journals and will communicate significant findings via the University communications teams to ensure adequate dissemination of our work both to local and international stakeholders. In the past our work has been covered by both the print and online media. Our work has been presented in our institutions annual research report on animal work which is available to the general public.

We will share negative findings by depositing manuscripts on an open access preprint server such as BioRxiv and also publish these finding in regular journals.

Species and numbers of animals expected to be used

- Mice: 39125

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For the vast majority of studies we will be using adult mice for the experimental parts of our project for several reasons. Firstly they are the lowest type of mammal for which models of feeding, behaviour and metabolism have been well characterised. They also represent good models of human metabolic diseases as the same genetic mechanisms that control metabolism in mice are found in humans. Mice are also prone to develop metabolic diseases such as obesity and they overeat in a similar way to that seen in humans. Mice are also the species that is most amenable to the genetic manipulations that are required for the proposed studies and robust protocols and techniques have been established in mice to study metabolism and metabolic disease. For a small number of studies we will expose pregnant mice to altered diet to assess the effects on their developing offspring. We will study their offspring as adults.

Typically, what will be done to an animal used in your project?

The overall aim of this project is to define the brain circuits that control metabolism through their effects on both feeding behaviour and the organs involved in energy balance. To do this we need to use genetically modified mice that allow us to manipulate specific types of neurons in the brain. This may require importation of sperm or embryos from commercial sources or collaborators that will be used to establish these mouse lines in-house using *in vitro* fertilisation (IVF) and embryo transfer into a recipient mother using established standard protocols. Where possible we will use male mice that are genetically altered to make them infertile, rather than having to surgically sterilise male mice. For any surgical procedures appropriate aseptic techniques and analgesia will be used to minimise the risks of infection and pain.

The mice will either be genetically altered by germline (i.e. passed from parent to offspring) or by introduction of a substance (e.g. a virus) which brings about the required genetic changes. The genetic alteration caused by the virus will be specifically in the brain and will be introduced by injecting directly into the brain under general anaesthesia. Our experience with using the genetically modified strains we propose is that the genetic modification *per se* does not cause adverse effects. Appropriate aseptic techniques and analgesia will be used to minimise the risks of infection and pain. Animals will be allowed a minimum period of 7 days to recover from the surgery before they undergo any further procedures. The effect these genetic alterations have on body weight, body composition, food intake, glucose levels, metabolic rate and behaviour will be investigated. These studies may be conducted on regular diet or on a diet where the composition has been altered e.g. a high fat or a high sugar diet, or after administration of substances such as hormones which can alter feeding and metabolic parameters.

An example of a typical study may involve groups of genetically altered animals on regular versus high fat diet with body weight measurements every week, food intake and metabolic rate studies performed at different ages. For food intake studies, it may be necessary to singly-house the animals to determine the exact amount that each animal is eating; animals will be housed like this for the minimum amount of time necessary to gain good quality scientific data. For metabolic rate studies the mice will be placed in a special ‘home’ cage system with water, food and oxygen capacity monitored continually, and assessed for a typical period of 7-10 days.

Alternatively, a study may involve groups of genetically altered animals on regular versus high fat diet with body weight measurements every week and body composition analysis and blood glucose measurements every 8 weeks from 2-6 months of age. For body composition assessment the animals will be placed individually in an imaging machine for approximately 3-5 minutes and then returned to their home cage. For the blood glucose measurements, the animals will typically receive an intraperitoneal bolus of glucose followed by regular collections (over 2 hours) of blood from the tail vein for measurement of blood glucose. Never more than 6 tolerance tests will be conducted in the same animal, with typically a minimum of 7 days between tests. Occasionally we may also need to take blood samples to determine levels of certain hormones (e.g. insulin). We limit the volume taken and limit the number and frequency of these blood draws.

In separate groups of mice, behaviours relevant to energy level balance, such as foraging, appetite and motivation, will be tested in various ways. Some of these tests will require the animals to work for food or liquid rewards. For these tests to work well the animals need to be hungry or thirsty and so we will limit their access to food or fluids prior to testing. Animals will be weighed and monitored daily during this period of limited food or water access and food or water will be supplemented if necessary. No animal will have food and water removed at the same time.

A large proportion of this project is to study brain activity of populations of nerve cells in different brain regions whilst mice are feeding or engaging in a particular behaviour. Therefore, at the same time as administering a virus to genetically alter the animals we will implant a device (e.g. a fiber optic or lens probe) that can detect changes in brain signals. Mice will typically have 4 injections into the brain but may increase to a maximum of 10 depending on the areas of the brain being injected. Mice will typically only have 2 devices implanted into the brain but when necessary this may need to increase to 4. Mice will typically undergo no more than 2 stereotaxic surgery sessions in their lifetime but when necessary this may need to increase to 3. Two to three weeks after the surgery we will connect the mice to fiber optic cables or a miniature microscope so that we can visualise brain activity while they engage in a particular task. In some cases we will implant a small plate to the skull of the animal so that we can temporarily restrain them by the head while they are free to voluntarily move on a platform suspended on an air cushion. Mice adapt very well to this, and it enables us to conduct specific behavioural tests e.g. responding to a sensory stimuli such as a smell.

In other experiments, we will shine laser light through the implanted fibre optics when the animals are engaging in a particular task. This light activates special proteins that are expressed by the injected virus and cause the nerve cells to become activated. This will allow us to determine if these nerve cells are involved in a particular behaviour e.g. feeding or foraging.

In some studies we will give hormones or other substances to mice including psychoactive drugs and monitor their effects upon feeding and related behaviours as we are interested in the links between food intake and emotional behaviours. In some cases these may need to administered chronically and in order to avoid giving mice multiple injections these substances may be administered via slow- release pellets or subcutaneous osmotic mini-pumps.
For aversive learning we may administer footshocks. The shock levels we use are as low as is practicable and cause only brief peripheral discomfort (an unpleasant prickling sensation in humans) rather than serious pain. We will typically train mice with 1-3 shocks, but in some cases may need to increase the number to 5.

Typically testing will take no longer than 6-9 months and after completion animals will be humanely killed and their organs taken for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

All expected impacts or adverse effects will be monitored carefully by a licensed member of our team alongside a named veterinary surgeon and named animal care and welfare officer.

The majority of animals are expected to experience no negative impact or adverse effects after procedures. We do not anticipate the genetically modified mice to have harmful phenotypes as we have used most of these strains before. All animals that have surgery are expected to make a rapid recovery within a couple of hours, and any sign of pain or distress will be rare. We do not expect to observe any neurological changes in the animals after administration of substances into the brain or after implantation of devices, such as fiber optics, into relevant brain areas. For some studies we need to treat mice with drugs that induce the expression of genes. One of these is a hormone that may cause irritation at injection sites or gastrointestinal disturbances, but these are rare and we will carefully monitor for them and intervene as required.

Animals that are fed a high fat diet may develop a greasy coat that tends not to bother them, although in rare cases they may develop slight skin damage.

Animals may suffer from mild and temporary discomfort at injection sites if substances are administered. If injections are repeated this risks pain, distress and increased sensitivity. To minimise these we limit number and frequency and vary injection site. Use of minipumps very occasionally leads to inflammation around the pump. We will monitor carefully and intervene as required.

Administration of endogenous hormones or peptides or substances that act at endogenous receptors will cause transient alterations in food intake, which will not significantly affect the body weight of the animals. However, if administered chronically we may see increases and decreases in body weight dependent on the substance being administered but we do not expect this to be to the degree that would affect their welfare. Animals will be monitored and weighed regularly.

The psychoactive drugs we plan to use will only cause a transient increase in activity, similar to levels that are seen in mice at night. Activity levels should return to normal levels within a short period of time (2-3 hours). If these drugs are given chronically then it will usually be for a maximum of 7 days as we have done previously. This has not elicited any adverse effects other than hyperactivity in the past. We have also not observed any signs of withdrawal with the doses used in any animals.

Animals that undergo enforced fluid or food restriction may experience weight loss or dehydration. Any animal who drops below 85% of their lean starting body weight for a period of 24 hours will be given additional food or water.

All tests for determining alterations in metabolism, imaging and behaviour are not expected to have any negative impact, and any sign of pain or distress will be rare. For some studies we will alter the activity of neuronal pathways that control anxiety as they overlap with the pathways that control feeding but our experience is that such behaviour is

transient. We do not anticipate seeing seizures in such studies as we activate discrete populations of nerves: to date we have not seen such effects in our studies on similar brain regions. In some studies we will reduce the caging temperature that mice are exposed to but we will acclimatise the mice to this and carefully monitor bodyweight, food intake and behaviour during these studies.

In most cases animals will be group-housed for experiments. However, in some cases (e.g. when determining food intake) it may be necessary to singly-house them. If this occurs then they will be singly-housed for the minimum time possible and will be given environmental enrichment in their cages. Their weight and general behaviour will be monitored.

After administration of insulin, animals will be closely monitored to make sure that they do not suffer a hypoglycaemic event (when blood sugar level falls too low for bodily functions to continue).

Footshocks are a well-established method to induce aversive learning with very limited exposure to the aversive stimulus, and therefore makes it a preferred method for studying aversive learning. The shock levels we use are as low as is practicable and cause only brief peripheral discomfort (an unpleasant prickling sensation in humans) rather than serious pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice used within this license are expected to fall under the sub threshold, mild or moderate severity categories. Based on our experience and the experiments planned we expect these to be divided as follows:

Sub threshold: 45%

Mild: 15%

Moderate: 40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The regulation of feeding, behaviour and metabolism in mammals is achieved by a complex system that includes the nervous system, key tissues that regulate metabolism such as the liver and body fat. In addition, a wide range of hormones, substances involved

in metabolism, and other substances that circulate in the blood stream, act inside the brain and allow this system to be responsive to changes in the environment. Furthermore, the end outputs of these systems, such as eating a meal or behaving in a particular way or changes in bodyweight and metabolism, are features of intact living mammals.

Therefore, the study of such complex systems, and how they work normally and go wrong in disease, requires the use of whole animals in which all these systems are still in place and talking to each other. While some features of these systems can be studied using animal tissues in a test tube breaking such things as the connections between the brain and tissues means that such approaches only give a limited insight into how these systems work. Finally, as we wish to eventually extend such studies to include humans and patients who are necessarily studied as a whole organism then studying intact mice is the best approach to build an understanding of human functions and disease.

Which non-animal alternatives did you consider for use in this project?

We considered using cell models, flies and computational approaches.

Why were they not suitable?

Long-term cultures of cells in the laboratory do not demonstrate the key features that are involved in metabolic regulation. This is particularly the case for nerve cells. In particular, the cells are not exposed to the hormones and nutrients and other features of the metabolic environment that are found in an intact animal. Furthermore, nerve cells in an intact animal are organised into complex circuits but this is not possible to achieve in a cell culture dish. Finally the features that we are interested in studying such as feeding and behaviour are not possible to study in simple cell preparations. Some behavioural processes can be studied in intact fly models but such systems do not reflect the complexity of mammalian biology and in particular the brain functions involved in many aspects of feeding behaviour. Modelling metabolism and complex brain function and behaviour has to date not been possible using computer based approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used the NC3Rs Experimental Design Assistant and statistical tools to carefully design our experiments and determine the minimum number of animals that we will need to achieve the scientific aims and objectives of this project. These numbers are further supported by our extensive experience with studies conducted under our previous Home Office Project Licence that used similar experimental approaches and mouse models

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In addition to being able to draw on our significant prior experience and published work, we have consulted the NC3Rs experimental design assistant allowing us to calculate the appropriate sample size based on each experiment. This will ensure that we are using the fewest number of animals and that each animal is being utilised to its full potential. We frequently design our studies so the same animals are used in both control and experimental studies (crossover design) and this reduces the numbers used. We use virus-based techniques to alter gene function when possible so that we can reduce breeding of mice with genetic manipulations. When planning studies we make use of published databases that describe the genes in cells and the connections between neurons so we can focus our studies on particular cell types and brain regions reducing the number of mice used for exploratory studies. We use databases of existing mouse resources and obtain mice from these archives as embryos or sperm rather than generating mice ourselves.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will monitor our breeding colony to ensure that we are correlating our sample sizes for experiments with the number of animals being produced, to avoid breeding unnecessary animals. We undertake pilot studies with a limited number of mice to establish the anatomy and existence of connections between specific nerves and the patterns of genes expressed in cells using brain slices before starting upon studies of feeding and behaviour in whole animals. Such pilot studies allow us to focus upon particular cell types and brain regions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.
We will use mice in our studies. These will include both wild-type (i.e. 'normal') and genetically altered mice with the latter largely obtained from existing commercial and academic sources. We will study mice with loss and gain of gene function (mainly in specific cell types) and also mice which express genes that allow specific cell types to be 'labelled' so that we can either manipulate them using viruses or identify them in studies of anatomy. By mainly targeting specific cell types we minimise the chance that genetic manipulations themselves have broad effects on animal well-being. With the models we use there is no pain, suffering, distress and lasting harm from the genetic manipulations themselves.

The methods we will use will include surgical approaches to allow us to inject viruses into mice. Such surgery is performed by highly experienced people using the best techniques under sterile conditions and general anaesthesia. We closely monitor animals during surgery keeping them warm and hydrated and after surgery give mice post-operative pain medication, antibiotic and hydration as required. We also give mice injections and these will use the best route and the lowest volume required. When taking blood from mice we

will again take the minimum volumes required using established best practice. For studies on feeding and behaviour we employ well validated approaches and acclimatise the mice to the studies and apparatus so that any distress to the animal is minimised. Many of our approaches use apparatus that permits remote monitoring of behaviour so that mice can go through the study without being disturbed by the investigator. It is important in studies on feeding and behaviour that the mice are familiarised to the experimenter and the apparatus as feeding and behaviour are sensitive to stress. Therefore to make sure our studies are robust we employ the best approaches to such studies. We provide mice environmental enrichment to make their cages more interesting and allow mice to live in groups to again maintain a good environment for them.

Why can't you use animals that are less sentient?

We wish to study feeding and related behaviours and metabolic regulation in adult mice with a view to understanding the potential causes of obesity and diabetes in humans. We therefore need to study free-living animals with the same level of brain complexity and metabolic regulation seen in mammals and humans. Thus we cannot use a more immature life-stage or species that are less sentient. We also cannot study feeding and behaviour in mice that have been terminally anaesthetised as such animals are not capable of undertaking these activities. Furthermore anaesthesia has effects on metabolism that would interfere with getting results that are relevant to normal function in mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We closely monitor animals during surgery keeping them warm and hydrated and post-operatively proactively give mice post-operative pain medication, antibiotic and hydration as required. Where possible we will give substances to mice by mouth rather than giving multiple injections. For studies on feeding and behaviour we employ well validated approaches and acclimatise the mice to the studies and apparatus so that any distress to the animal is minimised. We make extensive use of this training of mice to make sure they are not distressed during the studies. We undertake long term studies such as imaging of brain activity which benefit from such acclimatisation protocols, provide high quality data as well as reducing animal usage. We also make increasing use of approaches that employ apparatus that permits remote monitoring of behaviour and other areas of interest so that mice can go through the study without being disturbed by the investigator.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?
We follow governmentally published documents such as the Guidance of the Operation of the Animals (Scientific Procedures) Act, the ARRIVE guidelines, LASA guidelines (e.g. on administration of substances, blood sampling and aseptic techniques), the relevant published literature on studying metabolism in mice as well as the PREPARE guidelines, NC3Rs website and published guidelines from the local 3Rs advisory group.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult with such resources as the NC3R database and the local 3Rs advisory group. We will consult regularly with colleagues, CBS staff and vets about best practice and potential further refinement of our procedures. There are regular updates to how to

study mouse metabolism in the published literature and we will follow the published best practice.

22. Glia contribution in neurodevelopmental disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain, Neurodevelopmental disorders, Myelin, Neuron, Glia

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to investigate the interactions of neurons with the surrounding brain cells (called glia cells) during normal brain development and when the development of the brain is disrupted leading to disorders called neurodevelopmental disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK approximately 45 million cases were characterised as "brain disorders" with an estimated cost burden of £100 billion, the largest of which in terms of cost belongs to neurodegenerative, neurodevelopmental and neuropsychiatric disorders. Developmental

disorders of the brain (neurodevelopmental disorders) are often accompanied by autism and intellectual disability. These manifestations can be severely limiting, and they emerge after a disruption in the communication between neurons (nerves) or between neurons and surrounding cells (glia) in the brain. Autism Spectrum disorders is a group of neurodevelopmental disorders that develop in one in 100 children, affecting approximately 700.000 people in the UK. Autism spectrum disorder symptoms cover a wide range including stereotypic behaviours, poor cognitive functions, social and communicational deficits that develop early in life and persist until adulthood. These symptoms can be severely limiting for affected individuals, but we currently lack effective treatments.

The major benefit of this research is the identification of new drug treatments for people with autism- associated neurodevelopmental disorders. My research focus on glia cells called oligodendrocytes and their communication with the neurons they contact takes a new direction on neurodevelopmental disorder research that is now imminent if we wish to understand them. Oligodendrocytes produce myelin, a substance that covers the neurons and has a similar role to the insulation of wires, protecting the neuron. So far, how this insulation is affected and what happens to the underlying neuron in neurodevelopmental disorders has not been addressed. However, evidence from brain scans in humans and rodent models point to abnormalities in this insulation.

The goals of this project are:

To identify the specific molecular and cellular pathways that are affected in oligodendrocytes using rodent models of neurodevelopmental disorders.

To understand how these changes in oligodendrocytes affect the communication with neurons and how they lead to the behaviours that we see in neurodevelopmental disorders.

To target and restore the affected pathways with the idea to develop therapies that will restore the normal brain function.

This project will recruit a group of scientists and will generate new knowledge with the hope that it will be then translated into new strategies for the design of better treatments for people with neurodevelopmental disorders. As new therapies develop within the years the burden on affected people and their families will be progressively lifted and the quality of life will be significantly ameliorated.

What outputs do you think you will see at the end of this project?

This project will determine:

The mechanisms by which gene mutations causing neurodevelopmental disorders affect oligodendrocyte function and myelin formation during brain development and in the adult.

The effect mutant oligodendrocytes have on the insulation, nutrient supply and function of neurons.

The contribution of mutant oligodendrocytes to the apperence of behaviours associated with neurodevelopmental disorders.

The type and timing of effective oligodendrocyte manipulations for the restoration of normal brain function.

Who or what will benefit from these outputs, and how?

This project takes a new direction in the field expanding the current knowledge from neurons to neuron- glia communication in the context of neurodevelopmental disorders. Understanding how glia cells such as oligodendrocytes contribute to the formation of healthy brain networks during development will unfold new possibilities for effective treatments for neurodevelopmental disorders using a different route: that of glial cell manipulation. In addition, the project will assess the likelihood of currently available therapeutics to be re-purposed to treat neurodevelopmental disorders associated with autism and this would be the major benefit of this project. The identification of novel treatments, or the enhancement of existing therapies, would have a significant positive impact on affected individuals and their families by increasing their quality of life, while reducing the cost of care for affected individuals.

Another benefit of this project is the advancement of scientific knowledge on the mechanisms of neuron-oligodendrocyte communication. The beneficiaries of this include other scientists in field, as well as members of the institution and UK research councils who will benefit from any high-impact papers based on this research.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work I will disseminate the findings of this project with:

High-Impact peer-reviewed publications

Presentations in national and international scientific conferences

Collaborations with basic and clinical scientists of the scientific community

Public engagement events

Species and numbers of animals expected to be used

- Mice: 7500
- Rats: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project aims to better understand how neurodevelopmental disorders are caused and how we can reverse them. In humans, autism-associated neurodevelopmental disorder symptoms become evident in early post-natal life and persist throughout adulthood. It is therefore critical to study these disorders both during development and in the adult to understand not only how but when we can intervene.
Neurodevelopmental disorder biology is quite complex since different cell types in the brain carry the responsible genetic mutation. Each mutation can affect differently the development of neurons and that of glia cells and completely alter the ways these cell populations interact and form bigger brain networks. Mice and rats share more than 97%

genetic similarity with humans and the genetic mutations that cause neurodevelopmental disorders in humans affect the rodent brain in a similar way that we can reproducibly study. In addition to the genetic similarity with humans, rodents also have similar brain development with that of humans and show behaviours relevant to human neurodevelopmental disorder-related behaviours that we can monitor. For these reasons, the rodent models of neurodevelopmental disorders are ideal for us to study how these disorders develop before the appearance of symptoms and later on, for the identification of the optimal time-points for therapies.

Typically, what will be done to an animal used in your project?

We aim to study the interactions of oligodendrocytes and neurons in the healthy brain throughout brain development until adulthood and compare them with those in the brains that develop a neurodevelopmental disorder. For this reason, experiments will include the administration of substances or viruses that express fluorescent proteins to pregnant dams, neonates, juveniles, and adults or the use of genetically altered animals that will help us visualise and follow these cell types during brain development.

On some occasions we will need to manipulate either the number, the function of brain cells or the signals they receive from other cell types and the environment. This will help us to discover the signalling pathways and the cell functions that are important for a healthy brain network and how and when these change during neurodevelopmental disorders. This will involve the administration of drugs, substances in different stages during brain development, the administration of viruses that affect the expression of various genes and signalling molecules and the use of genetically altered animals with altered gene expression. Animals will receive drugs and substances via the oral route or via the intraperitoneal, intravenous, intramuscular, intranasal or subcutaneous routes. When this is not possible a surgery will be necessary to deliver them directly in the brain. The administration of viruses that change the expression of molecules will be done intravenously or by surgically injecting them in the brain. Animals will be then studied for a period of weeks or several months after each intervention.

To test if the transplantation of glial cells is beneficial for the restoration of healthy brain networks in neurodevelopmental disorders, some neonatal animals will get injections of cells in specific brain areas that will be monitored for a period of several weeks or months.

To test if each of the above interventions positively affects animal behaviour and therefore prevents the appearance of neurodevelopmental disorder-related symptoms, we will need to perform behavioural tests in the animals several days, weeks of months after the intervention. On rare occasions animals will need to have two separate surgeries (for example one to receive cell transplantation or a virus that labels cells followed by the administration of a drug or a substance later) separated by a period of time that will allow animals to recover before the second surgery is performed. None of the experiments will be performed in aged animals. Several experiments may end with animals being killed under terminal anaesthesia to allow fixation and removal of tissues for further examination or culturing of the different cell types in a dish.

What are the expected impacts and/or adverse effects for the animals during your project?

We will breed animals with disruptions in genes linked to neurodevelopmental disorders. We expect few animals to suffer from the effects of these genetic alterations but we will conduct most of our experiments before these adverse effects appear. The animals will be

killed by humane methods and their tissues used after their death to address the experimental questions of interest. We will also use animal tissue to obtain cells and sections of brain to grow in a dish to test possible therapies. This will also involve surgery for the administration of compounds in the brain when another route is impossible, which is of moderate suffering. To minimise this suffering these procedures will be carried by trained personnel using pain relief under NVS advice, and the animals will be closely monitored for signs of harm. In some cases, animals may be given drugs to study the effects on molecular, cellular, electrophysiological (properties of signal transmission in the brain) and behavioural processes, but it is not expected that this will cause any adverse effects other than mild clinical signs (i.e. decreased appetite, lower levels of activity). In some cases, we will test animals for their performance on learning and memory tasks. This will be necessary to reveal potential benefits from our drug treatments and animals should not experience any adverse effects other than mild clinical signs. All animals will be humanely killed at the end of the experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the genetically altered mice and rats bred and maintained on this licence some 70% should experience MILD severity or lower, with 30% experiencing MODERATE severity. All the rats and mice killed to obtain nervous tissue for other experiments will experience severity no greater than MILD. Of the mice and rats that undergo behavioural evaluation of the effects of the various genetic or pharmacological manipulations during brain development, some 60% are likely to experience MODERATE severity, with the other 40% not exceeding MILD severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aims of this project require the molecular/cellular and electrophysiological study of the mammalian brain and the assessment of complex behaviours to better understand how neurodevelopmental disorders are caused and how we can reverse them. Complementary work using culture systems from human derived brain cells will be performed when possible and will be a powerful tool especially for addressing simple biological questions and the effectiveness of potential treatments. This technology is new and a great replacement for animal work but still unable to faithfully replicate the complexity that we find in an intact mammalian brain. Therefore, we still need to study the intact mammalian brain using animals. Mice and rats share more than 97% genetic identity with humans and the genetic mutations that cause neurodevelopmental disorders in humans affect the rodent brain in an analogous manner that we can reproducibly study. Nevertheless, we will

always use human derived culture systems, human post-mortem tissue whenever available and pre-existing -omics databases for the investigation of molecular pathway changes prior to performing experiments using animals.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives:

Culture and co-culture systems using human-derived cells

Available databases for the investigation of molecular changes in neurodevelopmental disorders

Human post-mortem tissue

Why were they not suitable?

Datasets are very useful to find key molecules and molecular pathways that can be important for neurodevelopmental disorders.

Culture and co-culture systems using human-derived brain cells are also useful to address simple biological questions and pharmaceutical compounds before any experiment in animals. However, the brain is a three-dimensional structure with many interacting cells and complex networks that we cannot yet model in a dish or maintain for long enough periods to study neurodevelopmental disorders. For these reasons we still need to turn to animals, and in particular, mammals, to help with this complexity.

Human post-mortem tissue is restricted by the limited availability of tissue of adequate quality.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

For this project we will use minimal animal numbers to produce robust and reproducible scientific outcomes, considering severity. The numbers of animals that will be used for this project were estimated after statistical analysis calculations of previous data using specialised computer software.

This project requires the maintenance of a significant number of animals because:

According to our calculations, group sizes or at least 15-20 animals are required for most of the proposed experiments.

Certain experiments will require the use of at least 4 separate groups (for example when a specific drug is compared to placebo in GA animals and controls)

In some of the GA animal groups that will be analysed, the gene of interest is carried on the X chromosome and therefore it would not be possible to equally use animals from both sexes.

For the proposed behavioural and electrophysiological analyses, each will require a different cohort of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments will be performed according to the ARRIVE guidelines 2.0. In order to reduce the animals being used in this project, the following were taken into consideration:

Formulation of clear experimental questions, assignment of suitable controls, and independent replications for each experimental question.

Efficient experimental design (such as factorial, randomised block, unequal groups) was considered to reduce suffering and animal numbers.

Power analysis calculations of previous or small group data were and will be used prior to the assignment of larger animal groups for adequate power to detect genuine scientific differences.

To avoid bias groups will be assigned in a randomised fashion and experiments will be performed blind to genotype and treatment using codes kept by a person not involved in the experiment and file randomiser software such as the Fiji software File randomiser macro.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To further optimise the number of animals for this project we will:

Ensure that trained personnel perform the experiments in communication with the animal units to ensure good health, minimum animal stress and less variability.

For many experiments cultures of brain cells and brain slices will be used prior to any experiment in animals.

For the experiments that involve brain tissue, cell cultures and slices, the same animal material can be used for multiple experiments and by multiple scientists.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and rats have more than 97% genetic similarity with humans and the genetic mutations that cause neurodevelopmental disorders affect the mouse and rat brain in a similar manner that we can reproducibly study. Both mice and rats are the most tractable models for the in vivo study of neurodevelopmental disorders to determine the molecular, functional, and structural characteristics of brain networks. Mice and rats develop a range of neurodevelopmental disorder-like behaviours that are relevant to the respective human ones. However, the two species display distinct phenotypic characteristics for each neurodevelopmental disorder at the cellular and functional level and therefore it is critical to include both if we aim to find effective and relevant treatments for the human neurodevelopmental disorders.

For instance, the genetically altered model rats that have been generated for several forms of neurodevelopmental disorders develop more complicated cognitive disruptions that cannot be observed in mouse models. This is because rats have better developed brain areas than mice, responsible for these behaviours. At the same time, there are more available mouse genetic tools and commercially available reagents we can use to study the molecular mechanisms that underlie neurodevelopmental disorders which are not available for rats.

Hence, mouse and rat models of neurodevelopmental disorders have been established and show high relevance to the human neurodevelopmental disorders, some of which will be used for this project. The use of mice and rat models of neurodevelopmental disorders is a refinement to the use of other higher mammalian organisms as they have a lower degree of neurophysiological sensitivity and exhibit less severe behavioural symptoms.

Nevertheless, some of these genetically altered animals do develop moderate symptoms. As a refinement we will use established severity scales and monitoring systems that have been tailored specifically for each line. Each of them contains distinct trigger points (i.e. for instance ≥10% of weight loss over a period of 1 week) that will dictate necessary interventions for the improvement of animal welfare (body weight monitoring twice a week and administration of food supplement), clear observational points that define the severity (i.e. phenotypic scoring scales including mobility, gait, tremor, breathing and general condition) for each line, and well-described humane endpoints (such as ≥20% weight loss or a total score of 15 in the severity scale) that will lead to the humane killing of the animal and the termination of the procedure.
The animals in these studies will be cared by trained staff within a well-resourced and well-equipped modern animal facility with adequate environmental enrichment. Half of the methods that will be performed for this project include the in vitro culture of neurons and oligodendrocytes or the culture of brain slices. These methods are also used as a refinement for the use of in vivo models since they will allow us to study the behaviour of normal and genetically altered cells and the molecular mechanisms that underlie them using tissue derived from humanely killed mouse and rat pups and therefore minimising the pain and harm to the animals. The same systems will be used for testing the efficiency of viruses, drugs and cells before any administration in vivo. Only the more effective drugs/viruses/cells will be administered in vivo. As an additional refinement, we have chosen to test the efficiency of drugs and substances that have already been successful in other pre-clinical models and/or already used in human clinical trials. Tissues that will be used for the histological and electrophysiological analysis will be obtained by animals that will be humanely killed.

In some cases, we will need to use surgery to deliver drugs/viruses/cells directly in the brain when another root of administration is not possible. For each surgery we will use aseptic conditions to minimise unnecessary and harmful inflammation and post-operative analgesia to reduce pain and suffering after the surgery. Animals will be closely monitored and scored by well-trained staff and will be allowed to fully recover before any subsequent procedure. These short-term surgeries are usually well tolerated by the animals and induce only transient suffering that we expect to minimise with the post- operative care and analgesia. Finally for the assessment of the animal's behaviour we will perform behavioural tests that are not expected to cause any adverse effects other than mild or transient discomfort. Any animal that will show any unexpected signs of suffering that is not minimal, or transient will be humanely killed.

Why can't you use animals that are less sentient?

A major goal of this research is to identify and correct the disruptions in neuron-glia communication in neurodevelopmental disorders using pharmacological and genetic strategies. The use of the genetically altered rodent models is critical to this goal because they effectively model the human mutations that cause these disorders and because it is necessary to study the complex interactions of an intact mammalian brain.

Even though the oligodendrocyte generation and migration to different locations in the brain happens early in development, the insulation of neurons with myelin is primarily a post-natal process that continues into adulthood in vertebrates. It is therefore critical to follow this process in time something that is not possible using less sentient and less evolved animals. In addition, complicated cognitive functions and behaviours are closely linked to neurodevelopmental disorder research. These behaviours and the effectiveness of treatments cannot be assessed if animals under terminal anaesthesia. Finally, this project requires the use of genetically altered rat models that will allow us to assess more complicated cognitive disruptions that cannot be observed in mouse models, due to the better developed brain area responsible for these behaviours in the rat, the prefrontal cortex.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animals in these studies will be cared by trained staff within a well-resourced and well-equipped modern animal facility with adequate environmental enrichment. For the animal lines with expected moderate phenotypes we will use established severity scales and monitoring systems that have been tailored specifically for each line. Each of them contains distinct trigger points (i.e. for instance ≥10% of weight loss over a period of 1 week) that will dictate necessary interventions for the improvement of animal welfare (body weight monitoring twice a week and administration of food supplement), clear observational points that define the severity (i.e. phenotypic scoring scales including mobility, gait, tremor, breathing and general condition) for line, and well-described humane endpoints (such as ≥20% weight loss or a total score of 15 in the severity scale) that will lead to the humane killing of the animal and the termination of the procedure. Onsite veterinary assistance will provide advice if and when necessary.

Tissue for the in vitro, ex vivo, histological and electrophysiological assessment of cellular functions will be obtained from humanely killed animals. In some cases, we will need to use surgery to deliver drugs/viruses/cells directly in the brain when another root of administration is not possible. For each surgery we will use aseptic conditions to minimise

unnecessary and harmful inflammation and post- operative analgesia to reduce pain and suffering after the surgery. Animals will be closely monitored and scored by well-trained staff and will be allowed to fully recover before any subsequent procedure. Onsite veterinary assistance will provide advice if and when necessary.

Measures of distress for all animals will be assessed (such as hunched posture, abnormal feeding and drinking, weight loss, levels of animal activity). All animals will be carefully monitored and if there is any evidence of suffering greater than minor and transient or in any way compromises normal behaviour, they will be killed using humane methods before reaching the humane endpoints (the humane endpoints are well defined for the models that we plan to use).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- Published best practice guidance will be obtained by: Local AWERB guidelines
- ARRIVE and PREPARE guidelines of the NC3Rs
- Guidance on Animal Testing and Research from the Home Office
- LASA and RSPCA guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the advances in the 3Rs by:

- Communication and frequent discussion with the NVS, NACWO and NIO. Attending on-site or online NC3R seminars.
- Registered for NC3R newsletters. Frequently visiting FRAME, LASA websites.
- Attendance of scientific meetings and continued review on scientific literature for the identification of new emerging technologies that can minimise suffering and replace animal use.
- Updates on animal handling and enrichment through http://www.procedureswithcare.org.uk and www.enrichmentrecord.com

23. Provision of an outsourced drug discovery platform for the development of therapeutic drugs for neurological disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

neurodegeneration, stroke, brain, neuron

Animal types	Life stages
Rats	adult
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to test the efficacy of drugs (how well they produce a desired effect) designed for use against human diseases of the brain, such as Alzheimer's and stroke.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurological disorders involve damage to the brain, spinal cord or nerves; they can be progressive or sudden, intermittent or unpredictable. They can cause significant burden to the patient, their families, and society as a whole; 14% of the social care budget in England is spent on people living with neurological conditions, so it is a group of conditions that need significant investment and patient care.

Conditions involving neurodegeneration (when brain cells are progressively or immediately damaged or lost) are particularly devastating for older people. The leading cause of death in the UK in 2018 was dementia and Alzheimer's disease, accounting for 12.7% of all registered deaths (Office for National Statistics; ONS). This is expected to rise year-on-year as the population grows and lives longer. Patient quality of life is usually affected more as the degeneration progresses. Life expectancy changes with age of diagnoses, but on average 4.5 years is the median (average) for survival from onset of dementia.

Ischemic stroke is where a blockage (a blood clot) causes a sudden loss of blood supply to an area of the brain, and accounts for 85% of strokes. A stroke can cause various changes to movement, speech, or cognition (the way your brain understands, organises and stores information). The number of deaths through ischemic stroke have almost halved in the last twenty years, most likely through greater wider public knowledge of spotting early signs and therefore providing early intervention. Despite this, the incidences of stroke are set to rise due to an aging population; age-related diseases, such as heart disease or diabetes can increase the risk of having a stroke. Furthermore, quality of life for stroke patients is significantly affected and, in a large proportion, permanently life-changing with the significant risk of a second stroke also a factor in the continued management of the disease in these patients.

Our work aims to use animals, in combination with experiments that take place in the laboratory, to support the development of new treatments for neurological disorders and address the unmet clinical needs for treatments. The use of animals is currently an essential part in the process of developing new treatments and enables us to replicate complex aspects of the disease in the entire biological system. For neurological disorders this includes the interaction of brain cells directly affected by damage, with other nearby cells, and the effect on the animal as a whole (for example how its movements are changed by the disease). They enable us to test the effect of new treatments in a relevant and intact biological system. This work will enable key decisions to be made regarding which treatments will continue to be developed, and ultimately, which will make it into clinical trials, where they are tested in humans. Our approach to the work ensures that this is done in the most efficient way possible, and that the benefit gained from every animal is maximised.

What outputs do you think you will see at the end of this project?

Work carried out under this licence will involve the testing of new drugs to treat neurological disorders (diseases of the brain) in a way that is closely related to human disease. As part of this project we expect to test the effects of at least 5 new drugs for neurodegeneration (diseases like Alzheimer's), and at least 3 new drugs for treating stroke. Our clients are experts in developing their potential (candidate) drugs, and our bespoke studies that closely replicate both disease and potential ways of treating the disease. Combining these two approaches, the candidate drugs have significant potential to enter clinical trials. The way the drug works (mechanism of action), or the kinds of biological processes we look at (targets) will be different depending on the client we have, but the aim of treating the specific diseases will remain the same.

This project will provide important information to progress new treatments through the phases of drug development. New test agents will be evaluated for their ability to treat animals with symptoms that closely match those in human neurological disorders. The information gathered will enable us to identify the most appropriate treatments to take forward to human clinical trials. The information gathered will also enable us to quickly determine which drugs should not be progressed any further.

In addition, this work will increase our knowledge of how new drugs work and will help us to identify changes in the body that occur in response to the drug. We can use this information further down the line to monitor responses in humans during clinical trials.

Data from studies under this project may be used to support patent applications and applications by clients for additional funding. Data produced may also support the design of regulatory studies for clients.

Who or what will benefit from these outputs, and how?

This project will generate important data in the development of new drugs. To assist with this, we will utilise our test agent dosing project licence to allow us to understand how drugs distribute in the body after dosing, how quickly they are eliminated, and the dosages that are well tolerated in rodents. This will aid in the design of dosing strategies for studies under this licence. Ultimately, work carried out under this licence is expected to result in the progression of new neurological disorder treatments through various stages of drug development and ultimately into the clinic to treat patients.

Our focus on a science-led approach will enable key decisions to be made at each development stage on whether a test agent is likely to become a successful drug. This allows unsuitable drugs to be abandoned at an early stage and enables us to use the fewest number of animals possible per drug development programme. The identification of test agents as unsuitable for use in humans at an early stage of development will ensure a better success rate in the drug discovery process than has been seen previously in the pharmaceutical industry. Ultimately, this project will contribute to the successful development of new drugs, which will benefit patients with various neurological disorders who may otherwise have their quality of life greatly reduced by their condition.

How will you look to maximise the outputs of this work?

All studies are designed such that the outputs from each animal are maximised. Expert knowledge is gathered not only from within the preclinical (animal) team performing the animal studies, but from other teams within our company, or our clients' companies. This ensures that all relevant work that has been performed in the laboratory is taken into consideration when designing animal studies. The in vitro (in the test tube) and bioanalysis teams at our company are experts at analysing tissue and blood samples collected from animals, and they help with details of sample collection and storage to ensure that the samples are collected and stored in the best way possible. They are also experts at working with small quantities of samples, particularly small volumes of blood samples, meaning that they can often analyse lots of different biomarkers (a measurable indicator of a disease state or other physiological state) and test agent levels from each animal.

In addition, we will seek expertise from our established networks, to ensure that we make use of any new knowledge or incorporate better methods of performing animal studies. We will also use these networks to provide information and training to others on the models and techniques we use in our research. We will maintain good communication with

managers of the animal facilities to ensure that any tissues from animals being killed that are not required for our work can be made available to other researchers if suitable.

Although there are times where we will not be able to share animal model information (for example, where it would put us at a competitive disadvantage), we aim to publish or share our findings (especially control data) wherever possible. Likewise, we hope to pass on any 3Rs progress we make in real time to colleagues, but this will ultimately be available locally to other researchers through the AWERB retrospective review for this project.

Species and numbers of animals expected to be used

- Mice: 300
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are the most common type of animal used for developing new treatments for neurological diseases. These rodents are well characterised, meaning that a lot is already known about how their bodies work, and the techniques used to mimic the human diseases are well developed. This means that for the brain diseases we wish to study, using rats and mice will produce data that is very close to how the diseases behave in humans.

Adult rats and mice will be used for the work outlined in this project licence as we want the biology of the animals to be fully developed as this will better represent the patients we aim to treat. Both rats and mice are needed are needed for this project; each species has different characteristics that suit different types of experiments (for example rats are better suited to studying behaviour). Also there are sometimes differences in how each species reacts to the substances used to bring about the diseases (for example one drug we use is tolerated by mice but is toxic to rats).

Typically, what will be done to an animal used in your project?

The majority of animals will be part of studies that aim to test whether new drugs can be used to prevent or halt neurological damage associated with stroke or neurodegeneration. Therefore, each animal will be given some kind of new drug at some point during a study, either once or several times. Drugs will be administered more commonly intraperitoneally (into the body cavity), subcutaneously (under the skin) or orally (by mouth), and less frequently intravenously (into a vein), via a slow-release device under the skin, or very rarely into the nose. For intraperitoneal, subcutaneous and oral administration, mice will be held securely by a trained researcher for the dose to be administered. For intravenous dosing, mice will be placed briefly in a specially designed rodent restrainer (a ventilated Perspex tube where the animal can be observed), the tail will be warmed using warm water or more commonly by being placed into a warming cabinet to dilate the blood vessels and make them easier to see before administering the dose. For intranasal dosing, mice will be briefly anaesthetised and placed onto their backs to allow the dose to be administered directly into the nostrils.

The dosing of new drugs should not cause significant harm or distress overall; dosing might be once a day for a week, or once a week and cause only brief discomfort each time.

All animals will either have surgery on one occasion or be given certain chemicals to induce the disease we will be studying. Some of these animals will have the surgery but not have the vital step; these will act as control animals (to show what would have happened if they experienced all the steps without inducing the disease). Surgery is performed under anaesthesia (the animals will be asleep for the duration of the surgery and will feel no pain). Recovery from the types of surgery in this licence should be unremarkable. Most importantly, anything administered or surgery to induce disease should only cause minor impairments in the way the animal moves, only detectable by special tests.

Most of the animals will undergo some tests to assess how well they can coordinate their movements to complete tasks such as grasping for a treat, or removing a piece of tape from the top of their paw. Sometimes, tests looking at more general movements, such as grip strength, balance, and gait analysis (how the animal walks) will be used. These tests will generally not cause any stress or discomfort.

Sometimes, taking blood samples may be necessary to look at levels of indicators of disease (biomarkers) or how much drug is in the blood. Blood samples are usually small in volume and are taken from a superficial (near the skin surface) vein.

At the end of the studies, most animals will be put under terminal anaesthesia (made unconscious permanently) while a large blood sample is taken, and a stain or fix is injected to mark the brain for further analysis ex vivo (in the lab). The animals will be humanely killed while still under anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

In most cases neurodegeneration will be induced under anaesthesia (while unconscious) if surgery is needed to block blood vessels or give chemicals directly into the brain. Sometimes chemicals may be administered into the body through common injection routes previously detailed (only transient discomfort) if it is known to reach the brain. Stroke will always be induced under anaesthesia.

The symptoms felt by inducing neurodegeneration or stroke, after recovery from any surgery, will be very minimal, and should only be noticeable by special tests. Some of these tests may cause temporary anxiety while the animals get used them, but overall the tests will not cause any lasting harm.

Sometimes the chemicals used to induce neurodegeneration might cause abnormal movements, but these are expected to be mild and will not cause lasting stress to the animal.

The test drugs given are not expected to cause lasting harm, although sometimes the animal may lose some body weight while adjusting to them. Blood sampling is not expected to cause any lasting discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Mild 35%

Moderate 65% Rats:
Mild 20%

Moderate 80%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The work to be performed in this project cannot be fully replaced by using models in a laboratory. Wherever possible, work is performed either using cells (a large proportion of a typical work program will be done in tests done with cells grown in the lab) or tissues taken from a dead animal before moving into live animal studies. This is to make sure that the animal studies are well designed and that the maximum amount of data is gained from each animal study.

Which non-animal alternatives did you consider for use in this project?

Our company regularly uses a range of in vitro (taking place in a test tube in the laboratory dish) methods utilising cells to understand how a novel test agent might affect the cellular functioning of those cells. From these experiments we can prioritise test agents and only take forward those that have the desired effect, and therefore those that look the most promising for the treatment of neurological disorders.

Why were they not suitable?

Cell-based methods are useful to test the impact that novel test agents have on a cellular level, for one particular type of cell, but they do not model how cells interact with other types of cells and organs, which is particularly important with how brain cells communicate. In addition, cell-based methods do not test the effects that the body might have on a test agent, for example, how it is absorbed, distributed and removed from the body, all of which can alter how effective the test agent might be. Testing a new drug in a well-understood, whole biological system enables us to study the complex interaction in the body, as well as monitoring how the test agent performs in a whole animal. None of the

alternatives mentioned can replicate this, though cell-based testing enables us to prioritise drugs and only take the best candidates forward for further development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used has been estimated by analysis of the number of animals used on previous projects, looking at the number of animals required for each type of study. This was then combined with a prediction of likely demand of future projects to give the numbers in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have extensive experience in the design of experiments of the types in this project, which has given us confidence in the number of animals required to ensure that no animals are used unnecessarily, but also that the data generated is reliable.

We regularly refer to the PREPARE and ARRIVE guidelines and make use of the NC3Rs Experimental Design Assistant to ensure that we are using the correct number of animals for every study.

Where information is not available in published literature or from contact with other researchers, pilot studies in a small number of animals will be used first where appropriate to assess the action of test agents, and well as the variability in replicating the disease.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Data from pilot studies and previous experience are used to ensure that the numbers used are both as low as possible, but also large enough to generate reliable data. Within our company, a member of the wider team has generated a tool for performing power calculations (a way of telling whether the number of animals in a study is enough to produce data that can be trusted) and can be consulted as necessary to assist with study design.

Sometimes animals are produced on our breeding project that don't have mutations (wild-type) that would be suitable for this project, so these animals will be used whenever possible. This will reduce the need for obtaining animals externally. Where animals are obtained from external sources, only the number of animals required for the study will be purchased or imported.

Wherever possible, our in vivo (animal work) scientists will be blinded to the treatment status or even which animal has had which kind of surgery, reducing bias. This enables more reliable information to be gathered from a smaller number of animals.

Baseline data (e.g. bodyweight) are recorded and animals spread across treatment groups to ensure there are no differences between the groups at the start of the study (pseudo-randomisation).

Good planning ensures that within any series of studies we can control for variability that might be introduced. To limit this variability we look at using animals of a similar age/weight range, testing different batches of test agent in the lab first, using the same source of reagents (chemicals used during the experiments), keeping records of observations made and standardising as many components of an in vivo model as is possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals will be housed in a purpose-built, state-of-the-art facility, that is specific pathogen free (SPF), which excludes certain disease-causing organisms such as bacteria, viruses and parasites that would compromise the health of the animals and the quality of the study output (how good the data is). They will have access to food, water and items that enhance their environment, such as tunnels, chew sticks and mezzanine levels to climb on. Our company staff and the animal care staff are competent in rodent welfare and will ensure that animal suffering is minimised. We aim to house mice and rats in social groups to promote normal behaviour. However, aggressive behaviour can occasionally result in animals being singly housed to prevent injury.

All animals will be wild-type; this is because the human diseases will be mimicked by making changes to the brain, either with changing blood flow to different areas, or by giving chemicals that change how the brain functions.

Why can’t you use animals that are less sentient?

Adult rodents such as rats and mice are the lowest species of mammal that allow us to adequately study the complexities of human neurological disorders. Mice are used wherever possible for studies not involving behavioural tests more suited to rats. Due to the need to conduct simple behavioural tests to assess how the animals move and behave, terminal anaesthesia is not a possibility. It is also important that we are able to monitor the behaviour of the animals both after the neurological disease is induced, and while giving test agents as this allows us to monitor for adverse reactions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Husbandry (animal care) after procedures involving surgery is very important; we will make sure that the animals are kept as comfortable as possible after surgery, and will

include pain relief, soft bedding, and a warm cage to help recovery. In-depth daily monitoring of body weights and general condition will be in place for approximately 10 days after surgery. Where possible, pain relief will be given by putting it into a palatable food like Nutella; this means that the animals will take the medication by choice rather than an injection.

When blood sampling or dosing, we will use the smallest needle size possible to minimise any pain and distress to the animal. We also give drugs via drinking water instead of by mouth where possible.

Where it is hard to predict how a drug will affect an animal, a tolerability or safety study will be performed beforehand on our related project licence to ensure that the drug is tolerable for long-term dosing in our surgical animals.

When testing how the animals move, they will be trained to get used to the tests before data is recorded. This reduces anxiety over the course of the tests. Likewise, animals will be acclimatised to (allowed to get used to) new environments and handling before the studies start.

The choice of strain of rat or mouse will be considered carefully for each study. Based on published work and our own experience, we will consider how each strain is more or less susceptible to different chemicals or potential treatments. Likewise, we will consider the known behavioural characteristics and husbandry needs of the strain; for example, how easy it is to train a rat to perform the behavioural tests because they are naturally less stressed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the PREPARE guidelines for the planning of studies (Smith et al., PREPARE: guidelines for planning animal research and testing. 2020. Laboratory Animals). LASA (Laboratory Animal Science Association) also has a range of published guidance documents with principles that can be applied to our animal studies which are found at https://www.lasa.co.uk/current_publications/.

Specific to ischemic stroke, we will refer to the IMPROVE guidelines where possible. Sert NP et al (2017) The IMPROVE Guidelines (Ischaemia Models: Procedural Refinements Of in Vivo Experiments). JCBFM 37(11): 3488-3517. doi: 10.1177/0271678X17709185.In addition we will also refer to the following when conducting our work:

Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217

LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. (E Lilley and M. Berdoy eds.). http://www.lasa.co.uk/publications/

Smith D, Anderson D , Degryse A, Bol C, Criado A, Ferrara A, Franco NH, Gyertyan I, Orellana JM, Ostergaard G, Varga O, Voipio H (2018) Classification and reporting of severity experienced by animals used in scientific procedures: FELASA/ECLAM/ESLAV Working Group report. Lab Animal 51(1S): 5-57. doi: 10.1177/0023677217744587

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

When designing animal studies we consider the appropriate guidelines, including the guidance from LASA, the NC3Rs, and the PREPARE guidelines. This guidance will influence our study design.

24. Treating diabetic retinopathy through targeting mitochondria

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

diabetes, therapy, mitochondria, retinopathy, inflammation

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

There is evidence to suggest that by enhancing the replacement of damaged mitochondria (the small batteries that produce energy inside the cells) that sight loss associated with diabetes can be reduced. The aim of this PPL is to understand how this works, and identify drugs that can be used for this purpose.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diabetes is an overwhelming and increasing public health problem, with 415 million people affected world-wide, and projected to rise by 35% within the next 25 years. Diabetic retinopathy (DR) comprises one of the most common complications, affecting ~80% of people who have had diabetes for 1-2 decades, and is driven by numerous insults in addition to high-blood sugar, importantly systemic inflammation. Even with optimal control

of risk factors (e.g. blood-sugar levels), the incidence of DR remains very high, and is aggravated by the lack of effective and safe treatment. Given the deterioration of mitochondria in diabetes, including the eye (causing DR) and immune system (causing inflammation that exacerbates DR), developing new therapeutics capable to replace the damaged mitochondria may offer innovative solutions to fight against this devastating visual condition.

What outputs do you think you will see at the end of this project?

Based on promising data, we want to further understand whether drugs capable of replacing damaged mitochondria can help prevent eye damage commonly seen in diabetes. Therefore, by the end of the project we expect to:

Understand how mitochondrial damage contributes to diabetic retinopathy and in the systemic, low- grade chronic inflammation that contributes to its progression.

Develop and evaluate the potential of novel mitochondrial therapies to treat diabetic retinopathy in animal models.

Inform the scientific community and the general public (e.g. diabetic patients) about the potential of these experimental therapies, through patient and public events, conferences and high impact peer reviewed publications.

Therefore, the information gained from this project may lead to the development of potential therapies to treat DR.

Who or what will benefit from these outputs, and how?

This project will enhance our basic understanding to Diabetic Retinopathy (DR) and how its progression is influenced by the chronic low-grade inflammation that accompanies this condition. We aim to alleviate DR by targeting the damaged mitochondria that accumulate in the retina and in the immune system, so demonstrating the preclinical efficacy of our therapies is a key step to enhance their implementation in the clinic. Therefore, this research has the potential to significantly reduce the clinical, economic and patient burdens associated with diabetic retinopathy (DR). In the UK, around 2% of people who have had diabetes for 1-2 decades have DR, which poses a significant emotional and physical burden for patients.

Short-term (within the five-year project): the beneficiaries will be the local, national and international academic communities involved in diabetes, retinopathy and mitochondrial-based therapies. Benefits will include both scientific discovery and technical expertise, which can be shared through conferences, meetings, publications and social media. Also in the short term, patients will be aware of our work through focus groups on diabetes and eye disease (this is currently running and will expand in the upcoming years).

Mid-term (5-10 years after this project): This project will determine the potential of new therapies to prevent eye damage which often occurs in diabetes (diabetic retinopathy). Such therapies showed promise in our preliminary studies, including improved visual function. Our multi-disciplinary team (scientists, doctors and pharmacologists) has good engagement with hospitals, patients and pharmaceutical companies who will help bring the treatment to diabetic patients. In addition, we will actively seek pharmaceutical partners who are currently developing drugs with a similar mechanism for application in other diseases, thus accelerating the path to implement our technology towards essential phase-

III trials.

Long-term (10 years after this project): Through knowledge acquisition and therapeutic discovery, patients and clinicians will be the most likely beneficiaries to this research. For diabetic patients, it will be the development of a treatment which alleviates sight loss, administered in a way that is patient acceptable (orally) and improve current practice in diabetes care. For clinicians, the availability of new oral therapies able to alleviate diabetic retinopathy, would involve a revolutionary approach.

How will you look to maximise the outputs of this work?

Knowledge sharing of positive and negative results and approaches: results from this project will be important for advancing our knowledge in diabetes pathology, new disease targets and any new treatments. The results of the models, techniques and data will be published in peer-reviewed journals to reach a wide audience (e.g. ophthalmology, diabetes care, mitochondrial biology). Any negative data will be addressed and described in order to allow others to learn and optimise methods. Social media and dedicated magazines for the general public will also be used to promote the research and its results.

Our group will maximize the results of this research locally, by banking a large number of diabetic tissues for future studies and also by sharing the surplus animal tissues with other colleagues. We will also maximize outputs nationally and internationally, by fostering collaborations, disseminating new knowledge, and publishing results and methods to inform the scientific community.

Collaborations: We have established a number of collaborations to investigate pharmacodynamics and the molecular targets of our mitochondrial therapies. This will enhance the translation of our therapies into diabetes care.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse models of diabetes have been extensively investigated and routinely used for vision research. Their ocular anatomy and functioning is very comparable to the human eye, and therefore is an ideal surrogate to model the human disease. In addition, mice also recapitulate the underlying pathology of human diabetes, including hyperglycemia and systemic inflammation that contribute to the development of diabetic retinopathy from juvenile ages. Therefore, mice that develop spontaneous diabetes in young stages (4 weeks of age) have been chosen for this project.
Typically, what will be done to an animal used in your project?

Typically, by 1-2 months of diabetes, hyperglycaemia and inflammation will be assessed in mice, using small volumes of blood. Animals will be then treated with oral therapies (in the drinking water) for long- term (until 8-9 months of diabetes). During the treatment, animals

will have their blood withdrawn on occasion (e.g. monthly), to evaluate the effect of the therapy in relieving inflammation that contributes to diabetic retinopathy. Mice may undergo procedures under a final anaesthetic from which they will not recover: (i) non-invasive imaging of their eyes performed, using optical coherence tomography, and/or injected with a label to better allow post-mortem evaluation of blood vessel in the eye. At the end of the treatment, mice will be humanely killed and the eyes collected for further laboratory investigations, so we can understand the level of eye protection achieved by our therapy. The experiments will typically last for 9-10 month.

What are the expected impacts and/or adverse effects for the animals during your project?

The mouse model used in this research have decreased pancreatic function and significant hyperglycaemia by 4 weeks of age. As with humans, the progression of diabetes may induce adverse effects in some mice, including a reduction in weight gain, polyuria, increased risk of moist dermatitis (urine scalding) and/or rare development of cataracts. Therefore, diabetic mice will be closely monitored and animals will be humanely killed if such adverse side-effects cannot be relieved in the short term. All the therapeutic agents that will be used in this application have undergone extensive testing via other methods, including cultured cells prior to use in living animals to minimise any risk of adverse effects, as well as in preliminary studies using a small number of animals. Nonetheless, mice will be closely monitored for any weight loss or abnormal behaviour for (unlikely) intolerance to the therapeutic agent and humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The protocols have been classified as:

- Mild (33%)

- Moderate (67%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal use is central to this project because of the complex nature of the pathology that occurs in the eye and that is influenced at the systemic level (e.g. hyperglycaemia and a chronic low-grade systemic inflammation). Eye damage in diabetes arise over a prolonged period and cannot be faithfully reproduced using tissue culture or organ explants. Therefore a fully functioning living system is needed so that we can model whether new

oral mitochondrial therapies can alleviate vision loss and the underlying diabetes pathology affecting this condition.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we do seek to use in vitro cell culture models within our laboratory (e.g. retinal and/or vascular cells grown under high glucose). These cellular platforms will be instrumental for identifying drugs capable of replacing damaged mitochondria in the retina, understand their mechanism of action, identify their possible adverse effects, and infer doses for the in vivo studies.

Why were they not suitable?

We want to understand whether drugs that replace damaged mitochondria can help prevent damage to the eye that occurs in diabetes (using treatments given in the drinking water). Whilst non-animal alternatives will be essential to identify suitable drugs and understand their precise mechanism of action, diabetic mice will be essential to understand whether our therapies work at a systemic level.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers estimated in this project are based upon 9 years of experience of experimental design and from previous experience of using the same diabetic model in previous PPLs. Most of the experiments have quantitative end points, and my previous experiments and/or published data have demonstrated that we require around 8-9 animals per treatment group in order to develop statistically sound results. Where these data is not available, we will perform pilot studies based on our experience to provide preliminary data for these calculations.

Although we will reduce the variability as much as possible, some diabetic mice have inherent differences in the development of retinal complications and, like humans, may present a less pronounced phenotype.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?
Our primary goal is to monitor the effects of such therapies to improve diabetic retinopathy and its underlying pathology (e.g. systemic inflammation). To avoid experimental biases that could jeopardize the validity of the results, animals will be assigned to different experimental groups randomly. We will only use drugs in vivo where in vitro approaches have indicated that they can successfully replace damaged mitochondria (using an innovative cellular platform).

All experiments will be hypothesis driven with clear end points to help aid the design. Study designs are checked against ARRIVE2.0 guidelines. The EDA tool will be used to

minimise any design error or bias and to ensure that we report the study results comprehensively. We often consult statisticians to help derive the correct powering of the study or to review our experimental designs before the study starts.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Initial studies will be designed based on previous experiments. Given that I have over 9 years' experience of using this diabetic model, I am confident in the experimental design for studying retinopathy and the underlying pathologies contributing to its progression (systemic inflammation). All of our therapies capable to replace damaged mitochondria have been administered by oral routes and thus, the experimental design protocols are already in place.

In addition, reduction in animal numbers will be achieved through:

The use of males as the only experimental mice, since the penetrance of diabetes is incomplete in females. Including diabetic females would thus introduce a high degree of experimental variability in our studies.

We will obtain a large number of readouts in each mouse, using non-invasive techniques to assess retinal degeneration and systemic inflammation. By the end of treatments, we will harvest the eyes, to understand if our therapy can protect the retina. This approach will allow us to obtain as much information as possible from each animal to drastically reduce their numbers.

We will use of both eyes to evaluate changes. This will enable eye tissues to be pooled for analysis where needed. We will also use molecular techniques from where we can evaluate retinal health using minimal quantities of tissue.

Since our therapy will be delivered systemically, in addition to the eyes, we will bank a large number of organs to evaluate multisystem therapeutic potential of the drug for future studies (pancreas, heart, kidneys, etc). This will optimise the data and information from all animals in all experiments, by allowing us to understand the potential of our therapy in treating different diabetic conditions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experiments detailed here will be carried out in a mouse model of type-1 diabetes. This model has been rigorously characterised and is suitable for use in diabetic retinopathy research, since it recapitulates both early and late disease signs with equivalent mitochondrial pathology that lead to retinopathy in humans. Whilst chemically

induced models of diabetes (e.g. streptozotocin) are arguably the most common mouse model of diabetes used worldwide, the streptozotocin model displays a more aggressive retinal degeneration that is not representative of early diabetic retinopathy in humans (thus, attributable to the neurotoxic effects of streptozotocin and making it less appropriate for this study).

Another advantage of the chosen mouse model is that unlike many other rodent models of diabetes they exhibit hyperglycaemia and hypoinsulinemia in the absence of insulitis or obesity which might otherwise complicate data interpretation.

Why can't you use animals that are less sentient?

Less sentient animals such as fish are not suitable for modelling human diabetes and their associated eye and underlying systemic inflammation. Unlike mammals, they are able to regenerate their injured retinae and therefore, will not be suitable to answer our scientific questions. In addition, the use of embryonic and terminal only procedures are not possible, given the need to evaluate the potential of our therapies to alleviate retinopathy and the associated systemic inflammation that slowly develops during diabetes. However, where possible, we will perform measurements at the end of the study under a terminal anaesthetic rather than repeated anaesthetic events.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As scientists we are aware of the LASA guidelines and have a strong sense of responsibility for the welfare and care of animals bred for and used within our work. The probability of encountering and adverse outcome will be diminished by planning preliminary studies and by putting in place stringent physiological end point criteria and close monitoring:

We also opted to deliver drugs by the least invasive manner (in the drinking water).

If a new dose for a drug needs to be determined for administration in drinking water, a small preliminary study will be performed to discard any adverse effect (using 2-3 mice).

Welfare of diabetic mice will be optimized by providing more absorbent bedding (due to excessive urination volume).

Animals will be humanely killed in the event of them reaching their humane endpoints with regard to body weight loss, urine scald, and body condition, as judged using a bespoke welfare scoring sheet.

These refinement steps, and those still in progress, will streamline experiments and reduce the use and suffering of animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE2.0 and PREPARE guidelines will be used to help plan, design and report on the experiments in order to ensure our studies are conducted in the most refined way possible, according to LASA guidelines.

How will you stay informed about advances in the 3Rs, and implement these

advances effectively, during the project?

I will use the NC3Rs website to stay informed of latest developments, together with newsletters from our animal facility. I have previously attended the "UK Home office project licence (Module 5) course, and this knowledge will be key to be pro-actively informed and continuously improve my animal research practice by attending local workshops and engaging in seminars and events given by the NC3Rs (https://nc3rs.org.uk/webinars).

25. Leucocyte Trafficking in Health and Disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Immunology, Leukocyte trafficking, autoimmunity, cancer, therapy

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the basic mechanisms of leukocyte migration and how these are altered during disease. Importantly, we aim to develop strategies to correct leukocyte trafficking as novel therapeutic tools for human diseases and test these strategies in relevant models of disease to allow their fast progression to clinical use.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

New therapies are needed to control and manipulate unwanted immune responses in multiple diseases such as autoimmunity, cancer and transplant rejection. Leukocyte migration is a key step of immunity.

Understanding and comparing the mechanisms that regulate leukocyte trafficking in health and disease will help identify new targets for innovative therapeutics - as we have successfully done in the last 5 years of tenure of the project licence.

What outputs do you think you will see at the end of this project?

We are confident that this project will create new knowledge (in the form of communications at meetings, through publications and data sharing), leading to new therapies for diseases in which these are lacking, for example myocarditis. The focus on metabolism will allow the repurposing of existing drugs, developed for other or similar diseases, as we have done successfully in the past (see Kishore et al. Immunity 2017).

Who or what will benefit from these outputs, and how?

The primary potential benefit of this project relates to new knowledge about the mechanistic regulation of leukocyte migration in health and disease. This study will generate numerous research outputs all of which will be disseminated in the form of publicly available open access research papers, research datasets, new methodology and reagents. The data generated will also aid developing experimental refinements to improve animal welfare and refine the experimental design by identifying confounding factors or uncontrolled variables to improve reproducibility. The information will be of interest to basic immunologists.

The secondary key benefit relates to the translational value of the results to clinicians, particularly in the field of immunotherapy, and to the possibility that new molecular targets may be identified, for which new drugs could be developed for a variety of human diseases in which inflammation plays a major part, from cancer to transplant rejection. These treatments will be able to be applied to patients after further pre-clinical studies. We believe that these are likely to improve survival and quality of life of a large number of patients. Treatment costs for these patients may also be reduced.

The studies will be relevant to diseases which have a high (diabetes, pre-eclampsia, cancer) prevalence in the populations, as well as helping the diagnosis of diseases, such as myocarditis, whose frequency has been underestimated as many patients are asymptomatic during the acute phase of disease and present years later with acute or chronic heart failure. Survival of transplanted organs, as well as patients bearing a transplant, has not improved in the last 20 years, due to imperfect knowledge of the mechanisms of immune cell migration to the graft as well as the severe side-effects attached to conventional immunosuppression (many patients die from infections and cancers). We aim to provide new knowledge and, subsequently, new therapies to prevent transplant rejection by selectively preventing migration of immune cells to the graft, while preserving the rest of the immune system (hence reducing severe side effects).

The success of the proposed project strategy is underpinned by the identification, in the previous tenure of the license, of a drug that induce migration of anti-inflammatory, regulatory T cells to inflamed tissue, thus resolving inflammation. As a result of these observations 2 clinical trials are already on-going.

How will you look to maximise the outputs of this work?

The outputs of this project will be maximised by dissemination of results, datasets and methodology in open access, which will be easily available to the research community internationally.

The translational value of this study will be maximised by parallel clinical studies conducted in vitro with blood and tissue samples from patients. This will allow selecting mechanisms and therapeutic targets, which can swiftly translate to clinical settings.

Collectively, our approach will lead to new therapies, attach further prestige to UK Academia and create new jobs in science for outstanding individuals.

All these outputs have substantial economic benefits for the UK.

Species and numbers of animals expected to be used

- Mice: 9800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodent models are typically used in immunological research. A large body of literature exists on leukocyte trafficking in mice, which will avoid the need to reproduce/develop well established findings. In addition, a plethora of reagents relevant to this project are commercially available with well-defined dosing for in vivo studies. Finally, genetically altered strains with lack or modification of molecules relevant to this project are already available, thus reducing the need to generate new genetically altered animals. We will use animals in which sex and life stage are relevant to human disease (e.g. adult male mice in Myocarditis).

Similarly, validation in robust preclinical models of disease is required for the progression of potential therapeutic strategies into clinical trials. All the disease models in this project have been selected based on their extensive use to validate the effect of drugs that are now used in human disease.

The life stage and sex of the animals has also been chosen based on the relevance to the human diseases under investigation.

Typically, what will be done to an animal used in your project?

Typically, an inflammatory process will be induced in animals in order to study the role of selected molecules involved in leukocyte trafficking and the effect of modulation of these molecules in inflammation.

Inflammatory and disease models will include administration of pro-inflammatory substances or cells, skin or heart grafts, myocarditis and tumours.
In some of these animals the immune system might be modified prior to the induction of inflammation by using recipient animals with altered expression of molecules of interest, or disease-prone and pregnant animals (type I diabetes and pre-eclampsia respectively), or by bone marrow replacement to modify immune cells. In the latter instance, we will generate mice bearing a modified molecule of interest only expressed by hematopoietic stem cells (HSC i.e. leukocytes) from GA animals with tissue-non-selective modification or

by in vitro genetic modification of the HSC (using for example shRNA transfection) when appropriate GA strains are not available or are not leukocyte-selective.

After induction of inflammation, animals will be treated with drugs that modify leukocyte migration or with cells that are made to migrate better by ex-vivo treatment to reduce inflammation or, in tumours, increase inflammation and tumour rejection.

Of note, our experimental endpoint is the measurement of leukocyte migration which occurs at early stages of the inflammatory process, hence in most of the protocols animals will be humanely killed prior to full disease development, thus avoiding unnecessary suffering.

What are the expected impacts and/or adverse effects for the animals during your project?

The proposed experimental models have been chosen based on their relevance to human diseases and the least possible suffering for the animals. Except Protocol 1 (mild), all Protocols are of moderate severity.

We have proposed this level of severity based on careful refinement of the protocols to substantially reduce animal suffering, while enabling the delivery of highly informative and translationally relevant data.

For example, in the myocarditis model, which involves the use of Freund's adjuvant, optimising the injection site in an area where local pathological responses cause least pain (based on animals' behaviour) and the introduction of analgesia, has substantially reduced the severity of this model.

All transplants in the mouse will be performed in a dedicated operating suite by skilled personal license holders according to strict Home Office, Institutional and laboratory guidelines and kept under constant review by an institutional review panel and institutional veterinarians. Anesthesia, analgesia and post- operative recovery protocols have been developed in close consultation with the institutional veterinary service and represent current best-practice to minimize distress. Recovery from surgery is closely monitored and importantly, animals return to normal patterns of behaviour (movement, feeding, drinking) within twelve hours of surgery.
Monitoring of transplant outcome requires a simple visual inspection of the transplant (skin grafts), or finger-tip evaluation of transplant function by palpation (heart grafts).

In the skin graft model, animal movement will be partly restrained by application of a cast to prevent them from scratching the graft and causing infection. We have refined this model in such a way that the cast is kept for no longer than 7-8 days and the movement restraint is minimal by cutting the cast appropriately based on the behaviour/mobility of each of the experimental animals.

In the cancer model, our studies will focus on early stages of solid tumour development. The cancer model we propose will involve injection of non-metastatic tumour cell lines in subcutaneous tissue left to grow locally and investigate the mechanisms by which immune cells that can destroy early tumours are excluded thus allowing the tumour to progress. From pilot experiments under the current project license, we have established that a tumour of approximately 5 mm diameter is sufficient for analysis of infiltrating leukocytes. Animals bearing tumours of this size in the subcutaneous tissue do not display any sign of suffering or altered behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Except Protocol 1 (mild), all Protocols are classified as moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The plan is to identify key molecules that regulate leukocyte migration. This involves a lot of preliminary in-vitro laboratory work, using tissue culture techniques. Migration of leukocytes, however, is an extremely complex process, which requires the leukocytes to localise to different site of the body by interacting with other cells and crossing complex barriers (vessel walls), in a coordinated manner. Appropriate testing requires a fully formed vascular network, which is not achievable by using computer-based systems, lower organisms and embryo stages, cultured cells, tissue, and organoids. Only living animals can be meaningful models for the purpose.

Which non-animal alternatives did you consider for use in this project?

Prior to undertake experiments in animals, we typically conduct a series of in vitro experiment which help to optimise in vivo experiments and reduce the number of animals required. For example, we use flow chambers which can reproduce some of the events which happen during leukocyte migration in vivo.

In addition, we check the availability of existing data sets and/or existing data within the lab that can be used to conduct novel meta-analyses before collecting new data.

Why were they not suitable?

The in vitro models only give a limited amount of information, and cannot faithfully reproduce physiological settings, due to the complexity of leukocyte trafficking events which occur in vivo.

Importantly, pre-clinical validation of therapeutic regimens needs to be done in order to evaluate their effects and potential off-target effects prior to- and as a condition of- their use in human diseases.

Reduction

Explain how the numbers of animals for this project were determined. Describe

steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The relatively large number is due to the inclusion of genetically altered animals, which are extremely useful to clarify the role of specific cells or molecules in the regulation of lymphocyte trafficking. These mice need to be bred for several generations before they are suitable for experimentation so a large part of them (40%) will not undergo more than one procedure (breeding). In addition, my lab includes 15 researchers, of whom 12 work with experimental models.

A minimum colony size sufficient to generate animals for our investigations will be maintained for each strain. With advice from our NACWO we monitor animal numbers and adjust breeding programmes accordingly. We carefully consider minimal group sizes, number of groups to be studied, use of one or both sexes of animals as appropriate and optimisation of protocols. Small-scale pilot studies are always conducted to see if larger scale studies are warranted.

The number of mice to be used in each Protocol has been estimated by power calculations to include the minimum number of animals to obtain statistical significance. We regularly input our experimental designs- and run our power calculations using- the NC3Rs EDA tool.

Advice on the proposed experimental designs and methods of analysis of the results will be taken from the Statistical Services Unit. Where relevant, factorial experimental designs will be used, rather than the one-thing-at-a-time approach, to maximise the information obtained from the minimum resource. For most of the quantitative experiments, sample sizes will be set using power analysis, generally using a significance level of 5%, a power of 80%, and a least practicable difference between groups of 25%.

We are committed to ensuring reduction of animal numbers through appropriate experimental design and looking for alternative approaches and using statistical analysis packages to ensure that we only use the minimum required to generate statistically meaningfuldata.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A wide literature search has confirmed that our project is original, and that there is no duplication with previous reports. For quantitative experiments, animal numbers needed are statistically determined using power analysis. We have refined suitable models over the years, which allow using a small number of animals to achieve statistical significance. To assure reproducible outcome, which will maximise the information obtained from the minimum resource, experiments will be carefully designed and performed, including randomisation of treatment or control groups, allocation concealment, and blinded assessment of outcome, and explicit inclusion and exclusion criteria. In addition, tissues from the same animal will be used in as many analyses as possible to minimise the number of animals required.

Of note, the use of bone marrow (BM) replacement, using BM from GA animals or wild-type BM genetically modified in vitro, has allowed substantial reduction of our breeding

programme by approximately 50%, hence this procedure is included as a step in a most protocols.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continuously strive to refine our protocols to minimise animal suffering, but also to reduce the number of mice needed to reach statistical significance. For example, we have been able to increase the incidence of disease in our model of myocarditis from 40 to 70%by optimising the injection site. This means that we need only 50% of the animals to power our experiments.

In breeding of genetically altered animals, efficient colony management will ensure that only colonies that are actively being used are mated and produce animals. Those that are no longer required are cryopreserved and closed at the earliest opportunity. We now archive sperm or embryos as the main method of cryopreservation, which reduces the number of animals required to secure a line. We will use good practice in experimental planning, including statistics such as power and resource equations and breeding calculations using current breeding figures to predict the number of matings required for experimental cohorts.

Finally, whenever possible, we will source/purchase animals externally to avoid unnecessary breeding of large number of animals under this licence.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice mainly of the C57BL/6 strains, which are the most suitable for this large-scale basic and translational study. Importantly, there are a plenty of useful research materials (like antibodies) for mice. General features of leukocyte trafficking in murine models are sufficiently equivalent to humans to obtain translational data. In addition, we will be able to use genetically altered animals, an extremely useful tool to elucidate basic and pathologic mechanisms while reducing procedures on animals (e.g. continuous administration of drugs etc.).

We will breed genetically modified animals which have alterations in molecules of interest involved in leukocyte trafficking. Whenever possible we will use animals in which alterations of the molecule of interest is restricted to leukocytes, and this will avoid potential pathologic phenotypes due to whole- body modifications.

We will use a variety of models that closely reproduce either physiological or pathological leukocyte migration.

For the study of physiological leukocyte migration we will use a model of peritoneal recruitment of leukocytes and one model of intra-lymph node injection, which allow studying leukocyte egression from lymph nodes. In addition, we will study leukocyte migration during pregnancy and angiogenesis. These models have been refined to minimise animal suffering while reducing the number of animals needed for statistical significance. Refinement in these models has been achieved by well-designed pilot studies to reduce the number of animals and procedures in the relevant protocols, by minimising the dose of pro-inflammatory substances to a minimum which allows the measurement of a biological effect without animal suffering, and by using leukocyte migration-eliciting substances with negligible pain- inducing effect (for example, we use chemokines instead of LPS).

For the study of pathological leukocyte migration we will employ established models of human disease, including graft rejection, autoimmunity, dysmetabolism and cancer.

In graft rejection models (including human tissue xenografts), surgical and anaesthetic techniques have been refined. Post-operatively, animals will receive intensive care for several hours in special recovery cages. Post-operative pain will be prevented using analgesics. Infection will be prevented by using aseptic procedures in dedicated surgery and recovery rooms. Dehydration will be prevented by administration of fluids and minimal blood collection. To minimise mortality due to surgical procedures, cardiac grafting will be exclusively conducted by a permanent member of the group who is extremely skilled in microsurgery. In skin grafting, impaired mobility of animals due to Paris Cast has been minimized by optimising the cutting of the areas around the animal limbs as well as the use of Jellonet under the casts.

Experimental autoimmune myocarditis closely resembles human myocarditis (histopathology, sex bias, autoantigen etc.). We have refined our technique to minimise animal suffering by identifying an injection site where local pathological responses cause the least pain (based on close monitoring of the animals), and can be readily observed and treated if necessary. Based on a pilot study we are also going to introduce analgesia, as we have observed that this intervention does not interfere with the induction of autoimmunity.

In the dysmetabolism model, we have introduced an acclimation step prior to transferring the animals to metabolic chambers, which has substantially reduced sings of stress in the animals.
Finally, we have refined the model to study leukocyte migration to cancer so that we can conduct our analyses when the tumour (subcutaneous) has reached a mean diameter of 0.5cm, a size that does not normally lead to tumour ulceration, movement reduction, or any sign of cachexia. Further, we have selected non-metastatic tumour cell lines for this study. This refinement has also improved the quality of our data, as tissue necrosis associated with advanced tumours also affects infiltrating leukocytes.

Why can’t you use animals that are less sentient?

Less sentient species are not suitable for the project, due to to the physiological and genetic distance from humans, the lack of suitable reagents for investigation and of relevant genetically altered models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In the skin graft model, animal movement will be in part restrained by application of a cast to prevent them from scratching or chewing the graft and causing infection. We have refined this model in such a way that the cast is kept for no longer than 7-8 days and the movement restraint is minimised by keeping the animals' limb areas totally unrestricted.

The cancer model will involve injection of tumour cells under in subcutaneous tissue to grow locally. From pilot experiments under the current project license, we have established that a tumour of approximately 5 mm diameter is sufficient for analysis of infiltrating leukocytes. Animals bearing tumours of this size in the subcutaneous tissue do not display any sign of suffering or altered behaviour. Whenever possible, we will use tumour cell lines that do not spread by metastasis, hence further reducing potential suffering.

Surgical and anaesthetic techniques have been refined. Post-operatively, animals will receive intensive care for several hours in special recovery cages. Post-operative pain will be prevented using analgesics. Infection will be prevented by aseptic procedures in dedicated surgery and recovery rooms. Dehydration will be prevented by administration of fluids and limited blood collection. In an unlikely event that animals do not recover from surgery well or develop unexpected complications, they will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will refer to the following:

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our NACWO/NIO regularly distributes updates from the HO and NC3Rs to all personal and project licence holders.

In addition, we regularly check the https://www.nc3rs.org.uk for updates on replacement, reduction and refinement.

Any new refinement relevant to this project will be discussed with the NVS and implemented whenever possible.

26. Adaption and pathogenicity of bacterial pathogens at the host interface

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

bacteria, infection, host adaptation, colonisation, therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this work is to understand how bacteria adapt to distinct locations around the body, termed ‘niches’. This knowledge is essential for understanding how pathogens colonise and persist within a host. Furthermore, this information can be exploited to design targetted therapies against infection, such as the development of drugs that inhibit the infection processes or identification of vaccine targets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antimicrobial resistance (AMR) is the process of a microorganism changing over time, ultimately resulting in a lack of response to medical treatments therefore rendering such drugs ineffective. AMR is spreading throughout the community and clinic, and is a global threat to human health. The Medical Research Council has estimated that without action

the annual global deaths related to AMR will increase from ~1.4 million currently to ~10 million by 2050 and there are currently very few new drugs in development. This highlights the urgent need to understand how prevalent pathogens cause infection and develop new treatment strategies to overcome AMR.

The bacterial species Escherichia coli is formed of both harmless and infectious types (infectious types termed pathotypes). E. coli pathotypes are capable of causing a wide range of illnesses including severe diarrhoea, urinary tract infections and infection of the bloodstream. Treatment of E. coli infections is very challenging due to the increasing spread of AMR, particularly in E. coli recovered from patients presenting with bloodstream infections. These “extraintestinal pathogenic E. coli” (ExPEC) isolates are often resistant to multiple drugs. This is worrying as infection of the bloodstream is a precursor to potentially lethal sepsis, which affects ~50 million people worldwide each year with a one in five chance of death. E. coli is also the leading cause of bloodstream infection and responsible for ~300,000 AMR related deaths annually.

One strategy to overcome AMR is to design alternative treatments that block specific bacterial functions. To do this, we must first understand how pathogens function at the locations around the body where they infect. Laboratory studies of infection are inherently limited in scope because bacterial behaviour is controlled in response to the their environment. Locations of infection are unique with respect to both the structure of the organ as well as the molecular composition of the environment. It is currently impossible to recreate this complexity artificially in the laboratory, therefore making animal models of infection hugely advantageous in studying details of infection that would otherwise not be identified in the laboratory.

Molecular analyses of genetic material isolated from the precise location of infection (such as gene expression levels) can reveal important information about how pathogens are causing the infection. The importance of specific genes identified by this approach can then be confirmed through the testing of modified bacteria lacking these genes in their ability to infect animals. Therefore, genes that contribute to the pathogens infectious capacity represent potential targets for drug or vaccine development.

What outputs do you think you will see at the end of this project?

By the end of the project, we will have developed a clearer understanding of how the bacterial pathogens E. coli and C. rodentium adapt to distinct locations within the host and cause infection therein. This will enhance our basic understanding of bacterial disease by identifying the most important genes involved in the infection process. In addition, the research has the potential to identify drug or vaccine targets in the process. This knowledge will be shared with the scientific community through publication in peer reviewed journals, presentation at national and international specialist conferences, and through public engagement activities

Who or what will benefit from these outputs, and how?

What will benefit:

This project will contribute to our basic of knowledge bacterial infection by providing a deeper understanding of the fundamental mechanisms used by specific pathogens to infect the host.

Who will benefit:

In the short term, this research will benefit the infection biology community. The findings will be used to expand our understanding of host-pathogen interaction by identifying the key genes that are regulated in response to distinct host sites. This novel information will be disseminated to the research community through publication and presentation at scientific meetings. Some of our data will be archived in a publicly accessible repository to facilitate colleagues in the field taking advantage of the resource.

In the long term, this work will increase our fundamental knowledge of infection mechanisms used by important human bacterial pathogens and will potentially reveal therapeutic targets that can be exploited in future studies, possibly leading to future treatments for human patients

How will these benefits be realised:

The findings will be disseminated throughout the scientific community via publication in peer reviewed journals and presentation at national and international specialist conferences. Additionally, the findings will be communicated to the public through engagement activities to raise awareness of bacterial infections and AMR. Any relevant data derived from the findings will be shared upon publication of the work, via the most appropriate public repository.

When will these benefits be achieved:

Specific outputs relating to the role of key genes in niche adaptation is possible within the lifetime of this project. The identification and development of viable therapeutic targets will likely take much longer than the lifetime of this project.

How will you look to maximise the outputs of this work?

In the past I have benefitted immensely from academic collaboration. I will therefore offer expertise in the models described here in the form of collaborations to address specific scientific questions related to infection. I will also offer advice and guidance to other colleagues wishing to pursue their own project application adapting the models described within this project.

My methods have been described in recent publications and I will continue to disseminate research related to my existing and newly developed models in the form of peer reviewed papers. Additionally, further dissemination of the research outcomes will be made more widely by presentation of the findings at national and international scientific meetings.

Species and numbers of animals expected to be used

- Mice: 450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice around 8-10 weeks of age will be used in this project as they are fully mature and have an intact immune system capable of responding to bacterial pathogens. Mice will allow the investigation of dynamic and specific interactions that occur between specific pathogens and the host, in real time.
Mouse models offer parallels to human infection, such as infection of specific body sites, that allows us to investigate key steps in the infectious process. This can ultimately lead to the identification of novel therapeutics, which can be tested directly in the same model for an ability to limit host-pathogen interaction. There is a significant body of literature available related to the mouse immune system and response to infection. Furthermore, the protocols described in this project are well established in the literature. Collectively, this makes mice the best model for studying bacterial interactions with the host in the context of pathogen adaptation.

Typically, what will be done to an animal used in your project?

Animals will be housed using standard husbandry prior to any infection experiments. Prior to infection, animals may be subjected to a course of antibiotics via the most appropriate route to eliminate the commensal microbiota and may be maintained on this treatment for the duration of the protocol.
Animals will be infected with the stated bacterial species and at the stated timepoint by either oral gavage (O.G.) thereby directly introducing the organism into the stomach (maximum of two occasions) or by intravenous (I.V.) injection into the bloodstream via the tail vein of the mouse. Monitoring of infection will be performed by sampling bacteria from the faeces of infected animals. Alternatively, infection may be monitored by use of the in vivo imaging system (IVIS) whereby animals will be subjected to general anaesthesia and imaged using the IVIS at most twice on the first day and once daily thereafter. The final experience of the animals will be humane culling by a Schedule 1 method.

The three protocols used in this project and their expected outcomes are all well established in the literature and supported by extensive pilot studies performed in a previous PPL holders lab.

What are the expected impacts and/or adverse effects for the animals during your project?

For single or multiple O.G. inoculations, the impact on animals is largely limited to the stress associated with the procedures used to infect the mice. This will be minimised by employing low stress handling techniques and ensuring the users are competency trained in the O.G. procedure. The animals are not expected to experience any lasting adverse effects such as pain or lasting suffering as a result of the procedures. The infections are self-limiting, but mice may experience some symptoms such as mild weight loss or mild diarrhoea.

For I.V. infections, animals may experience some minor stress and pain due to the injection used to infect the mice. This will be minimised by employing low stress handling techniques, heating of animals to dilate the tail vain and use of a micro sized insulin needles. All animals are expected to experience some mild symptoms such as weight loss, reduced movement, hunching, piloerection and partially open eyes due to the acute infection of bacteria into the bloodstream. It is possible that some animals may experience more moderate symptoms. However, these symptoms are expected to peak within the first 24 hours and resolve thereafter and it is expected that these symptoms will not extend beyond mild-moderate in measure. In longer experiments, the multiplication of the bacteria within the animal could lead to more prolonged symptoms beyond 24 hours but current

data suggests it is not expected that they would increase in measure and it is likely that symptoms will resolve.

For IVIS scanning, the impact on animals is largely limited to the stress associated with the procedures used to anaesthetize the mice and the cumulative nature of multiple exposures. This will be minimised by employing low stress handling during the procedure and ensuring users are fully trained and competent in anaesthetic procedures, using the shortest duration possible.

Careful monitoring in accordance with detailed score sheets will be employed to cover all expected and potential impacts and adverse effects. For all protocols, procedural stress will be minimised throughout by ensuring good technique is used. This will be facilitated through competency training for all procedures delivered by staff within the PPL holders animal unit.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For O.G. and I.V. infections, >95 % of animals will experience mild discomfort likely to be associated with the procedures used and < 5% of animals may experience moderate symptoms as a result of the infection. Careful monitoring in accordance with detailed score sheets will be employed to monitor all expected or potential symptoms and will limit the suffering of any individual animal to, at most, moderate discomfort.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Infection is a dynamic process in which disease outcome is often dependent on several factors including the intrinsic responses of both organism and host to one another, the response of bacteria to specific environmental conditions at different body sites or metabolic/dietary status. Whilst some alternatives (including laboratory grown human cells or tissue models) are able to replace the need for whole animals in the study of specific aspects of infection, such as tissue invasion, there is currently no model which reflects the complexity of challenges, stated above, that bacteria encounter during growth within and colonisation of a host. Specific questions related to infection will be addressed in the laboratory as a first approach wherever possible.

Which non-animal alternatives did you consider for use in this project?

It is possible to make use of non-animal alternatives in this project to address specific scientific questions. For example, we can use genetics to test the impact that specific gene

deletions have on the ability of specific E. coli strains to express virulence factors or use cultured eukaryotic cell lines to test the ability of said mutants to bind to host cells. Using this approach, we have identified several metabolic genes that impact on virulence factor expression in the gut pathogen enterohaemorrhagic E. coli (EHEC) via metabolism of nutrients that can be encountered in vivo. The use of cultured cell lines will always be employed as a pre-requisite to studies involving mice to ensure that only the most likely genes to be involved in infection are tested in vivo. Additionally, cultured macrophages can be used to study immune evasion mechanisms by extraintestinal pathogenic E. coli (ExPEC) for the investigation of specific genes.

New alternative laboratory-based systems for modelling infection processes are also in development. For example, organoid based human epithelial cell culture systems are currently in development that recreate the oxygen gradient naturally found in vivo at the epithelial cell surface and are capable of culturing anaerobic gut microbes. Using this system, it may be possible to test if EHEC interaction and competition with gut bacteria can be studied using this ex vivo model.

The use of these models, in combination with our increasing knowledge of pathogen adaption to the site of infection, will offer further opportunities to recreate in vivo conditions within the laboratory, potentially reducing the need for animals in this type of research in the future.

Why were they not suitable?

While cell culture models can offer insight into specific aspects of infection, they cannot reproduce the dynamic and ongoing process of infection at distinct body sites, interaction with the microbiota or immune response. Thus, in order to determine the importance of individual pathogen genes for infection, modelling using whole animals must be employed for the most promising targets. Organoids offer a promising alternative that may potentially be able to recapitulate such complex interactions in the future, however the use of these systems is still very much in its infancy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

The number of animals estimated is based on the programme of work described and existing experience of the minimal number of animals needed in each experimental group to provide statistically robust outcomes. Group sizes are constantly being re-evaluated and updated when necessary. In situations in which new mutant bacterial strains, or modification to methods are used, work will initially be limited to small numbers of animals, with several sequential experiments undertaken to achieve publishable data. This will allow measurement of the inherent variation in outputs between experiments, which will help determine the number of animals required for subsequent experiments. Additionally, the continued development of animal alternatives, such as tissue organoids (mentioned in ‘Replacement’ section above), may lead to the reduction in animal numbers required in

future experiments by being able to address specific scientific questions without the need for whole animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The published online tools G*Power (Faul et al., 2007 Behavior Research Methods 39(2):175-191) and SISA (http:/www.quantitativeskills.com/sisa/) were used to calculate the approximate experimental group sizes based on existing experimental and published data using these protocols and to determine the minimal number of animals needed for use in each experimental group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, the number of animals required will be minimised through testing of multiple mutant strains of bacteria (for example, strains deleted for particular genes important for infection) in one experiment, therefore requiring only one control strain on each occasion. Additionally, approaches such as competitive index analysis will be used. This approach tests a 1:1 ratio of mutant and wild type bacterial strains in a co-infection of the same animal (the same overall number of bacteria in the inoculum as per a single strain infection so no cumulative suffering expected). This reduces the number of animals by avoiding the need for control animals as it allows direct comparison of infection and the control in the same animal (by calculating the relative ratio of mutant to wild type in the output).

Tissue and blood from infected animals will also be preserved where possible to generate a biobank of relevant material that can be tested to maximise the output from an experiment without the need for further animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models described support the study of host-microbe interactions and replicate several features of the infections associated with the named bacteria in humans, including intestinal infections by EHEC and bloodstream/systemic infections caused by ExPEC. Refinement in this project includes the use of non-lethal models to study bacterial factors involved in host colonisation and persistence.
This allows us to study features of the infection and answer relevant biological questions related to colonisation and transmission whilst reducing animal suffering. Additionally, genomic technologies is helping us identify which key genes are most important during infection. This information will be used to refine animal experiments by potentially offering opportunities to test multiple mutants of bacteria simultaneously within one animal, without

increasing the severity of infection due to the bacterial dose used for infection being consistent. Furthermore, animal stress has been reduced by the adoption of low stress handling techniques.

Why can’t you use animals that are less sentient?

Bacterial infection is a dynamic process that requires the presence of both the pathogen and a mature immune system capable of responding to the pathogen as it grows and adapts to the host environment at the particular site of infection. Adult mice are used in these studies to facilitate an effective response to bacterial infections and limit the risk of an immature animal becoming rapidly overwhelmed with disease. Furthermore, whilst insect/round worm models and more recently zebrafish have been used to study bacterial infection, they offer limited opportunities to understand the adaptative mechanisms of pathogens to body sites and organ structures closely related to humans, as well as the corresponding responses made by host.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures and score sheets will undergo continual review by the PPL holder and the local NACWO, NTCO and Veterinary team to ensure any improvements in methodologies that reduce the number animals and degree of severity suffered by animals are employed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Advice on best practice will be followed through alignment with the PREPARE, ARRIVE and LASA guidelines. Additional resources will be obtained through the NC3Rs website and use of their online Experimental Design Assistant (EDA) tool for the design of all new experimental procedures, as well as input on this project from our local AWERB. E-mail updates about 3Rs advances are also regularly provided to researchers at this my home establishment via the mailing lists and intranet sites.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The local AWERB, NIO, NACWO, NTCO and Veterinary team regularly inform, and disseminate improvements and recent studies involving reduction, replacement and refinement

Alongside external resources including (but not limited to); collaborators, peers, conferences and lab animal and animal welfare bodies.

During the 1, 3 and 5 year review of the project licence I will update on implementation or consideration of the 3Rs that has occurred during the previous period, alongside a review of the linked training plan, score sheets etc. in collaboration with the NACWO, NTCO and Veterinary team with a particular focus on refinements.

27. Establishing a link between bacteria metabolites and colonic cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Escherichia coli, Cancer, Bacteria, Diet, Colibactin

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to determine if toxin-producing strains of *E. coli* play a role in the development of colonic cancer and whether changes to our diet are increasing the frequency and levels of toxin production by these bacteria. This may help explain why rates of disease are increasing globally.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Colorectal cancer (CRC) is the third most frequent malignant disease worldwide, with 1.85 million new cases and 0.88 million deaths occurring every year. According to current predictions, the global burden of CRC is expected to increase by 20-25%, reaching 2.2

million new cases and 1.1 million deaths per year by 2030. The effect of bacterial metabolites on CRC is under intense investigation, with research showing links between diet, gut microbial community and physiological states of the host. The role of nutrition in the development of CRC has been broadly studied, with research showing positive associations between CRC and the consumption of red and processed meat, inverse correlations between tumour development and fish intake, and the protective effect conferred by the consumption of dietary fibre.

What outputs do you think you will see at the end of this project?

Outputs from this work will include greater understanding of the role of a toxin producing E. coli in the development of colonic cancer and whether diet modification could reduce toxin production and limit disease occurrence. Our results will be shared with the scientific community by presentation of the data at conferences and through publication in scientific journals. The information will also be discussed with the general public through events such as Pint of Science, Cafe Scientifique and Science festivals. If the data suggests a strong link between these toxin producing strains and colonic disease, this will be discussed with companies that currently include these bacteria in foods that are marketed as offering probiotic benefits.

Who or what will benefit from these outputs, and how?

Short-term, the impact of this research will depend on establishing a link between colonisation of these toxin producing strains and colonic cancer. If this is proven, the longer-term impacts are significant as this may indicate that patients carrying these strains could be more vulnerable to disease. In this case, understanding how and when the toxin is produced and whether diet can influence toxin production will be essential. In the very long term, this may highlight how diets could be changed to reduce colonic cancer development.

How will you look to maximise the outputs of this work?

There is an opportunity to discuss our results with food manufacturers, especially those promoting the use of foods containing live bacteria for health benefits. Through collaborating with such companies, it may be possible to remove or replace strains expressing this toxin. It may also be possible to work with the healthcare sector to determine whether there is a link between carriage of these organisms and cancer development, and this may allow us to consider how diets in vulnerable individuals may be modified to reduce the risk of disease.

Species and numbers of animals expected to be used

- Mice: 240

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Adult mice will be used in these studies as they allow us to study the capacity of these toxin producing *E. coli* strains to initiate tumour growth directly in the gut, which is a

complex environmental niche that is difficult to replicate in a test tube. For example, growth of these bacteria in the gut will be affected by factors including availability of oxygen, food, competition from resident bacteria and the need to avoid destruction by the host immune response.

Mice are the model of choice as there is an increasing body of knowledge about how different bacteria within the gut control the growth of bacteria including *E. coli.* There is significant knowledge that allows us to study, in parallel, the animals' natural response to *E. coli* infection.

Typically, what will be done to an animal used in your project?

Typically, animals will be given an injection to increase their susceptibility to tumour development, followed by oral infection with bacteria. Animals will further be treated with a drug that modifies the mucosal layer that covers the gut, allowing the bacteria to interact with the cells of the gut wall. Animals will be killed several days after this treatment and any tumour development will be analysed for gross (number and size of the tumours) and microscopic (for cellular dysplasia) changes.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are expected to develop tumours in the colon and may consequently experience pain, weight loss and changes to bowel movement as a consequence. In published literature, signs associated with tumours development are observed over a 10-day period.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Up to 90% of animals will be expected to develop tumours as a consequence of these procedures. However, several signs of tumour development are known and will be used to minimise suffering of animals to a moderate or mild level.

Control animals, which will be treated with the drug to increase susceptibility to tumour development but not infected with *E. coli,* may also develop tumours, although these would be reduced in number, with the percentage of animals expected to develop tumours also reduced to around 50%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We believe that certain conditions within the gut can cause the *E. coli* to produce the

cancer-causing toxin, colibactin. While it is possible to investigate how the bacteria and its toxin cause induce changes in cells grown in the laboratory, it is not possible to understand the influence of toxin production within the unique environment, found within the gut. As this niche is influenced by numerous other bacteria that grow, survive and modify the conditions found within the colon, it is not possible to replicate these conditions in vitro. Using animals, we hope to understand how diet, modified by the resident microbiome, can influence toxin production and ultimately cancer development.

Which non-animal alternatives did you consider for use in this project?

Multiple studies have already been completed in the laboratory using cultured cells. These experiments confirmed that *E. coli* expressing these toxins caused cell enlargement and DNA alterations that are typical of cancerous cells. These changes were not observed when cells were infected with bacteria that did not carry the genes for the toxin, nor when the growth medium used to feed the cells contained specific amino acids that have previously been shown to reduce expression of the toxin.

Why were they not suitable?

Studies carried out on cultured cells provide clear evidence of the ability of these colibactin toxin- producing *E. coli* to cause cellular changes found in cancer. However, they can only provide limited information as they cannot reproduce the the complex and dynamic environment of the gut, which is altered by the bacteria that live there. Many of these bacteria cannot be grown in the laboratory, as they are highly sensitive to oxygen and are often interdependent on each other, making it impossible for them to be grown and studied in isolation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Published studies show significant differences in the number of tumours that develop in animals infected with toxin-producing bacteria compared to tumour susceptible but uninfected controls. Estimates of the numbers of animals to be used are based on these data. This will allow us to determine whether altering the diet of animals can reduce the amount of toxin produced, reducing tumour development.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal numbers are based on approximate estimates of usage over a 5-year period. The NC3R Experimental Design Assistant has been used to assist in experimental design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies, using small numbers of animals will be used to establish the extent of biological variation in tumour formation between susceptible uninfected and infected

individual animals. Whenever possible, numbers of control animals will be minimised through the testing of several experimental variables (bacterial strains etc) in one experiment. Tissue and blood from infected animals will be preserved where possible to generate a biobank of material, offering an opportunity for further testing without the need to use further animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse model described has been developed to understand the role of bacterial infection in colonic tumour development in man. Consequently, tumour development is an inevitable outcome of this study. However, suffering and distress will be limited by careful monitoring of animals, which will ensure that animals will be killed with minimal suffering, while still allowing scientific aims to be achieved.

Data will be continually reviewed to reduce experimental times to further minimise suffering. Animal stress has also been reduced by the adoption of non-aversive handling techniques.

Why can’t you use animals that are less sentient?

Tumour development in this context is believed to be dependent on the capacity of the bacteria to make the toxin and on how the toxin-producing bacteria are controlled by the behaviour of other members of the bacterial gut community. Younger animals fail to control the growth of the *E. coli* as effectively as mature mice and can be rapidly overwhelmed. Terminally anaesthetised animals also offer limited opportunity to study the role of bacteria in cancer development as the development of tumours will occur, over a number of weeks, rather than hours.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will undergo continual review to ensure any improvements in methodologies that reduce the number and degree of severity suffered by animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance has been sought through the NC3Rs website and use of their online Experimental Design Assistant, and through guidance highlighted by the local AWERB team. E-mail updates about 3Rs advances are also regularly provided.

How will you stay informed about advances in the 3Rs, and implement these

advances effectively, during the project?

Advances in 3Rs are continually provided including email updates, 3Rs seminars and culture of care subgroup outputs. These provide updates on new approaches and provide guidance regarding published methods. There are also opportunities to discuss new methods with the Named Veterinary Surgeon (NVS) and the Named Training and Competency Officer (NTCO) who offer help and support around training for the adoption of new methods. The NC3R website provides an additional excellent resource.

28. Developing novel neuromodulation strategies for the treatment of brain disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain disorders, brain stimulation, brain-computer interface, neurology, psychiatry

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is understand how specific parts of the brain control movement and cognition and to use this knowledge to develop new treatments for brain disorders using electrical stimulation. We will use ways of monitoring and manipulating the brain, including optical stimulation, to identify new targets and patterns for electrical stimulation, and test the capacity of these novel approaches to change brain activity and behaviour in ways that could provide new or better therapies for brain diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brain disorders are common and cause considerable suffering and cost the UK economy more than £100 billion per year. Drug-based treatments for brain disorders have stalled and many pharmaceutical companies have reduced their investment in these diseases, but treatments are urgently needed. Stimulating the parts of the brain with electrical current provides an alternative way of treating brain disorders, and has proven an effective treatment for disrupted movement in Parkinson's Disease. Finding ways of using brain stimulation more effectively and for other brain disorders could alleviate the suffering of people with these diseases and provide significant economic benefits.

What outputs do you think you will see at the end of this project?

We aim to produce the following outputs:

Publications describing novel findings as to how specific brain areas control and contribute to movement and cognition

Publications describing novel methods of stimulating the brain and the effects of these methods on brain activity and behavior

Publications and/or patents describing specific code and/or electrical circuits to deliver novel methods of brain stimulation

Who or what will benefit from these outputs, and how?

Short/medium term

The sizeable community of researchers working on function/dysfunction in the basal ganglia and their partner brain circuits, including those researching the causes and consequences of neurological disorders.

A wider community of researchers in neuroscience, neurology, psychology and bioengineering. Bioengineers who can use the circuits and computer code to design new medical devices.

Long term

Patients with brain disorders will benefit from findings that ultimately influence clinical devices.

How will you look to maximise the outputs of this work?

Publish our data on "preprint" servers and in peer-reviewed international journals.

Share our data (published and unpublished) through presentation at conferences as well as at specialist user groups (e.g. clinicians, industry). We will share raw data on sharing repositories.

Communicate and share are findings on other platforms such as the MRC Brain Network Dynamics Unit (MRC BNDU) is committed to supporting a culture of open science, including the timely sharing of well annotated primary data sets (and metadata) that are generated by our research using animals.

Through public engagement activities, such as school and patient group open days.

Species and numbers of animals expected to be used

- Rats: 5250
- Mice: 17500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In our project, we will mostly use adult small rodents (mice and rats) for the following reasons:

They are the most widely used animals that have sophisticated motor and cognitive behaviours. The anatomy and physiology of the mouse and rat brain is well described. The experimental methods that will be used have been specifically designed for and successfully used in this species.

In rare cases we will use juvenile animals to look at the connectivity between brain areas measured in brain slices.

Typically, what will be done to an animal used in your project?

Some animals will be anesthetised and have surgery to place or implant devices in their brains, so that we can monitor and manipulate animals' nerve cells and behaviour. These experiments typically take place over weeks or months.

We will motivate the behaviour of some animals by carefully controlling their access to food or fluids. We will then deliver food or fluids in response to specific behaviours. These experiments typically take place over weeks or months.

Some animals will have devices for recording and stimulation of brain activity permanently attached to their heads.

Some animals will have their heads temporarily fixed in place while they are awake, so that we can monitor and manipulate animals' nerve cells and behaviour. These experiments typically take place over days or weeks.

Some animals have substances injected into their brains to mark nerve cells and the connections between those nerve cells that can under a microscope after the animals brain has been removed (post mortem). These experiments typically take place over weeks.

Animals will be killed by a humane method and, typically, tissues taken for analysis after death.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that have had surgery will experience some pain and discomfort, but are expected to recover quickly (over hours) and will be given painkillers and post-operative care, just like people recovering in hospital.

Animals that have the availability of food or water controlled will be hungry or thirsty for short periods (over hours), but we do not expect this to impact greatly on their wellbeing.

Head-fixed animals might initially experience frustration or stress for short periods (over minutes), but we do not expect this to impact greatly on their wellbeing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats:

90% Moderate

10% Mild/Subthreshold

Mice

30% Moderate

70% Mild/Subthreshold

(Mice have a large percentage of mild due to their greater numbers on breeding protocols)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studies in animals provide the best way of studying cognitive and motor aspects of behaviour and the brain processes that control them. Many brain diseases or the symptoms of those diseases can be accurately modeled in rodents. Recording and stimulating brain activity in animals greatly facilitates the development of novel treatments for brain disorders.

Which non-animal alternatives did you consider for use in this project?

Computational modelling of the brain areas of interest

Why were they not suitable?

Our knowledge of the mammalian brain and the complexity of computer simulations is not advanced enough to replace the experiments in that can address our scientific aims,

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals based on our experience of the number of experiments we plan to perform to address our scientific objectives and that we have performed in similar projects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where ever possible we apply experimental designs that compare parameters within animals. For example, we can use the same animal to test the effect of different patterns of brain stimulation on the activity of nerve cells and behaviour. This allows as to evaluate the importance of the brains temporal dynamics very precisely in the same animal.

For experiments involving behaviour and/or the effect of brain stimulation on neuronal activity. we identify statistical methods and experimental variables that will allow us to control for as many variables as possible using limit numbers/groups of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use both male and female animals in the majority of experiments and use efficient breeding strategies.

We will make use of pilot experiments to provide proof-of-principle that new experiments are viable before committing to enough animals for statistical analysis.

We have designed experiments that maximise the amount of behaviour and/or recordings of brain activity that we can obtain from individual animal. This produces data of high quality and quantity that reduces the overall number of animals that need to be recorded. We make extensive use of in silco simulations to develop methods of brain stimulation that deliver stimulation in response to detecting specific aspects of brain activity.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Disease models. We will use methods that model aspects of brain disorders, while still allowing animals to behave normally with respect to feeding, grooming and other normal behaviours. For example, by destroying a group of neurons on one side of the brain only, animals have unaffected function on one side of the body and/or have mild cognitive impairment that does not impair their ability to perform these normal activities.

Implanting devices to record and stimulate brain activity. Many animals will undergo cranial surgery to implant devices that allow the recording of brain activity over weeks or months. While surgery will cause initial pain and discomfort over hours or days, animals receive medication to reduce this and, once recovered, are able to behave normally without further distress or discomfort.

Recording and stimulating brain activity. We use methods of placing electrodes into the brain that are aimed at reducing disruption to normal behaviors by being as small and light as possible, while still enabling many brain areas to be monitored simultaneously.

Why can’t you use animals that are less sentient?

Using animals that are less sentient than rodents would not provide and adequate model to study neural activity and behaviour that is relevant to function of motor control and cognition in humans and the treatment of human brain diseases. The brain areas that we study are similar enough to humans to make a valid comparison.

The majority of experiments will require the fixation of a device to the animals skull. It is necessary to use adult animals for all of these experiments, as larger animals can support such devices without disrupting normal behaviour

While some questions can be addressed using terminal anaesthesia, in most cases the brain activity associated with either function or dysfunction in the brain areas of interest cannot be reproduced accurately unless the animal is awake.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Operative and post-operative pain relief. All animals that undergo surgical procedures receive pain relieving medication that lasts for several that lasts for several hours after the procedure and can receive further medication until recovery is complete

Post-operative care. We have introduced high energy palatable foods that prevent post-operative wieght loss and will look for other methods to speed post-operative recovery.

Video monitoring. Many of our recording set ups have video that can be used for enhanced monitoring of animals.

Cranial Implants. We will continue to try and achieve smaller and lighter implants for head-fixation and recording/stimulation of neuronal activity. We will monitor alternative materials and/or designs that could achieve this.

Wireless recording. For recordings in freely-moving animals, we will explore the possibility of implanting self contained recording/stimulating devices that can operate wirelessly. This would provide less restriction on the animals behavior.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We receive all updates for NC3Rs – National Centre for the Replacement, Refinement and Reduction of Animals in Research. https://nc3rs.org.uk These include webinars, links to specific relevant publications e.g. Minimising mouse aggression, Sci reports (Oct 2019) as well as principle and practice videos. Experiments will be set-up in line with the PREPARE guidelines. We will follow LASA guidance on aseptic surgery and administration of substances. All of our publications will comply with the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As part of the host institutions structure for regulating animal work all licence holders must attend termly animal welfare meetings. These groupings are organised to map onto local AWERBs, ensuring that participants share common research practices. A specific agenda item for these meetings explores advances in the 3Rs, ideas are exchanged and best practice discussed. Three crucial communities also present at these meetings are the vets, NACWOS and the Regional Programme Manager NC3Rs – National Centre for the Replacement, Refinement and Reduction of Animals in Research, all of whom provide updates and advice for implementation of any advance.

29. Investigation of Rift Valley fever virus (RVFV) invasion of the brain using an intranasal infection model in the ferret (Mustela furo)

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Zoonosis, Encephalitis, Virus, Intranasal

Animal types	Life stages
Ferrets	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to develop an intranasal infection model in ferrets to investigate Rift Valley fever virus infection and cell tropism in the brain in humans.

A further aim will be to share biological material produced by this study with collaborating partners in Europe.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Rift Valley fever virus is a significant zoonotic disease in Africa and parts of the Middle East. It causes devastating outbreaks in human and livestock populations with a range of severe disease manifestations including febrile illness, haemorrhagic fever and

encephalitis. Brain infection (encephalitis) as a result of infection with Rift Valley fever virus is rare but can have damaging consequences of infection for humans who experience it. Globally, Rift Valley fever virus is poorly studied as rodent models do not consistently replicate infection of neuronal tissue. Consequently, results are not robust enough to be generalised to wider animal or human infections. The ferret offers an alternative model that reflects many features of human physiology and pathology, which make it suitable for understanding Rift Valley fever virus infection in humans.

The study is funded by the European Union to encourage sharing of reagents and research samples from investigations. This study will generate biological material that can be shared with researchers in Europe to increase the information generated by this project and avoid repetition of this experimental study by other investigators. This paradigm reduces the requirement for future animal studies in this area and minimises the amount of biological material wasted following sampling as multiple assays will be undertaken.

What outputs do you think you will see at the end of this project?

Development of a novel well characterized model of RVFV encephalitis that can be extended to non- ferret mammals.

Improved detection of RVFV in brain tissue samples and the ability to visualise virus infection in the context of brain structures and any associated neuropathology.

Biological products, such as whole genome assessed cultured virus and formalin fixed tissue samples, for the scientific community

Collaborative publications on RVFV infection using ferrets as a model.

Who or what will benefit from these outputs, and how?

Researchers investigating viral encephalitis in models of human disease. This benefit will be apparent upon publication of data, within three years following the start of the project.

European researchers working in the field of virus infection and Rift Valley fever detection. This will be a short-term benefit as collaborative partners receive biological samples from the initial investigation.

Medical pathologists who want to differentiate RVFV infection in humans. This benefit will be apparent upon publication of data, within three years following the start of the project.

How will you look to maximise the outputs of this work?

The findings of this study will be published in a project report to the European Community (via the VetBioNet Project) and in a peer-reviewed journal. Due to the multidisciplinary nature of the project it is likely that more than one publication will arise as the investigation will look at a multifaceted approach to understanding RVFV infection in ferrets. This paradigm maximises research outputs and therefore wider scientific community understanding, while minimising the animals required for such detailed outputs.
Shared knowledge with European collaborators in understanding RVFV infection in a ferret model. Following publication of findings from this investigation we would also disseminate this knowledge at national and international conferences in the hope that it maximises its potential target audience and can assist in understanding RVFV impact globally.

Samples collected will be made available through the VetBionet transnational access program to enhance scientific collaboration.

Species and numbers of animals expected to be used

- Ferrets: 18

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The ferret has been successfully used as a model for intranasal infection and aerosol transmission for viruses such as Influenza A and SARS Coronavirus 2. It has also been shown to be susceptible to RVFV infection (Barbeau et al., 2020, mSphere 5, e00798). Consequently, ferrets are likely to make an ideal model for understanding intranasal exposure to RVFV, and multiple samples can be generated from a single animal, which minimises the need for high animal numbers and increases potential research outputs. In this study we plan to use this approach to understand the mechanism of brain infection following intranasal exposure to virus preparations to elucidate this transmission route and its subsequent impact. This data will provide a deeper understanding of RVFV in humans as the ferret model has similar physiology and pathology.

Typically, what will be done to an animal used in your project?

Animals will undergo short-term anaesthesia prior to any procedure. Individual ferrets will have a biochip inserted subcutaneously to facilitate individual identification and allow remote measurement of body temperature. A non-surgical removal of blood (pre bleed; <2mL) from a superficial blood vessel will take place before the infection study begins. One nasal wash, oral and rectal swab prior to and one after virus challenge. Virus challenge, which consists of an intranasal inoculation with a defined quantity of RVFV, which is known to infect ferrets (or tissue culture medium for control animals).

Animals will be randomly assorted into groups of three (experimental n=15 animals, control n=3 animals) and sampled at defined intervals or until animals develop signs of virus infection of the brain, at which point they will be killed by a Schedule 1 method to prevent unnecessary suffering.

What are the expected impacts and/or adverse effects for the animals during your project?

As infection of the brain occurs, infected animals may experience a raised body temperature, early neurological signs and agitation. A quantitative clinical assessment in association with a decision algorithm will be used define a humane endpoint for the experiment. Given the intranasal route of virus instillation, the animals could develop upper or lower respiratory tract infection presented as sneezing or coughing. Due to daily, routine observations the duration of these effects would be detected within 12 hours.

If disease progresses rapidly, the animals could present with reduced activity and limb weakness as the virus infects further regions of the brain. This could be associated with

increasing pain, weight loss (due to inappetence) and aggression. It is likely that if allowed to progress some animals would die from the infection within a number of days.

With daily observations and welfare assessments we will ensure that these effects do not occur. At first sign of any of these signs we would immediately treat this as a humane endpoint to the investigation and terminate using schedule one technique. A detailed clinical scoresheet will determine the earliest possible endpoint.

There may be adverse responses to anaesthesia, as has been observed occasionally in other ferret studies, and all animals would be monitored until they are assessed as being fully recovered and active. Animals may experience mild pain from the pre-bleed puncture wound.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Animals infected with RVFV would develop encephalitis and experience severe pain. We will identify early signs of infection (raised temperature / behavioural changes) and terminate the experiment when animals reach moderate pain levels as indicated on the clinical scoresheet. It would be expected that 80% of animals in the virus challenge group would reach this severity.

Control animals would not be expected to develop any adverse effects following inoculation with tissue culture medium. However, these animals could develop short-term sneezing and coughing following intranasal exposure of buffer solutions.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The biological process of neuroinvasion by a virus, which involves crossing the olfactory portion of the nasal cavity and into the brain via the bony ethmoidal tissues, cannot be recreated in cell or tissue culture. Visualising the infection process in the context of a complex organ structure such as the brain requires a living animal. These outputs are essential for understanding exposure to RVFV-containing fluid and subsequent impact of RVFV in mammals.

Which non-animal alternatives did you consider for use in this project?

A neurological cell model of infection, potentially developed in a three-dimensional matrix might offer the ability to investigate the cellular response to RVFV infection.

Why were they not suitable?

Cell culture or organ models cannot show structures that are found in the intact brain or respiratory tissues that are present within the nasal cavity, and therefore no inference on pathology and viral tropism following infection can be made.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have planned to use 15 animals within the virus challenge group and 3 age-controlled animals as un-infected controls. The 15 animals infected with virus will be randomly allotted into 5 groups and sampled at 5 pre-defined timepoints to day 21 post inoculation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The numbers estimated for use are the minimum number required to deliver sufficient infected animals that will be sampled at three day intervals with five sampling timepoints. Groups of three will generate sufficient infected material to investigate disease outcomes and offer the ability to share biological material with European collaborators (the ultimate goal of the VetBioNet project). An assessment of the study design by the organisations statistician with the study of Barbeau et al., 2020, concluded that the use of multiple timepoints should provide more power to compare viral load between tissues as well as between stages of disease development.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

This project will maximise the volumes of blood and tissue samples derived from each animal to enable sharing of biological material derived from this experiment. Samples will include serum, fixed organ tissue and extraction of RNA from fresh tissue. We will avoid duplication of this type of study and thus reduce the number of animals needed to achieve scientific goals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The intranasal inoculation method will be used to instil virus into the nasal cavity. This is the most effective way to enable infection of virus through the olfactory bulb to simulate exposure to virus- containing fluid and reduce the need for inoculation by injection, which would increase the potential harm caused to experimental animals.

Ferrets will be co-housed in their groups as they are naturally a social animal and provided environmental enrichment to encourage normal behaviour.

The anaesthesia protocol has been significantly refined in recent projects using ferrets as a model for Influenza A infection to make it shorter and safer to use without adverse effects with inhalational and reversible agents.

A clinical score table have been developed for this project that considers a range of potential disease signs related to particular organ systems that may be affected by the protocol. It will be used to identify endpoints. These will be reviewed at the end of the project to identify any improvements that could be introduced.

Why can’t you use animals that are less sentient?

Due to a similar physiology and pathology the ferret is the only mammalian model available that will experience neuroinvasion following RVFV aerosol inoculation in a similar manner to infection in humans. In addition, non-vertebrate animals would not facilitate meaningful insights into RVFV in mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Ferrets will be kept for a period of acclimatisation, co-housed in cages and provided environmental enrichment.

A clinical scoring system will be used to monitor all animals participating in the study for early identification of clinical signs or signs of distress. Where necessary, increased monitoring of animals will help to reduce harm to individuals.

Ferrets undergoing anaesthesia will be provided with extra cover to ensure they remain warm during the procedure.

A NVS with extensive experience in using ferrets will be available throughout the duration of the project.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidance on housing and husbandry of ferrets as per the Code of Practice and review recent literature that has used ferrets as a model to ensure we are operating the most refined, up-to-date methodology and best practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project licence holder will check the 3Rs website (https://www.nc3rs.org.uk/) and other accessible sources of information on animal challenge models. This includes information on the housing and husbandry of ferrets (https://nc3rs.org.uk/housing-and-husbandry-

ferrets), legal guidance on housing ferrets (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/388 535/CoPanimalsWeb.pdf) and lists appropriate conditions for their maintenance.

The project license holder will ensure that all researchers are kept up to date with current guidelines and practices by having direct conversations before, during and after the experimental protocol, and recording evidence of these welfare meetings. The NIO will provide up to date guidance on welfare and housing of ferrets for the duration of the project.

30. Developing vaccines against infectious diseases and cancer

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

vaccines, immunology, antibodies, T cells

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to test new candidate vaccines and therapeutics in a small animal model (mice), enabling us to evaluate their effectiveness and safety, to optimise their design, and to select the most promising candidates for assessment in human clinical trials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines are among the greatest success stories of modern medicine. Even prior to the covid-19 pandemic, the World Health Organisation have estimated that vaccines prevented at least 10 million deaths worldwide between 2010-2015. However, the emergence of covid-19 and its devastating impact on worldwide health and economic prosperity has highlighted the critical importance of developing new vaccine technologies against current and emerging infectious diseases. New vaccine technologies including

mRNA and viral vector vaccines that have not previously been used widely in mass vaccination programs have been at the forefront of mankind's response against covid-19. Pre-clinical studies in small animal models are an essential pre-requisite for development of new vaccines. The immune systems of mice have been extensively characterised, and decades of research has shown that many aspects of the mouse immune system behave in a similar way to the human immune system making the mouse an excellent small animal model for vaccine studies. Almost all of the vaccines and therapeutics successfully used in humans today would not have been developed without studies in mice.

What outputs do you think you will see at the end of this project?

Identification of several lead candidate vaccines against infectious agents such as bacteria or viruses that pose a major risk to human health. Accumulation of data on safety and effectiveness to support further development of these products into clinical trials.

Identification of lead candidate cancer vaccines and/or therapeutics; accumulation of data on safety and effectiveness to support further development of these products into clinical trials.

Improved vaccination strategies, and a better understanding of the type of immune responses required to generate protective immunity against target infectious organisms and for the successful treatment of cancers.

Improvements in our understanding of new vaccine technologies, increasing their versatility, and exploring new ways in which we can use these technologies to develop better vaccines.

Who or what will benefit from these outputs, and how?

In the short term, promising data from pre-clinical studies in mice will support translation of our lead vaccine candidates into clinical trials in humans. Data generated from pre-clinical studies will be publicly disseminated where appropriate, in scientific publications, and at international conferences enabling others in the field to benefit from the knowledge gained from these studies. Collaborations with other scientists may be initiated to explore new ways to utilise new vaccine technologies.

In the medium to long term, new efficacious vaccines against difficult to target infectious diseases, and new treatments for cancer would considerably improve the health and wellbeing of the general public, both in the UK and worldwide. As the recent covid-19 pandemic has demonstrated, improvements in pandemic preparedness strategies could also have significant economic benefits to society in future pandemic scenarios. Improvements in our understanding of novel vaccine technologies could have wider implications for scientific research, leading to further research and innovation in new areas of biotechnology.

How will you look to maximise the outputs of this work?

The aim of this project is to develop new effective vaccines. To achieve this aim, pre-clinical studies in mice will be essential to support further testing of lead candidate vaccines in human clinical trials. We are already conducting human clinical trials with two candidate vaccines, and over the next five years we will design new vaccines and therapeutics to target other infectious diseases and certain types of cancer by generating an immune response against them. We have already formed, and will continue to form

collaborations and agreements with other scientists to secure the expertise and facilities required to accelerate development of our lead candidate vaccines. Data from pre-clinical studies will be disseminated where appropriate through publication in scientific publications, and will be presented at national and international scientific conferences.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice (typically from 6-8 weeks of age) will be used for this project. Mice are the animal species that have the best characterised immune system. Mice have been used in the vaccine field for decades as a model species in which to test new candidate vaccines, and immune responses generated by vaccines in mice have generally proved to be very good indicators of vaccine effectiveness in higher species including humans. Almost all currently available vaccines and therapeutics have at some stage been tested successfully in a mouse model. Because the mouse immune system has been so well studied, numerous tools are available to study vaccine induced immune responses and mechanisms of protective immunity that are not available in higher organisms. We typically use adult mice, since these animals have a mature immune system and therefore generate stronger immune responses making it easier to test new vaccines.

Typically, what will be done to an animal used in your project?

In a typical experiment, mice would first be injected with a candidate vaccine. This would typically be performed intramuscularly (i.e. injection into the muscle, which is how vaccines are normally administered in humans) but may also occur by other common vaccination routes including intranasal or oral. Intramuscular injections are performed with the mice under general anaesthetic to reduce pain and to restrain animals. After a period of time, typically between two and three weeks, a sample of blood (<10% total blood volume) may be taken from the tail vein to assess immune responses. Following the tail vein bleed, mice could receive a second dose of candidate vaccine as previously described.

Between two and three weeks after the second vaccination the mice will be killed, after which blood and tissues will be collected to assess immune responses.

What are the expected impacts and/or adverse effects for the animals during your project?

Discomfort as a result of vaccine administration and/or a mild local reaction to the vaccine with symptoms including redness and swelling at the administration site. Pain will be significantly reduced using anaesthetic, and should be transient with the animal recovering rapidly without lasting impairment. Discomfort may increase upon repeat administrations, but the number of repeat administrations and the time interval between repeat administrations will be restricted.

Systemic reaction after vaccination due to overstimulation of the immune system. A human would experience a systemic reaction as fever, fatigue, headache etc but mice can present with piloerection (ruffled fur), altered behaviour and in some cases changes to breathing pattern. We would expect these symptoms to be rare and to improve rapidly (within 24 hours).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - 90 % mild, 10% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is essential for the development of any candidate vaccine to demonstrate that the vaccine can generate a strong immune response, because it is through immunity that vaccines can provide protection from a target infectious disease. The mammalian immune system is incredibly complex. The generation of an immune response involves the interaction of a large number of different cell types, in multiple different organs located at different sites throughout the body. It is therefore impossible to adequately replicate a mammalian immune system in tissue culture, in silico, or in lower organisms such as bacteria or yeast. The mouse immune system has been extremely well studied, and has been used extensively in the testing of vaccines and therapeutics. We can therefore use the mouse model to effectively evaluate the potential efficacy of early vaccine candidates without needing to test the candidates in more sentient mammalian species.

Which non-animal alternatives did you consider for use in this project?
It is not possible to adequately replicate a mammalian immune system using any existing in vitro, ex vivo or in silico techniques or models. However, where possible we will replace studies in mice with ex vivo or in vitro techniques. For example, a critical aspect of vaccine research is to assess whether antibodies generated by a vaccine can prevent infection by a target disease organism. Using serum from vaccinated mice, we can perform an in vitro neutralisation assay to test this, rather than experimentally infecting the animal with an infectious organism. In vitro neutralisation assays have been shown to strongly correlate with protective efficacy in both mice and humans for many disease targets, and so we are confident that we can effectively replace animals in this aspect of our research without compromising in scientific rigor. We will also ensure that we perform extensive quality control testing and screening of vaccine candidates in vitro (such as testing that they have the required physical and chemical characteristics) before administering them to animals (thereby replacing animals in the early screening process).

Why were they not suitable?

Since the mammalian immune system is highly complex, involving multiple different cell types within multiple different organs, it is impossible to replicate the complex interaction between these cells and organs without studying them in a complete, living, mammalian organism. This is why ex vivo culture of immune cells and in vitro 'organ on a chip' technology cannot recapitulate the generation of an immune response in a mammalian species after vaccination. Indeed, our current understanding of the mammalian immune system is also insufficient for us to be able to adequately model the interaction between vaccines and the immune system in silico using computer simulations.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experience from previous vaccine studies has been used to assess the number of experiments in animals likely to be conducted over the next five years. In each animal experiment, the number of groups required will be determined by the number of different vaccines we need to test, and the number of control groups required. The number of groups per experiment, the number of mice per group, and the total number of experiments required to select each lead vaccine candidate have been estimated based on our previous experience of performing pre-clinical studies in mice prior to initiation of clinical trials in humans.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted current PREPARE guidelines on the experimental design of animal studies, to ensure that studies are as scientifically rigorous, reproducible and translatable as possible, thereby reducing the need to repeat experiments. Studies in animals will be performed with a clear hypothesis and formulated through extensive analysis of recent literature and our own experience to ensure that all experiments are informative and necessary. Group sizes (typically n=6-8) were designed to be as small as possible but sufficient for firm (statistically significant) conclusions to be drawn. Power calculations were used to determine these optimum group sizes. Mice will be obtained through commercial suppliers, and only the exact number required for each experiment will be ordered. They will also be age and sex matched, to increase the reliability of the data. Where possible, data obtained from each animal will be maximised through the collection of multiple tissue samples and/or sequential sampling from the same animal i.e. collection of blood samples from the same mouse at multiple timepoints rather than using several mice. On publication of our data generated using animal research, we will endeavour to comply with current ARRIVE guidelines on the conduct and reporting of animal experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Early candidate vaccines will be quality control tested and screened in vitro prior to starting animal studies to reduce the number of vaccines that require testing in animals and ensure than only high quality prototype vaccines are used. We will perform pilot studies using small numbers of animals to test new concepts prior to conducting larger studies that require more animals. As we proceed with our product development program we will introduce project GO/NO-GO points to assess progress and to enable us to decide in an efficient manner whether or not to continue with a particular vaccine project, thereby avoiding the unnecessary use of mice in projects that will cease to continue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will require the use of adult mice to test the effectiveness of new candidate vaccines and therapeutics. The project will involve the administration of substances (such as vaccines and therapeutics), primarily through injection into the muscle (since this is the route of administration most commonly used in humans). Intramuscular injection will be performed under general anaesthesia to reduce pain and stress. Best practice will always be followed regarding administration volumes and frequency. Blood samples may be taken during the course of each experiment to assess immune responses. Best practice will be followed regarding the volume and frequency of blood sampling, as well as sampling technique. Animals will be humanely killed at the end of the experiment.

Why can’t you use animals that are less sentient?

Vaccine induced immune responses in the mammalian immune system are highly complex physiological processes and cannot be adequately modelled in lower organisms, necessitating the use of a mammalian species. The mouse immune system has been extensively studied and has been shown to serve as a highly translatable model system for vaccinology, enabling us to avoid using a more sentient mammalian species. Adult mice are required for these studies, since they have a mature immune system and therefore generate stronger immune responses.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Substances will be administered at the lowest doses possible and with the fewest number of administrations possible to achieve the required effect, reducing the likelihood and severity of pain and reactogenicity. The number and frequency of repeat administrations will be restricted and kept to a minimum. Quality controls will be performed on candidate vaccines and therapeutics, including endotoxin testing of recombinant proteins, to reduce the risk of adverse events. As our primary aim is translation into human clinical trials, we will mainly use adjuvants (substances designed to increase immune responses) that are approved for use in humans (or substances that are bioequivalents of approved

adjuvants). We will also avoid using adjuvants that are known to be ulcerative, such as Freund's adjuvant. As stated previously, intramuscular injections will be performed under general anaesthetic to reduce pain, with the depth of anaesthesia controlled to avoid unnecessarily deep or prolonged exposure. The frequency of blood sampling will be kept to a minimum. From previous experience we can identify the most informative sampling timepoints for measuring different types of immune response, avoiding any unnecessary sampling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In order to ensure compliance on 3Rs guidance, publications by the National Centre for the Replacement, Refinement and Reduction of Animals in Research will be followed. The norecopa website (https://norecopa.no) also contains a variety of links to current guidance on best practice in conducting animal experiments, such as the PREPARE guidelines (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence). The Laboratory Animal Science Association (LASA) also publishes guidance on best practice (https://www.lasa.co.uk). Our establishment's Named Information Officer can provide further guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly check for updates to 3Rs guidance on the website of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (www.nc3rs.org.uk) and the RSPCA website on guidance for the use of animals in research (https://science.rspca.org.uk). We will attend regular internal 3Rs meetings at the establishment, and seek guidance from the NC3R's regional manager.

31. Studies of cancer inflammation and immunity in vivo

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunotherapy, Inflammation, Tumour immunity, Immune-escape, Cancer immunology

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our main objective is to elucidate which signals trigger anti-tumour immune responses, and to distinguish mediators favouring tumour elimination from those that support cancer progression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The recently reported unprecedented efficacy of immunotherapy in a proportion of cancer patients has revolutionised the way we treat cancer. In turn, this has highlighted the need for more mechanistic studies to determine why some patients show partial response or do not respond. In this context, the study of the mediators that regulate the function of immune cells in the vicinity of the tumour, distinguishing mediators promoting tumour immunity from those that support tumour growth, is critical to our ability to maximise the efficiency of therapy for cancer patients. The benefits of this project will be: 1) The identification of drivers of natural and therapy-induced tumour immunity in mouse models of

cancer that recapitulate the human disease. 2) To inform and advance our ability to identify cancer patients likely to respond and benefit from cancer therapies aimed at harnessing the anti-tumour activities of the immune system. 3) The generation of novel therapies to disrupt immune suppression and enhance the efficacy of conventional and immune-based cancer treatment in patients.

What outputs do you think you will see at the end of this project?

The output of the research will be shared with other researchers in the field and the broader community through presentations in conferences (nationally and internationally) and publications in peer-reviewed journals. In addition, our work has direct translational and clinical applications that we will investigate through collaborations with clinicians at the Establishment and other medical cancer centres worldwide.

Who or what will benefit from these outputs, and how?

The benefits are:

The identification of regulatory pathways of natural and therapy-induced tumour immunity using mouse models of cancer that recapitulate the human disease; distinguishing inflammatory mediators that favour tumour elimination from those that support cancer progression alterations in preclinical models (short-term).

To inform and advance our ability to stratify subgroups of cancer patients with an immune-promoting tumour environment who are likely to benefit from existing immunotherapy from those with inhibitory pathways resulting in local immune suppression (mid-term).

To further inform the design and guide patient stratifications in investigator-led clinical trials that will be ran in multiple centres across the UK in which the scientific rational was provided by work undertaken in our previous PPL (mid-term). 4) To develop novel targeted interventions to disrupt immune suppression, stimulate the tumour inhibiting function of the immune system and enhance the efficacy of conventional and immune-based cancer treatment in patients (mid and long-term).

We will achieve these benefits through the use of: 1 genetically engineered mouse lines with select immune and inflammatory alterations, 2 genetically engineered mouse models of cancer, and 3 the use of cutting-edge immune profiling techniques in both animal models and patient samples.

By combining fundamental and translational research our ultimate goal is to develop novel targeted interventions to enhance the efficacy of cancer treatments that harness the anti-tumour function of the human immune system.

How will you look to maximise the outputs of this work?

Our findings will be made available to other scientists through collaborations, publication in high profile peer-reviewed journals and presentations at scientific conferences and meetings. Our Institution has a policy of ensuring that all publications generated are available on free access to all.

Species and numbers of animals expected to be used

- Mice: 9200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The development and function of an inflammatory and immune response involves many different cell types interacting in a dynamic three-dimensional environment. For example, the progression of an immune response within a whole organism involves changes of antigen expression and presentation that evolve with both time and spatial distribution. Similarly, cancer development and spread involves a plethora of interactions between cancer cells and their surrounding cells, governed by multiple signals originating from both their immediate neighbours and from distant tissues. These factors combined with the involvement of multiple host cell-types and the expansion and migration of rare tumour-specific effector cells mean such research cannot be carried out in tissue culture alone or reproduced in silico and can only be addressed with the use of animals.

The mouse is one of the model organisms that most closely resemble humans. The human and mouse genomes are approximately the same size, and display an equivalent number of genes, which are functionally conserved. Further, mice have genes not represented in other animal model organisms (e.g. Caenorhabditis elegans, i.e. nematode worm, and Drosophila melanogaster i.e. fruit fly) such as those involved in adaptive immune responses. Mice can be genetically altered, there is extensive literature concerning the topics of our investigation, and our own studies can be enhanced by combination with many complementary models developed by others in the field. Definitively, mouse models are important for placing the findings of in vitro (test tube) studies or correlative analysis of human samples into an appropriate and meaningful in vivo (living organism) context. It is the combination of in vitro, in silico (computer) and in vivo studies that provides the insight needed to understand cancer biology and develop new therapeutic approaches, and there are no effective approaches to hand that can replace the in vivo studies, as these allow the in vitro findings to be tested in an appropriate environment. For our studies we need animals with a functionally mature immune system, therefore we will only use adult mice.

Typically, what will be done to an animal used in your project?

Mice may have tumours induced by chemical agents or implanted subcutaneously under the skin, intravenously, orthotopically (e.g. intradermally for skin cancer cells of in the mammary fat pad for breast cancer). The growth of tumours will be assessed by either imaging with ultrasound or when possible, such as in the case of subcutaneous or intradermal tumours, using callipers. Some mice will be irradiated to replace their immune-system with specific populations of cells from donor mice or to treat their tumours. Chemical agents, such as existing cancer therapies, potential new therapies or agents may be administered by a variety of routes including orally or by injection. Typically, a single mouse will not experience more than 4 procedures.

Some mice will undergo surgery, for primary tumour removal, and these will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing, this is not painful.

The health of all mice will be observed daily. Notwithstanding this, all the mice will be humanely culled at the end point of the experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals (up to 95%) are not expected to show signs of adverse effects that impact on their general well-being apart from the development of tumours. The vast majority of the procedures will result in no more than transient discomfort and no lasting harm. However, some mice in which we are investigating the effects of treatments upon the spread and progression of tumours (~3% based on recent experience) might be unexpectedly found dead overnight when monitoring indicates that they are normal. This can be due to a sudden impact of the spread of cancer cells from the original location to other body organs. The health of all mice will be observed daily. Notwithstanding this, all the mice will be humanely culled at the end point of the experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on our vast experience using these procedures and experimental models we anticipate about 85 to 90% of mice to experience Moderate severity, 10 to 15% Mild, and less than 1 to 3% a Severe one.
Thus, the vast majority of mice are only expected to experience mildest to moderate clinical symptoms due to tumour growth before they are humanely killed. Some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery. We will aim to utilise the least stressful route of administration wherever possible.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development and function of an inflammatory and immune response involves many different cell types interacting in a dynamic three-dimensional environment. For example, the progression of an immune response within a whole organism involves changes of antigen expression and presentation that evolve with both time and spatial distribution. Similarly, cancer development and spread involves a plethora of interactions between cancer cells and their surrounding cells, governed by multiple signals originating from both their immediate neighbours and from distant tissues. These factors combined with the involvement of multiple host cell-types and the clonal expansion and migration of effector cells mean such research cannot be carried out in tissue culture alone or reproduced in silico and can only be addressed with the use of animals.

The mouse is one of the model organisms that most closely resemble humans. The human and mouse genomes are approximately the same size, and display an equivalent number of genes, which are functionally conserved. Definitively, mouse models are important for placing the findings of in vitro studies or correlative analysis of human samples into an appropriate and meaningful in vivo context. It is the combination of in vitro and in vivo studies that provides the insight needed to understand cancer biology and develop new therapeutic approaches, and there are no effective approaches to hand that can replace the in vivo studies, as these allow the in vitro findings to be tested in an appropriate environment.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives are cancer cell lines, primary immune cells and tumour explants. We use these routinely in our research however the aims of this study cannot be achieved without using living organism. There are not good alternatives to address our research questions and achieve our translational goals. Additionally, use of animals will be minimised by bioinformatic analysing publicly available datasets through computational means and, where suitable, further using in vitro model systems.

Why were they not suitable?

The study of cells in culture (in vitro) and less sensitive organisms provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above to allow us to investigate the impact of the relationship between the immune systems in the promotion of cancer cell growth and spread.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume or tumour incidence following manipulation of a gene of interest or treatment with a drug can be determined using the minimal number of animals.
Based on past experience, group sizes of between 5 and 8 animals (dependent on the readout, typically fewer for transplanted tumours compared to spontaneous tumours in GEMM mice) per experimental group suffice. For instance, in implantation experiments where we deplete a gene in a cell line by genetic manipulation in vitro, we will use two independent approaches targeting the gene as well as a control for that approach. Moreover, we would typically examine more than one model cell subpopulation/line. Likewise, we may use several doses of a drug, or several different drugs or treatment combinations to test a hypothesis. We have estimated the total number of mice to be used over the licence lifetime taking into account our previous experience in PPL PDCC31AAF.

What steps did you take during the experimental design phase to reduce the

number of animals being used in this project?

The use of mice will be minimised in several ways:

By considering on-going statistical estimation of power requirements in each of the studies, using prior results in order to use the minimum number of animals while retaining sufficient numbers for statistical significance. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.

By incorporating as many test groups as possible within a single controlled experiment, reducing the number of controls required compared to a series of smaller experiments.

By utilising tissues and tumours from different sites on one mouse for both treatment and control samples.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The use of mice will be minimised in several ways:

By optimising our breeding programme to maximise use of mice in experimental protocols minimising the number of mice we do not require. Breeding is performed in a different PPL, by a dedicated group in our Establishment.
By doing as much preliminary work as possible in culture models in vitro and in silico analysis prior to engaging in in vivo studies.

By minimising variability in results through utilising inbred strains and by housing them under identical conditions to limit variability.

By performing pilot studies using few mice when no information is available in the literature so that the number of mice utilised in experiments is reduced to minimal levels.

In all new experimental models and protocols, we will establish the base line by procuring help and advice from BRU staff and researchers at the Establishment but also from our experienced collaborators outside across the UK and internationally. Furthermore, we will design small pilot experiments, carried out referring to https://www.nc3rs.org.uk/conducting-pilot-study, that will allow us to select the ideal cell line so fewer animals are used, to calculate the minimum cohort size given the rate of expected events and also to determine gravity of these, allowing more accuracy for statistical powering calculation of group sizes in potential repeats. Lastly, pilot experiments, potentially for all aspects of the Protocols, will enable us to better plan the length and size of the experiment and to help monitor for side effects at the critical time points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why

these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The use of inbred and fully back-crossed mice not only reduces intragroup experimental variability but also eliminates incompatibility when cell transfers are carried out between various knockout, transgenic and wild-type strains.

Why can't you use animals that are less sentient?

The cancer mouse models that we will use very closely recapitulate the human disease and thus allow to understand the molecular and cellular events and steps involved in the activation of tumour immunity and tumour-related inflammation during tumour development and progression. Some mice in which we are investigating the effects of treatments upon the spread and progression of tumours (up to 3% based on recent experience) will be unexpectedly found dead over night when monitoring indicates that they are normal. This is due to a sudden impact of the spread of cancer cells from the original location to other body organs. The health of all mice will be observed daily. We believe we can justify this because we have seen unprecedented outcomes with our approaches in multiple malignancies, including some once thought to be treatment refractory.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where possible, procedures will be undertaken under anaesthesia with the administration of analgaesia to minimise the experience of pain.

We constantly work to improve husbandry and procedures to minimise actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare. Mice will be maintained in individually ventilated cages under barrier environment, to avoid infections.

When considering which route of administration of substances to employ, we will strive to use the least invasive route whilst maintaining direct control of dose. The choice of route to administer a drug or cells will be such as to achieve "best practice", i.e. to minimise or avoid adverse effects, reduce the number of animals used, and maximise the quality and applicability of substances and cells to achieve the scientific objectives.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgical procedures will be carried according to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.

Unless otherwise specified, this project will follow the "Guidelines for the welfare and use of animals in cancer research" and the administration of substances and withdrawal of blood will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm (Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally.

Through discussing refinements with our NACWO, NVS and ASRU. I am a regular attendee and contributor to our Retrospective Review and Licensees meetings and the 3Rs Poster session, all of which take place annually at our Establishment.

32. Pharmacology and physiology of CNS neurotransmission

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Psychiatric disorder, Neurotransmitters, Drug therapy, Risk factors

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Neurotransmitters are the brain's main signalling molecules. The overall aim of this programme is to utilise animal models to gain new knowledge on the pharmacology and physiology of brain neurotransmitters, and to use this knowledge to help make advances in the treatment, prevention and detection of individuals at risk of poor mental health.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Mental illnesses such as depression, anxiety and schizophrenia are common, seriously disabling, and are linked to self-harm and even loss of life through suicide in a significant number of sufferers. Despite this, even the most modern drug treatments do not achieve useful therapeutic effects in all patients and often have a delayed onset of action of many

weeks. Moreover, these treatments can cause unwanted side effects including when patients try to stop their medication, and some of the drugs have been linked to later life problems in the offspring of mothers who are prescribed drugs to treat mental health problems during pregnancy.

One of the main reasons for all this is that we still don't fully understand how the drugs work in the brain or what makes individuals vulnerable to the mental illnesses that they are aimed to treat. In particular, there is a need to increase knowledge of the neurotransmitters that underpin psychiatric symptoms and their subsequent relief by treatment. With increased knowledge of brain neurotransmitters drug treatments could be developed rationally rather than by empirical means as at present, and safer treatments could be prescribed with a prior knowledge of whether they will work in a particular patient or not.

What outputs do you think you will see at the end of this project?

Our data will contribute to new knowledge on the pharmacology and physiology of key neurotransmitter systems and complex brain microcircuits, and how changes in these neurotransmitter and microcircuits bring about changes in emotion and cognition.

We will generate data that will speed up the development and design of future drug therapies that will be more effective than current drug treatments of psychiatric disorder and with fewer problematic effects such as potential harm to the developing brain.

Our data will reveal new information on the actions on brain microcircuits of environmental and genetic factors that put individuals at risk of developing psychiatric disorders such as depression and anxiety.

Through collaboration with computer scientists our data will generate computational models of the functional connectivity of key microcircuits relevant to psychiatric disorders. These models will help make a much more complete explanation of how microcircuits are changed by genetic and environmental risk factors and acted on by drug therapies.

Who or what will benefit from these outputs, and how?

New understandings of neurotransmitters and brain microcircuits will be of interest to a large community of researchers in many disciplines including neuroscience, pharmacology, psychology, psychiatry and computational neurobiology.

New data on drug development and design will benefit industry that is making considerable investments in new drug therapies. Also, it will be helpful to clinicians who are treating patients and developing prevention strategies. It will also be of value to patients and their carers themselves, who are trying to understand and cope with psychiatric disorders.

New information on the mechanism of psychiatric disorder risk factors will be helpful to clinicians who are treating patients and detect those at risk. It will also be of value to patients and their carers themselves, who are trying to understand and cope with psychiatric disorders.

Developments in computational biology will have benefit the 3Rs in terms of reducing and replacing animal use.

How will you look to maximise the outputs of this work?

We will continue to maximise output from our programme of work in a number of ways:

Contribute to the UK knowledge economy through timely publication of high-quality research accessible to academics and clinicians.

Maintain and develop links with local research groups and clinicians to explore how our findings can inform potential drug discovery and clinical practice.

Maintain and develop existing links with the pharmaceutical industry.

Contribute to the economic competitiveness of the UK through enhancement of researcher career development and the training of young scientists.

Develop an animal research framework that reduces the number of animals required through maximising data yield.

Promote greater public understanding of science through continuation and expansion of our current public engagement activities.

Species and numbers of animals expected to be used

- Mice: 9,000
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We need to use animals (mainly mice but also rats) in our research programme for several reasons:

The rodent brain is a simple model of the human brain but significant advances in our understanding and treatment of psychiatric disorders are under-pinned by studies on small animals.

The rodent brain is the most investigated of all vertebrate brains and provides an incomparable database to aid our investigations.

Our studies on neurotransmitters are focused on complex neural pathways that cannot currently be modelled without animals.

Emotional and cognitive responses are complex behaviours with human correlates and these cannot be studied in non-sentient animals.
The influence of genetic and environmental (eg. developmental) factors on emotional responses and cognition cannot be modelled in vitro or by computers.

By using animals we can administer pharmacological agents at doses and over intervals that have direct clinical relevance. The relevance of drug doses in in vitro preparations to doses experienced by patients is often uncertain.

We will utilise adult animals but also animals at earlier life stages because we wish to study brain development, a complex process which cannot be modelled in other ways.

Typically, what will be done to an animal used in your project?

We will manipulate brain neurotransmitters in a number of ways including the use of animals with genetic modifications and novel optical and chemical approaches that allow manipulation of neurons with a high degree of control.

We will make molecular and cellular measurements in post-mortem tissue as well as measurements of neuron activity in vivo.

Behavioural analysis will also be carried out and include measurement of natural emotional and cognitive responses that are highly relevant to symptoms of psychiatric disorder.

We will use a social defeat paradigm as a model of environmental stress because of its good construct, face and predictive validity. Social defeat is a natural stressor in animals, and a source of depression, anxiety, low self-esteem, and social withdrawal in humans.

Some experiments involve the surgical preparation of animals under general anaesthesia, for example to deliver genes to the brain or for implantation of microelectrodes or other miniature recording devices. On occasions animals will be treated for several weeks with drugs, the majority of which will have proven tolerability and safety in animals (and humans).

At the end of the experiments animals will be killed by humane methods.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects associated with these surgical approaches are rare but range from wound breakdown and infection to a build-up of fluid on the brain, which may result in neurological signs. Appropriate surgical methods (eg. aseptic conditions) and post-operative care (eg. pain-relieving drugs) will be used to minimise adverse effects such as neurological signs.

Surgically prepared animals will be monitored to detect signs of adverse effects before they fully emerge and thereby allow us to adjust our experiments to reduce their frequency and severity.

Some drugs may cause short-lasting behavioural stimulation or sedative effects and will be administered using doses that produce effects of the smallest magnitude appropriate to the experiment. Animals administered drugs will be frequently monitored and weighed, and if such adverse effects are observed they will be resolved by adjusting the dosing regimen. In certain behavioural tasks animals will be food-restricted to ensure that they are motivated to perform the task. These animals are generally healthier than animals with unrestricted access but we will carefully monitor for excessive weight loss and use endpoints that trigger supplementary feeding to return weight to acceptable levels.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice; 50% sub-threshold, 25% mild, 25% moderate.

Rats; 50% subthreshold, 25% mild, 25% moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals (mainly mice but also rats) in our research programme for several reasons:

Our studies on neurotransmitters are focused on complex neural pathways that cannot currently be modelled without animals.

Emotional and cognitive responses are complex behaviours with human correlates and these cannot be studied in non-sentient animals.

The influence of genetic and environmental (eg. developmental) factors on emotional responses and cognition cannot be modelled in vitro or by computers.

By using animals we can administer pharmacological agents at doses and over intervals that have direct clinical relevance. The relevance of drug doses in in vitro preparations to doses experienced by patients is often uncertain.

In some experiments we will utilise animals at earlier life stages because we wish to study the brain as it develops, a complex process which cannot be modelled in other ways.

Which non-animal alternatives did you consider for use in this project?

Our animal work is complemented with studies on neurotransmitter signalling in cultured cells and we collaborate with computational biologists to analyse, understand and model large complex datasets.

Why were they not suitable?

It is not possible to model complex neural circuits, emotional and cognitive responses, or brain development in cultured cells.

Computational approaches have not yet proven to accurately model the functions of integrated living brain circuits and their complex functions. These approaches are limited by factors such as dimensionality, the availability of incomplete data, and outcomes and predictions that require testing and verification in an experimental setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimated the number of animals on the basis of previous experience, our technological approaches, and experimental design which take into account the following to minimise the number of animals used:

Use of good surgical methodology and practice to minimise loss of animals by maximising chance of recovery (eg. asepsis, use of short acting anaesthetics, minimal surgery time and postoperative care and analgesia).

Where possible use of in vitro experiments to generate models and hypotheses to guide in vivo experiments.

Rather than repeating controls, use of "rolling controls" for experiments spread over time.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will continue to conduct our experiments so that they comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines). This includes but is not limited to:

Use methods of statistical analysis and randomised, blinded experimental designs combined with power calculations to establish the minimum number of animals required to achieve a meaningful result.

Where necessary use of alternative methods of statistical analysis to minimise the need for repeating experiments and/or maximise the conclusions drawn.

Use appropriate controls to prevent false positive/negative results (eg. use of drug vehicles, an inactive drug of similar chemical structure, or pharmacological blockade to confirm specificity of action).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Use of well-managed and conservative genetic mouse breeding strategies and use of both male and female mice, as well as heterozygote mice where appropriate.

Use of electrophysiological recording methods that detect many tens of neurons in a single animal, thereby reducing the number of animals required and at the same time generating large biological datasets to capture neural circuit complexity.

Sharing of datasets with collaborating computer scientists to develop computational models of key neural networks to aid further hypothesis development and prediction testing.

Use of pilot experiments before embarking on full-scale studies, and literature searches will be carried out to avoid replication of experiments already published.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Although the rodent brain is a simple model of the human brain significant advances in our understanding and treatment of psychiatric disorders are under-pinned by studies on small animals, as exemplified by recent evidence of the dawning of a new generation of rapid-onset antidepressant drugs. The rodent brain is the most investigated of all vertebrate brains and provides an incomparable database to aid our investigations.

Our studies on the effect of drugs and psychiatric risk factors (environmental stress, genes) on neurotransmitter function are focused on complex neural pathways that cannot currently be modelled without animals. Moreover, by using animals we can administer pharmacological agents at doses and over intervals that have direct clinical relevance. The relevance of drug doses in in vitro preparations to doses experienced by patients is often uncertain.

We will also investigate neurotransmitter function and neural network formation during brain development, which is a process unique to mammals and cannot yet be modelled in vitro or by computers.

The vast majority (>95%) of drugs that we use will have known pharmacological profiles and proven safety in animals at the doses selected.

We will measure key emotional and cognitive responses with close correlates to those exhibited in healthy humans and dysfunctional in patients with psychiatric disorders. These responses also cannot be studied in non-sentient animals.

The majority of our behavioural paradigms are harmless and capitalise on natural and spontaneous behaviour to test emotional and higher cognitive functions. Anxiety paradigms are largely exploratory-based tests that generate a natural approach/avoidance conflict response. When used, rewarding stimuli are natural motivators and readily accepted.

Some behavioural paradigms will probe aversion learning and stress vulnerability and involve the delivery of an acute aversive or stressful stimulus, which is calibrated to be brief and cause no lasting harm. A large scientific literature attests to the value of using aversive/stressful stimuli to investigate the neurobiology of stress mechanisms in a controllable, reliable and refined way.

The neurobiology of stress vulnerability cannot be studied without exposure of animals to stressful stimuli. We will use an ethologically-based model that uses a natural stressor (social defeat) that is more refined than other stress models based on non-natural stressors such as inescapable physical restraint.

Why can’t you use animals that are less sentient?

Animals less sentient than those selected:

do not have neurotransmitter systems and complex neural circuits that are representative of the mammalian brain.

cannot be administered pharmacological agents at doses and over intervals that have relevance to those experienced by patients.

are unable to perform complex emotional and cognitive tasks that model similar tasks in humans and are dysfunctional in patients with psychiatric disorder.

do not demonstrate the process of brain development that is characteristic of mammals.

have nervous systems that are much less investigated than the mammalian brain, and do not have comparable databases to aid our investigations.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Use of health monitoring of adverse effects with humane endpoints.

Use of health monitoring to avoid cumulative effects of experimental steps and circumvent where necessary.

Use of peri-operative analgesia which will be administered and continued after surgery for as long as required to alleviate pain.

Optimise experimental parameters to produce reliable effects with the minimum duration and frequency of treatment (eg drugs, aversive/stressful stimuli) exposure.

Use of literature and other databases to aid selection of drug treatments that produce optimal effects and minimal adverse effects. Treatments with the latter potential will be detrimental to our studies and avoided.

Drugs to be administered in volumes and routes that are the least harmful and most appropriate to the species.

Drugs with uncertain safety and tolerability will initially be tested acutely at low doses in pilot experiments.

Use of ARRIVE guidelines (https://arriveguidelines.org) to ensure the use of the most refined methodology.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

www.nc3rs.org.uk, plus regular retrospective reviews by local ethical review committees and updates from our Named Information Officer.

guidelines for administration of substances (volumes/routes), e.g. Handbook of Laboratory Animal Management and Welfare, Sarah Wolfensohn & Maggie Lloyd (2013, 4th Edition), Blackwell publishing.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are on the mailing list of www.nc3rs.org.uk. We have an NC3R's regional manager available to us and we regularly attend internal 3R's meetings.

33. Helminth regulation of disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

soil-transmitted helminth, cancer, prevention, treatment, immune system

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the mechanisms for how helminth (worm) infections influence the body's immune system.

This will help us to find new ways to prevent or treat important diseases they influence, such as cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Approximately 1.45 billion people (<20% of the world's population) are infected with one or more types of soil-transmitted helminth (STH). Infection mostly occurs within low-and-

middle income regions, including sub-saharan Africa, South-East Asia and South America. Heavy infection with STHs is associated with the impaired physical and cognitive development of school children, whereas heavy infections in pregnant mothers can result in reduced infant survival and birthweight. Overall, 5.2 million years of life are lost from a population's lifespan due to ill health because of a STH infection. Currently, there are no vaccines for disease and treatment relies on the use of mass drug administration. These drugs do not prevent people from becoming re-infected with STH and often, drug resistance develops, so people cannot be effectively treated.

From human studies and by modelling human STH infections in mice, we understand that they can establish themselves in the intestine for long periods of time. While in the intestine, they have a profound impact on the gut microbiome, our immune system, as well as our ability to harvest energy and nutrients from food. We also understand that one of the ways helminths can have these effects is through the secretion a set of molecules, termed “excretory/secretory (ES) products”. The ability of STH infection and the ES products to manipulate the immune response is linked to their ability to survive in the host and produce fertile eggs, without killing the host. This manipulation of the immune response has been shown to affect the development of other diseases, such as asthma and diabetes.

One in two people in the UK will develop cancer in their lifetime. Although the incidence of cancer is currently much lower in low-and-middle income countries (LMIC), than in high-income countries (HIC), it is anticipated to increase by 62% in LMIC, such as South Africa, when compared to an increase of 30% in HIC, such as the United Kingdom, by 2040. High levels of infectious diseases within LMIC are a risk factor for cancer development and were estimated to be the cause of 32.7% of new cancer cases in sub-Saharan Africa in 2008.

Although, STH infections have been found to be a risk factor for increased colorectal cancer in mouse models of disease and higher rates of human papillomavirus (HPV)-related cervical cancer in helminth endemic areas, our laboratory studies have linked exposure to ES products with decreased cancer. It is therefore currently not clear how STH infections and their ES products influence the development and progression of cancer, which is why we now wish to undertake this project. We will make use of established models to study the interaction between STH infection and the immune system in mice, to better understand this interaction and improve treatment strategies for the prevention and treatment of the important diseases they influence, such as cancer.

What outputs do you think you will see at the end of this project?

This project aims to generate new information on how soil-transmitted helminth (STH) infections influence our immune response and alter our risk of developing important diseases, such as cancer. This will help us identify new ways to try and treat STH infections, as well as new ways to prevent or treat cancer. This information will be shared at local and international conferences, within open access publications and through public engagement activities.

Who or what will benefit from these outputs, and how?

Within the timescale of the project, the scientific community is most likely to benefit from these outputs, through our increased knowledge of how soil-transmitted helminths influence the development of cancer. In the longer term, our discoveries aim to identify new pathways that can be targeted in order to prevent or treat disease. Through identifying

these mechanisms, the longer-term impact of developing potential therapeutics for the treatment and prevention of cancer is high.

How will you look to maximise the outputs of this work?

I am involved in a number of academic collaborations within the field (across several institutions within and outside the UK, including in relevant helminth endemic countries, such as South Africa). In addition, I have ongoing collaborations with clinicians in the field of colorectal cancer. These collaborations will continue and will support the impact of the current work.

In addition, I have a strong track-record of academic publication and conference attendance and presentation. This will continue across the life of the current project - supporting the wide dissemination of the outputs from this work. I am committed to the communication of science to the public (including invitation to speak at Soapbox science events, as well as Pint of Science events). I am further committed to "open science", through the communication of validated unsuccessful approaches within appropriate channels.

Species and numbers of animals expected to be used

- Mice: 5000
- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The soil-transmitted helminths we study can only complete their life cycle in living animals, in our case mice and rats. In addition, we and others have experience of using well-established mouse models of helminth infection, that accurately reflect infection in humans. Similarly, we and others have experience of using well-characterised mouse models of cancer, that reproduce human disease and allow us to study the influence of helminths on cancer development. Due to the complexity of the interactions between live intestinal helminth infections and tumour development in the body, there is currently no way to recreate these conditions in the laboratory. Our studies will use adult rodents, which can independently feed and have a fully developed immune system, as these most appropriately model the life stage of people infected with helminths, or who develop cancer.

Typically, what will be done to an animal used in your project?

In order to generate the helminths we need to study their interaction with the immune system, we will infect mice and rats with helminths so that we can grow the helminths and collect excretory/secretory (ES) products from them. These animals will be injected, or given helminths by mouth, just once.

In order to study how these helminths influence cancer development, a separate cohort of mice will be injected with tumour cells or agents that cause cancer, using the following

established models with a known time course. Approximately half of these animals will also be exposed to helminths by infecting them, or by injecting helminth secretions. Experiments will last 2 weeks up to 4 months.

Genetically altered mice will be given an agent that causes genetic changes that lead to cancer, similar to those seen in humans, either in their food or water, into abdominal cavity or under the skin of the colon, while under anaesthesia for a short time. Tumour growth will be monitored using in vivo imaging under anaesthesia for a short time, or at the end of the experiment, which will last a maximum of 4 months.

Animals will be injected with an agent that causes genetic changes that lead to cancer, similar to those seen in humans, into the abdominal cavity. They will then be given an agent that causes inflammation in the intestine for a period of one week, every fortnight on a total of 3 occasions, in their water. Tumour growth in the colon will be monitored using in vivo imaging under anaesthesia for a short time, or at the end of the experiment. Following injection of the agent that causes genetic changes that lead to cancer, these experiments will last a maximum of 10 weeks.

A cohort of female animals will be given a human papillomavirus virus (HPV)-like particle while under anaesthesia for a short time. Approximately 10% of mice will be vaccinated with the HPV vaccine Gardasil, before delivering the particle. The vaccine protects humans from infection with four different types of HPV, which cause almost all cases of cervical cancer. Infection with HPV will be confirmed by imaging the mice under anaesthesia for a short time. After the imaging sessions are complete, within 72 hours following human papillomavirus infection, the animal will be humanely euthanised.

In some mice, tumour cells will be injected a) under the skin while the mice are awake, b) at one site into the wall of the lower intestine (e.g. colon), while anaesthetised for a short time, or c) into the blood. Tumour growth will be monitored using a hand-held calliper measuring device in mice that are awake, or by in vivo imaging under anaesthesia for a short time, up to maximum of 3 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Most animals show no untoward effects of the helminth infection itself in the doses and time scales we use. Rats and mice infected with certain helminths will develop transient weight loss, which is associated with the natural lifecycle of the helminth (as it passes through the lung). We will monitor these animals for weight loss following infection, for a maximum of 9 days. If an animal loses >15% of their starting body weight, they will be humanely killed.

To test the effects of helminth infection on cancer development, some animals will develop stressful signs associated with cancer, including tumour growth, weight loss, intestinal discomfort or diarrhoea, depending on the model used. We will monitor tumour growth for a maximum of 4 months, or until the tumour reaches a predefined size, which we have set to avoid it causing any adverse effects to the animal. In addition, we will use our score sheet to monitor the clinical signs of cancer, for a maximum of 4 months. If an animal reaches a predefined clinical score, or they lose >15% of their starting body weight, they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild - 100% of rats, 75% of mice. Moderate - 25% of mice

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The soil-transmitted helminths we study can only complete their life cycle in living animals, in our case mice and rats. Infection causes prevalent diseases in humans and livestock and is a risk factor for cancer. The complex interactions between live intestinal helminth infections, the host immune system and tumour development depend on a complex integration of signals, which can only be found in the live mammalian animal.

Which non-animal alternatives did you consider for use in this project?

To date, we have established how helminth secretions influence cancer cell behaviour, using cancer cell lines. We have considered this alternative for this project, as well as laboratory cultivation of helminths without the need to infect live animals, as well as the use of tissue explants.

Why were they not suitable?

Currently, it is not possible to cultivate soil-transmitted helminths to complete their life cycle entirely in the laboratory, although this may become possible in the future and we will continue to monitor progress in this area. Interactions between live intestinal helminth infections and tumour development in the body are complex and depend on the integration of signals from the microbiota, tissues and the immune system. Cell lines and tissue explants are limited as they currently do not recreate this complex web of interactions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to estimate the numbers of animals we will use in order to achieve the objectives of this project, I have referred to the annual usage from my own research over the past 18 years, and that of relevant colleagues, having considered where the numbers of animals used could be reduced. In addition, data generated in my laboratory with cancer cell lines

and my experience with the murine models of cancer herein has informed the minimum numbers of animals required to achieve statistically significant findings.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have attended courses on experimental design and statistical approaches and have sought further statistical advice from colleagues whenever necessary.

Data generated in my laboratory with cancer cell lines has informed the minimum numbers of animals required to achieve statistically significant findings. In addition, the experience I have had with these murine models of cancer as a research fellow over the last 7 years, has allowed a prediction of the experimental variation we should expect.

Our previous experience with these models has also informed our ability to reduce the number of animals used. In all experiments, in-bred mice from the same litters will be used in order to reduce variation. Should we need to use differing litters, genetically altered mice or transgenic animals, we will mix the bedding of all mice and allow their microbiome to stabilise for 2 weeks, in order to reduce variation that can occur due to differences in the microbiota.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our studies will make use of known models of disease and helminth infection and will make use of methods like imaging in order increase the amount of data obtained from single animals.

My group will take the approach of performing pilot experiments, in order to determine the optimal number of mice to achieve statistical power. Experiments will then be performed on a minimum of two separate occasions to ensure reproducibility, following which data pooled from experiments are statistically analysed to reveal less pronounced effects without increasing overall animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models we use for helminth infection cause minimal suffering or distress to the rodents as they are naturally well-adapted to their host. The mouse models for cancer do inescapably cause a degree of suffering as they are designed to replicate human disease. Our approach is to select models which are very well established, well characterised and accurately model the course of human disease. In addition, we will regularly monitor and score animals based on the clinical signs indicative of disease, in order to select a window of time for analysis which minimises any suffering the animals may experience.

Why can’t you use animals that are less sentient?

The lifecycle of the soil-transmitted helminths we use has been developed in adult laboratory rodents, and no alternative host species is known. The animal models for cancer have also been developed in adult laboratory mice. As adults, these animals can feed independently and their immune system is fully developed, representing the stage at which humans become infected with helminths and develop cancer. Helminth infection can take up to 4 weeks to establish and cancer can take up to 4 months to develop, therefore it would not be possible to use animals that have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will minimise the welfare costs for the animals by following the guidance of the ARRIVE (Animal Research Reporting of In Vivo Experiments) guidelines, available through the NC3Rs website. We will also refer to the advice of our Animal Welfare and Ethical Review Body (AWERB), which produces specific guidelines that further refine and ensure best practice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Tumour studies will be undertaken according to the principles outlined by Workman et al., Br J Cancer (2010) 102:1555-1577. Guidelines for the welfare and use of animals in cancer research.

We also regularly consult the nc3rs refinement resource website (https://www.nc3rs.org.uk/3rs- resources), including their webinars, training material and other e-learning resources, in order to ensure experiments are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to discuss published advances in the 3Rs at regular laboratory meetings and through discussion with our Named Animal Care and Welfare Officers (NACWO) and Named Veterinary Surgeon (NVS). In addition, we will remain informed about advances in the 3Rs, including NC3R symposia, through our local named persons and our NC3Rs Regional Programme Manager.

34. Placental epigenetic programming

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Placenta, Epigenetics, Development, Gene regulation, Embryos

Animal types	Life stages
Mice	pregnant, adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to gain an understanding of the importance of early events in genome regulation in the development of a healthy placenta during pregnancy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pregnancy complications such as preeclampsia, miscarriage or preterm birth affect as many as one in four pregnancies, yet there remains a critical gap in our knowledge of the underlying causes. The placenta not only supports the growth of the baby, but helps the mother’s body adapt to pregnancy. A poorly functioning placenta can therefore not only impact the survival and health of the baby, but in many cases the mother as well. At present, we have a poor understanding of early events that lead to healthy placental

development because these developmental milestones occur during the first weeks of human pregnancy.

Evidence supports that pregnancy complications are linked to changes in genome regulation in the placenta. In particular, epigenetics marks (chemical changes to DNA or its bound proteins) are key to setting up the active and silent regions of the genome during development. The patterns of epigenetic marks are unique to each cell type in the human body. Importantly, the establishment of these patterns are critical for a tissue to form correctly and function.

We want to understand the patterning of epigenetic marks in early placenta development. We hope to reveal how these marks direct the formation of a functional, healthy placenta, using the mouse model. Critically, mouse and human placentas contain similar cell types, epigenetic patterns, and developmental milestones, making the mouse a suitable model for this research.

We hope that our research over the next five years will lead to an understanding of how epigenetic patterning of placental cells in the early embryo support healthy placental development throughout pregnancy. This work will lay the foundation for our understanding of changes that may underlie complications of pregnancy.

What outputs do you think you will see at the end of this project?

The main outputs from this project will be a better understanding of the importance for epigenetic marks in directing placental development. We will share our findings through presentations at national and international conferences, publication in peer-reviewed scientific journals, and exhibitions at public outreach events, such as science festivals. Alongside publication, all datasets generated from our projects will be shared with the scientific community in public data repositories.

Who or what will benefit from these outputs, and how?

In the short term, these studies will provide important discoveries of the processes involved in early placental development. Our findings will help both clinical and basic science research in reproductive biology and epigenetics to generate new research questions. This work will form the basis for future research funding applications. These studies will also provide sequencing datasets from the early stages of mouse embryo development, when cell types are first being established. These available datasets can be further explored by other research groups to address fundamental research questions.

Importantly, these studies will help work towards an understanding how molecular changes early in development may lead to placental dysfunction and complications of pregnancy in humans. At present, there is a lack of clinical tools to provide early detection to help improve outcomes for complicated pregnancies. Hence, obtaining a better understanding of the underlying contributors to pregnancy complications will be a crucial step towards better supporting these pregnancies. In the long term, this work will help the public through improved care options for mothers and babies during pregnancy.

How will you look to maximise the outputs of this work?

The outputs of this work will be maximised, in part, through collaborations. With a strong collaborative team, we will ensure the successful use of novel techniques and strong study designs. We will publish in high-impact, open-access journals, allowing us to widely

distribute the knowledge generated by our work. We will publicise major findings in the press to further improve visibility of the research. When possible, we plan to publish negative results and detailed methodologies in open-access journals.

Species and numbers of animals expected to be used

- Mice: 4900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using the C57BL/6 inbred strain of mice because this is the most common background for genetically modified lines of mice. C57BL/6 is the best known mouse genome for mapping of genomic sequencing data. The use of C57BL/6 will allow our data to be comparable to other studies in the field.

We have chosen to evaluate several stages of embryo development after the embryo implants into the mother's uterus, as this is when placenta formation and function begins. We will assess epigenetic marks, gene expression and placental structure at various critical stages for placental biology. First, we will assess embryonic days 4.5 to 7.5 because at this time the embryo contains stem cells that will later derive all of the placental cell types and coincides with the patterning of epigenetic marks. We will then assess embryonic day 9.5, which is a critical time point in mouse placental development, when the cells that generate the umbilical cord link the baby to mother. Finally, we will evaluate embryonic day 12.5 because at this stage the placenta is fully formed, containing all of the necessary cell types for its function.

Typically, what will be done to an animal used in your project?

For animals used for this project, no procedures other than observational handling and matings are planned. Mated female animals will be humanely killed at predetermined life stages for embryo and placenta collections. Tissues will be used for generating genomic sequencing datasets to investigate genome regulation and for analysing cellular and structural changes in the placenta.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect adverse effects on the animals during this project because we plan to assess mice with a loss of gene function only at embryonic stages. There are no plans to evaluate these animals past birth.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice Mild 100%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studying the earliest stages of placental development in humans is logistically and ethically challenging because these events occur during the first few weeks of pregnancy. The experimental tools to study embryo implantation in the lab have not yet been developed. Hence, the mouse model provides a mammalian system in which we can study the molecular events during the formation of the placenta.

Which non-animal alternatives did you consider for use in this project?

Human placental (trophoblast) cells can now be grown in lab, so we considered whether this would be a good alternative for this project.

Why were they not suitable?

Culture methods for human placental trophoblast cells are very new and still under development. As a result, these methods are not yet able to accurately model the early developmental windows of the placenta. Importantly, culture methods also cannot yet recreate the unique environment of the placenta. The placenta forms at the interface between mother and baby during pregnancy and contains cells from both mom and baby. Hence, the study of mouse development is essential in furthering our understanding of key steps in early placental development.

Importantly, prominent molecular features, such as the pattern of epigenetic marks on the placental genome are conserved between mouse and human. Mouse and human placentas have similar cell types, developmental milestones and cellular structure to separate the blood of mother and baby. As a result, our studies in mice will provide a critical foundation for future research into important regulatory events in human placental development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have prioritised investigating two epigenetic pathways in placental development. We will be studying knock-out (carrying two copies of a genetically modified gene) mouse models for the key enzymes in each of these pathways, which includes a total of 7 mouse lines. We estimate that each line will require 700 animals over 5 years to allow for enough matings to maintain the lines and perform experiments.

Maintenance of these mouse lines will be done by mating animals carrying a single copy of the genetically modified gene (heterozygous) to unmodified animals. This strategy is optimal for ensuring animal wellbeing and health. For each experimental mating, heterozygous animals will be mated together to obtain embryos. Embryo tissues will be used to generate molecular and sequencing datasets and to perform characterisation of the placental and embryonic features. Important considerations in this estimation of animal numbers are the frequency at which the correct genotypes can be obtained, the number of developmental time points being assessed in each line, and the number of experiments to be performed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have used the online experimental design tool provided by NC3Rs and the PREPARE guidelines to optimise of my study design, bias avoidance and sample sizes. I plan to collect embryos from heterozygous female animals bred to heterozygous male animals. This heterozygous breeding strategy allows the collection of control and knockout embryos from a single pregnant female. Furthermore, using this approach, the genetic status of embryos is unknown to the experimenter during collection.

The genetic status of each embryo is determined after samples are frozen or fixed, minimising any collection bias. Using Power Calculations, I have determined the minimum sample size needed for comparison of genomic sequencing datasets to be 3-5 per group. This will allow us to confidently identify changes in gene expression and/or epigenetic changes that are likely to impact cellular or tissue biology. Samples will be randomised for all molecular experiments to avoid technical bias.
Evaluating cellular and structural changes in the embryo and placenta will be done using 5 samples per group to identify large, easily observable changes because we expect features to be dramatically altered in knockout embryos. The genetic status of each tissue will be unknown for experimenters assessing placental structure and cell composition.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

My collaborators and I have developed cutting-edge adaptations of all sequencing methods. Rather than millions of cells required by the original protocols, we have methods that now only require hundreds to thousands of cells to obtain high-quality data. Without these advances, this project would not be feasible in mouse models.

In my postdoctoral work, I generated similar types of sequencing data from eggs and embryos collected from genetically modified mouse models. I also have performed pilot experiments in mouse embryos to demonstrate the quality and reproducibility of data that can be obtained from placental trophoblast cells. These studies have helped me accurately estimate the number of animals required to achieve our research goals.

The research project is designed with staggered aims, first focusing on one specific epigenetic pathway, followed by the other. This approach minimises the use of animals by avoiding unnecessarily prolonged breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our plan is to use genetically modified mouse lines for breeding and maintenance. We don't plan any procedures or protocols that will cause pain, suffering or distress. Animals carrying the genetically modified targets selected for this study do not show any adverse phenotypes. Knock-out animals will be evaluated before birth.

Why can’t you use animals that are less sentient?

To study placenta formation in pregnancy, it is necessary to study placental mammals. Hence, the mouse model is the least sentient model that we could use for these studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Stud males are those that are temporarily mated with females to obtain embryos at a specific stage. After pairing with a female, stud males cannot be returned to cages with other males, as this often result in fighting and aggression-related injuries. Hence, these males will be temporarily housed individually between matings. To ensure the wellbeing of these animals, we will singly house stud males for the minimum necessary time and utilise several refinement approaches, including the use of enriched environments and acclimatisation/rest periods between matings. To ensure the wellbeing of pregnant females after mating with stud males, females will be housed together until the relevant predetermined life stage.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?
For all animal work, I will follow the Laboratory Animal Science Association (LASA) guiding principles to ensure refined and considered protocols and approaches. I will adhere to guidance provided by NC3Rs strategies and PREPARE guidelines. I will frequently liaise with our Named Animal Care and Welfare Officer and Biological Support Unit facilities to review refinement of our approaches. We also plan to attend events and meetings, such as those provided by my organisation and NC3Rs, to stay updated on best practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay up-to-date on advances in the 3Rs from the National Centre for the 3Rs (NC3Rs) guidelines and updates, as they evolve through the duration of the project. We will also use the Norecopa resources and University of Cambridge 3Rs search tool to find recent articles and relevant 3Rs news. We will stay attuned to the latest practical guidance from Laboratory Animal Science Association (LASA). In particular, we will closely follow any updates on the refinement and usage of genetically altered mice.

35. Epigenetic regulation in cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Cancer, Epigenetics, Chromatin, Immunotherapy, Development

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Decipher epigenetic pathways in mouse models of oncogenesis to understand fundamental mechanisms and develop effective therapeutic strategies

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Normal development in mammals is driven largely by reversible and heritable modifications to DNA, RNA, and protein that do not alter the sequence information. These marks and their precise regulation of gene expression make up the field of epigenetics. These mechanisms work through widespread labelling with diverse chemical modifications and work in complex combinatorial ways through tightly regulated activating and repressive signals. Such regulation within our cells is dynamic and finely tuned through the

enzymatic action of epigenetic modifiers that add or remove these marks, known as “writers” and “erasers”, respectively. Many of these modifiers target protein tails extending off of core proteins around which DNA is wrapped. This DNA/protein structure referred to as chromatin resembles beads on a string under an electron microscope and it organizes our genome in the nucleus and determines how regulatory proteins are able to engage and read our genes. These protein tails can be labelled with many distinct marks and it is the interplay between these that regulates gene expression. Such broad capacity for fine-tuned control extends to DNA modifiers and over 100 different types of RNA modifications. When these exquisite regulatory mechanisms fail or become dysregulated, a wide array of developmental diseases, autoimmunity, ageing and cancer can develop. The work under this application will allow us to understand these aberrant epigenetic mechanisms and discover ways to reverse or prevent their occurrence in order to improve human health through the development of effective therapies.

In part, our aim in understanding fundamental epigenetic mechanisms is focused on two fronts. These are age-associated loss of immune function known as immunosenescence and cancer.

Age-associated epigenetic dysfunction leads to many disease states. This concept is perhaps most widely known by the public with DNA methylation clocks. These clocks accurately reflect the accumulation of aberrant DNA modifications with age in many animals. Such dysregulation is exemplified by excessive modifications to tumor suppressor genes, which serves to turn off the expression of these critical genes potentially leading to cancer. Age related epigenetic dysfunction also leads to immunosenescence, a state of immune cell dysfunction where T cell levels decline and immune cells lose effector or cytotoxic functions. This process drives many age-related disease states such as autoimmune disease, cancer and increased risk of infection. Our group hopes to better understand the epigenetic mechanisms driving this aberrant regulation through functional studies in immune cells from aged mice.
In addition to promoting the onset of cancer, epigenetic dysregulation allows cancer cells to rapidly evolve and evade immune detection through mechanisms that diminish tumor antigenicity and drive immune cell dysfunction. This is exemplified by “cold” tumors, which are characterized as having very few or completely absent infiltrating T cells. Several mechanisms have been shown to cause this lack of T cell infiltration including limited tumor antigen and the presence of suppressive immune cells within the tumor.

In addition, epigenetic mechanisms in immune cells can enforce a diminished state of functionality, such as that observed in exhausted T cells where chronic activation by tumor antigens and inhibitory signals on cancer cells essentially stop the antitumor T cell response. Through our research we endeavor to better harness the immune system to combat cancer through developing treatment strategies that rejuvenate or enhance immune activity for more effective cellular immunotherapies.
Using the immune system to fight cancer has demonstrated decades of success however only a minority of patients benefit from this treatment. With our work in mouse tumor models we are aiming to identify epigenetic mechanisms both in cancer and immune cells that lead to improved immunotherapy efficacy.

What outputs do you think you will see at the end of this project?

This project will provide significant benefits both in expanding our understanding of fundamental epigenetic mechanisms and in developing improved cancer immunotherapies that can move to clinical trials. In addition, any novel insight into these critical regulatory

mechanisms will be published and shared with the broader research community to advance our collective understanding.

Much of our work will revolve around one form of immunotherapy known as T cell transfer therapy or adoptive cell transfer (ACT), a cancer treatment harnessing a patient's own T cells to fight cancer. By targeting specific epigenetic enzymes in T cells collected from mice, we expect to address some of the current obstacles currently limiting the efficacy of this treatment. We expect that this will lead to significant improvements in tumor reduction and tumor clearance when infused into tumor bearing mice. These results will guide future research decisions, reach publication and potentially lead to clinical trials.

Who or what will benefit from these outputs, and how?

The scientific advancements that emerge from our work will ultimately benefit patients that perhaps currently do not have effective treatment options for unresponsive or "cold" tumors. The benefits of our work will extend beyond patients with disease by revealing new insights into epigenetic mechanisms that can be leveraged to develop effective preventative interventions for high risk factors and will reveal new therapeutic targets for pharmaceutical companies to develop epigenetic inhibitors.

More immediately, our work will lead to publications that will benefit the principal investigator and the research group through future funding awards. New biological insight from this project will improve our understanding of these fundamental mechanisms and will impact future work both in our research and for the broader research community. Much is currently unknown regarding the critical role of epigenetic regulation in these disease states and therefore a real need exists for this work.

How will you look to maximise the outputs of this work?

Epigenetic therapies that improve mouse T cell functionality in our preclinical models will be tested with in vitro based methods in human T cells to measure how our results translate into human therapies and whether future work or clinical trials is warranted. Novel biological data and all methods/approaches will be published and/or shared with the research community through presentations, online databases and collaborations, regardless of the experimental outcome. Collaboration with other experts will be central to maximizing successful research outcomes and disseminating new knowledge.

Species and numbers of animals expected to be used

- Mice: 7500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.
Our research draws extensively on mouse model systems. Many of the mechanisms that we study are conserved from humans to mice making this a vital part of our work. For instance, we can study the safety profile and efficacy of a new epigenetic inhibitor, develop a new strategy for expanding an immune cell subset or decipher a novel epigenetic

mechanism crucial for healthy development in mice to reliably understand how these same conserved processes work in humans.

Part of our work involves studying the interaction between tumor and immune cells and the function of these immune cells, particularly adaptive T cells, necessitating a vertebrate animal model due to their absence among invertebrates. With mouse tumor models we can study epigenetic mechanisms that drive these processes and successfully translate key findings to clinical studies because of existing mouse/human epigenetic and immunological conservation, which is not available with less sentient animal models such as fish. Mouse models are widely used in cancer research and have provided decades of important insights into tumor immunity.

Genetically modified mice are utilized in our work for studies of specific epigenetic factors, in vitro activation of T cells, and tumor studies. Using a mouse model with T cells deficient in a critical epigenetic enzyme, we are able to study how the absence of this factor increases T cell antitumor functionality.

Due to age related immune decline, 8-10-week-old mice with normal peak immune health (wild type) are often used for our tumor studies and age matched mice are used in control groups.

Typically, what will be done to an animal used in your project?

We will be using mouse tumor models, to study the interaction between cancer and immune cells. These models are transplantation models where cancer cells are injected into mice of the same genetic background as the donor mice. Much of our research will revolve around improving a form of cellular immunotherapy known as adoptive cell transfer (ACT) therapy. Broadly, we will be isolating CD4+ (helper) and CD8+ (cytotoxic) T cells from donor mice tumors, referred to as tumor-infiltrating lymphocytes (TIL). After epigenetic reprogramming and expansion in culture, these TIL will be infused into recipient tumor-bearing mice to study how various epigenetic perturbations impact T cell antitumor functionality.

Typically, the steps involved in our TIL-ACT study include tumor induction in donor and recipient mice, with the latter receiving the modified T cells collected from donor mice tumors. Tumor induction is performed with a single injection of cancer cells directly under the skin in both groups of mice and tumors generally develop for four to six weeks. When tumors reach 1000-1200 mm^3 in donors, the mice are euthanized and tumors are collected. T cells are subsequently isolated from these tumors, expanded and epigenetic factors are targeted for manipulation to improve functionality. Recipient mice with tumor volumes generally within 150-500 mm^3, receive a single intravenous infusion of T cells into the tail vein. The treatment efficacy is measured by changes in tumor volume quantified every 2-6 days (dependent on tumor cell growth kinetics or doubling time) until there is either complete remission (no measurable tumor) or a humane endpoint is reached, at which point, the mouse will be euthanized.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice are expected to develop tumors. These tumors are expected to grow for up to 6 weeks. As the tumour grows the skin around it may be affected with redness, soreness, peeling and scabbing, which will be allowed to persist for up to 14 days. Tumors may also

ulcerate (display a small round crater) towards the later stages of growth and animals showing ulceration will be humanely killed upon detection.

Animals will experience mild and transient pain and distress from brief restraint and an accompanying intravenous injection into the tail vein.

Animals may experience mild gaseous anaesthesia lasting no longer than 10 minutes during subcutaneous injection of cancer cells. Recovery is expected to be uneventful and swift.

Mice undergoing Adoptive Cell Transfer (ACT) may experience a mild form of autoimmune disease. The mice may exhibit depigmentation of the extremities which may last up to several months. A more severe response may be mild respiratory distress presenting as laboured breathing or lethargy which, if not resolved in 24 hours, will lead to the animal being humanely killed. Mice showing immobility or not responding to touch will be humanely killed upon detection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90% Mild

10% Moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse models allow us to study complex systems that cannot be properly modelled with other research tools such as cell culture. Being able to recapitulate the complex interactions between cancer and immune cells in a controlled way allows us to study the fundamental epigenetic mechanisms behind this interplay. Much of the epigenetic dysregulation driving tumorgenesis and immune evasion/suppression is shaped by signals in the tumor microenvironment (TME) and currently there are no alternative models outside of animals that can replicate these complex signals. With mouse models, we can implant tumors and study how epigenetic factors modulate the immune response and we can develop effective immunotherapy strategies that augment this response. Mice are a powerful resource in cancer research due to their extensive physiological/molecular similarities to humans, the availability of many different cancer models that accurately recapitulate features of human tumorgenesis, and the decades of acquired biologically relevant knowledge and genetic resources. To understand the fundamental mechanisms

driving these processes, we must first model them effectively, and mouse models provide that ability and therefore help bridge the gap between cell culture and cancer in humans.

Which non-animal alternatives did you consider for use in this project?

Developing 3D tumor models in cell culture as a replacement for some mouse tumor experiments was considered. In addition, our T cell expansion in culture protocol has been optimized for maximum expansion numbers requiring less donor mice for our experiments. Our culture methods and experimental assays are continually evaluated for improved efficiency and effectiveness, which leads to less mice needed for a study.

Epigenetic targets are screened in culture for improved T cell functionality before being tested in mice. Through functionality assays that measure important aspects of effective ACT such as T cell proliferation and cytotoxicity to phenotypic measurements that include staining of cell surface proteins with fluorescently tagged antibodies and sorting with flow cytometry, we carefully evaluate how epigenetic targets change T cells. Only epigenetic perturbations that lead to significant improvements in T cell functionality over untreated control groups in culture are selected for mouse studies. This requirement not only leads to fewer mice required throughout a project, but also drives faster discoveries.

Why were they not suitable?

Cultured 3D tumor models, or multicellular spheroids are still years away from replacing mouse tumor models. Tumors grown in culture lack the vasculature that develops in animal models (even in the presence of growth factors) and therefore rely on diffusion for oxygen and nutrients. A huge drawback of this kind of growth is the necrotic or dead internal tumor microenvironment that invariably develops.
Other methods for improving on this include co-culturing cancer cells with endothelial and fibroblast cells for more accurate tumor heterogeneity as well as drug induced blood vessel growth, but this approach is still a long way from replacing animal tumor models. Additionally, functional immune systems are required for much of our immunotherapy research. We manipulate the host response in mice and in culture to study how the antitumor response can be modulated. This requires recapitulating the complex interactions between the host and tumor, which is currently not possible outside of an animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

This estimate is based on previous data that we have obtained and published using these same mouse models. Additionally, we have consulted experienced colleagues for additional expertise throughout our experimental planning. Our research plan is centered on discovering epigenetic-based therapies that demonstrate large improvements in antitumor immunotherapy efficacy (or large effect sizes) over untreated or unmodified controls. Only T cell modifications driving significant functionality improvements (quantified through several assays) are selected for small scale pilot studies usually in groups of five

mice. Successful epigenetic candidates must demonstrate a large effect size or ≥ 2-fold reduction in tumor volume over control groups to be studied further in larger groups of 7-10 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Through experimental refinement and consulting experts in the field, we have been able to effectively reduce our mouse numbers. We have extensively reviewed the literature on activating and expanding mouse T cells in culture and much of our previous and ongoing work is focused on optimizing and refining this process. Improving T cell expansion reduces the number of tumor-bearing donor mice required for our tumor-infiltrating lymphocyte adoptive cellular therapy (TIL-ACT) experiments and ultimately creates a more durable T cell product that is more effective at lower infusion numbers with a greater effect size requiring fewer recipient mice to obtain statistical significance. Additionally, small-scale pilot studies are used to measure efficacy and effect size and provide a cut-off threshold to progressing to studies with larger group sizes and additional experimental groups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our measures for reducing mouse numbers start with optimized T cell culture conditions. This was achieved through an extensive review of current published methods on the expansion of mouse T cells as well as consulting experts in the field. Optimal T cell expansion, largely dependent on an optimal combination of cytokines, has reduced our donor mice requirements by half. Our current method allows us to passage T cells in culture longer while preserving enhanced proliferation functionality. Improving on this method even more is a constant pursuit in our work and will lead to future reductions in mouse numbers.

Efforts at minimizing mouse numbers continue with our tiered approach. Our earliest experiments involve epigenetic screens and functionality assays of T cells previously expanded in culture to workable numbers from a limited number of donor mice. Only after demonstrating significant improvements over untreated controls are specific epigenetic targets selected for mouse studies. These initial studies are conducted in small groups of five mice, a number previously determined sufficient for revealing moderate to large effect sizes. This pilot attempts to validate the findings in obtained in culture and measure how improved functionality translates to enhanced antitumor T cell activity within the tumor microenvironment. Only modifications that demonstrate a ≥ 2-fold reduction in tumor volume over controls are then eligible for further studies with larger group sizes (n=7-10) if needed. This requirement ensures that only T cell modifications with demonstratable antitumor activity are used more broadly in larger mouse studies and therefore further reduces our mouse numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Every step of the protocol has been carefully reviewed to ensure that any pain and suffering is prevented and if unavoidable, that it is mild and transient. Our welfare refinement is achieved in part by performing some procedures on unconscious mice to help eliminate acute pain and suffering. This approach also improves experimental refinement by creating more controlled conditions for performing successful subcutaneous injections.

Another important aspect of refinement in our research is frequent welfare checks of all mice in a study. These checks increase in frequency from every 2-3 days after cancer cell injection to daily when measurable tumor growth is visible. These daily checks include brief visual and hands on evaluations of overall health status and the tumor region and are performed for the duration of visible tumor growth. Daily checks will become twice daily checks in mice with decreasing Body Condition Scores or tumors presenting with signs of elevated ulceration potential (large tumors presenting with multiple visible signs of reduction to skin condition e.g. elevated redness, peeling, scabbing). In general, any mouse presenting with signs of impending reductions in health and wellbeing are assessed carefully and monitored with appropriate frequency to ensure that any welfare issues are promptly addressed or the mouse is humanely killed.

The restraint and tail vein injection of T cells are performed on conscious mice while anaesthesia is optional for subcutaneous cancer cell injections. Based on previous experience, it was determined that the anaesthetic induced cardiac depression would make tail vein injections more difficult, potentially increasing injection attempts, and leading to higher numbers of untreated mice or increased tissue damage and prolonged mild pain. Most procedures will be performed on conscious mice to limit adverse effects from frequent anaesthesia.

Tail vein injections are most refined by placing the recipient mouse into a 37°C incubator box for up to 15 minutes to induce vasodilation prior to restraint and injection. This approach aids in both the identification of blood vessels and positioning of the needle into the vessel lumen leading to shorter restraint times and successful injections.

Why can’t you use animals that are less sentient?

Ultimately, our goal is to discover and develop novel and effective immunotherapy approaches for treating cancer in human patients. With mouse models, our preclinical studies are more likely to translate to human cancer treatment than studies in a less sentient animal such as fish. Mouse models are widely used in cancer research due to their physiological and molecular similarities to humans and more recently, several cancer models have been genetically refined to better recapitulate human cancer development and heterogeneity. These characteristics and resources are absent with less sentient animals and therefore replacing mice with a lower species currently is not conducive to our research goals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All mice will be monitored every 2-3 days post-tumor cell injection until measurable tumor appears then monitored daily for duration of measurable tumor mass to monitor for ulceration. These daily checks consist of very brief visual/hands on inspections to assess general welfare condition. Mice presenting with mild forms of redness, soreness, peeling and scabbing at tumor site will be monitored twice daily for potential ulceration (cratering or pitting at the tumor).
Ulceration is a humane endpoint.

All mice with measurable tumor mass will receive Body Condition Scoring (BCS) every 2-6 days to be performed concurrently with tumor measurements and weighing. Mice with visible reductions in health and wellbeing are monitored more frequently and a weight reduction of ~10% will be treated with moist palatable food at cage floor. Mice presenting with low body condition scores or weight loss >15% are humanely killed.

Non-aversive supportive mouse handling with cupped hands/tunnel handling in place of picking up by the tail will consistently be implemented during monitoring both to closely examine the health of mice and to habituate them to handling.

Mice may be anesthetized up to two times in a protocol. Both occurring before subcutaneous tumor cell injections (primary and optional rechallenge)

Mice receiving intravenous tail vein injections will be placed into a 37°C incubator box for up to 15 minutes to induce vasodilation prior to restraint and injection. Restraint will be < 5 minutes.

Single use needles are used for all injections

Mice that received TIL-ACT are monitored closely for autoimmune disease through frequent welfare checks and Body Condition Scoring. Mice with visible reductions in health and wellbeing are monitored more frequently and receive moist food.

Mice with tumor rejection following TIL-ACT treatment with transformed T cells containing inducible apoptotic switches receive a bioinert small molecule intraperitoneal injection every 2 days for 4 injections. During this time, daily welfare checks are performed with visual and hands on assessments and Body Condition Scores/weight are assessed to monitor for signs of cytokine release syndrome and other complications of elevated cell death. These daily checks continue for seven days after the final injection or longer if required.

Dry food will be provided on cage floor for mice unable to efficiently reach the food hopper due to large tumor burden and mice with visible reductions in health and wellbeing or low Body Condition Scores/ ~10% weight loss will receive moist food on cage floor.

Alpha Dry Bedding will be used in place of traditional Aspen Woodchips for tumor bearing mice to provide a softer and more absorbent environment for larger tumors and potential wound management.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure that our mouse experiments are always conducted in the most refined way possible, we will communicate often with animal care staff, participate in workshops when they are offered and regularly consult the NC3Rs website for up-to-date references and

protocols that reflect current best practice of the 3Rs. Additionally, we will consult the online collection of best practice protocols offered through the 3Rs Knowledge Bank, when available.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The 3Rs training resources offered online through the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs) will be reviewed by the project license holder every few months and shared with all personal license holders. In addition, every member of the group working under the project license will register for the NC3Rs monthly newsletter and attending workshops and webinars will be continually discussed and encouraged during group meetings. We will take a team approach to our animal research through open communication and collaboration with all animal care staff in order to achieve high quality research with uncompromised animal welfare.

36. Neuronal communication in the brain of mice

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

brain, cortex, synapse, neuron, tau

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

A central goal of neuroscience research is to understand how the brain processes external and internal stimuli to coordinate cognitive and behavioural processes. Ultimately, this understanding must relate behaviour to the activity patterns of neurons and their synaptic connections within key circuits of the brain. Elucidating how the activity of these circuits becomes abnormal is also crucial to understanding pathological situations such as neurodegeneration. This project deals with these quetions in an unusually direct way - by observing the activity of neurons and synapses in the brains of live mice as they process sensory stimuli (1-4). Optical methods such as multiphoton microscopy now provide the resolution required to image neuronal and synaptic activity in awake animals and we will use these methods to make a circuit-level analysis of sensory processing and neuropathologies such as Alzheimer’s Disease.

Our aim is to understand how nerve cells and their synaptic connections convey information (e.g visual or spatial) during health and disease.

Our key questions are:

What is the nature of the neural signals by which information is processed and transmitted in the visual system and hippocampus in awake behaving mice?

How is the transmission of neural signals at the synapse altered by changes in behavioral state of the animal?

How is the processing and transmission of neural signals altered in neurodegenerative disease states?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is expected to have benefits in three broad areas:

1) By elucidating how different types of neuron respond to different types of visual stimuli, it will yield a greater understanding of how the brain executes vision.

2) By concentrating on imaging the activity of synaptic connections, it will reveal how these key neuronal compartments alter visual signals and how they alter the transfer of neuronal signals when the brain enters different states, such as switiching from "sleep' to "alert".

3) By studying how the operation of neurons and synapses is altered by the accumulation of proteins that are known to cause neurodegeneration, we hope to suggest novel therapeutic targets and strategies.

What outputs do you think you will see at the end of this project?

The main benefit of our research is to increase knowledge about brain function. We currently know little about how the brain works at a cellular level. We study this problem in the context of a key function of the brain - the processing of visual information. In partcular, we want to understand how the processing of a visual stimulus changes under different circumtances. This can occur when an animal changes it's behavioural state by becoming aroused, or when it habituates to a stimulus that has become familar or learns how a viual stimulus leads to a tasty food reward.

The goal of this project is to contribute the following milestones:

Understanding changes in visual processing assocated with arousal or learning

Understanding how these behavioural effects are mediated by the neural circuitry of the brain, including the retina and visual cortex

In addition to new knowledge about the brain, we will also contribute by developing techniques to learn about the brain. We will refine methods to record functional activity of single retinal ganglion cells (neurons that transmit information from the eye to the brain) over a long time period of weeks to months. We will also improve methods for observing the activity of the synaptic connections that transmit signals between neurons.

The knowledge we gain will be published in peer-reviewed articles. Manuscripts will also be published on a preprint repository so findings are available to public as soon as we deem them ready for publication. We will present findings at conferences and during invited talks.

Datasets of neural recordings and simultaneously recorded behaviour of animals will be published online, and code developed by our group to analyse the data will be made publicly available.

At the end, we will have a better understanding of the changes in viual processing that underly adjustements in visually-driven behaviour of mammals.

Who or what will benefit from these outputs, and how?

This work is expected to have benefits in three broad areas:

By elucidating how different types of neuron respond to different types of visual stimuli, it will yield a greater understanding of how the brain executes vision.

Short term (1-5 yrs): novel data sets collected showing how neuronal activity changes in an awake, behaving animal; alterations in these parameters occurring under different brain states (e.g. resting, aroused, locomoting); measurements of activation of noradrenergic or other projection neuron terminals concurrently with the above data sets. ·

Intermediate term (3-6 yrs): These data sets will be incorporated into models of how the visual cortex processes visual information under different brain states, contributing to worldwide efforts to understand the function of the cortex.

By concentrating on imaging the activity of synaptic connections, it will reveal how these key neuronal compartments alter visual signals and how their input-output relation is modulated under different brain states.

Short-term (1-5 years): novel data sets collected showing how synaptic activity contributes to signal processing in the cortex of an awake, behaving animal; how the strength of synaptic connections is altered under different brain states (e.g. resting, aroused, locomoting); how neuromodulatory inputs that the cortex receives from other brain areas alter synaptic function.

Intermediate term (3-6 yrs): These data sets will be incorporated into models of how cortical processing of sensory information is modulated under different behavioural states

Long term (>6 yrs): Improved understanding of the normal function of the sensory cortex.

By studying how the operation of neurons and synapses is altered by pathologies such as the deposition of tau fibrils, the project will determine the earliest functional deficits associated with neurodegeneration and suggest novel therapeutic targets and strategies.

Short term (1-5 yrs): We will have much improved understanding of how brain function is altered in mouse models of neurodegenerative diseases, concentrating on two key areas of the brain – the visual cortex and the hippocampus. The new data we will provide will be based on direct (real-time) observation of neural and synaptic activity in the awake, behaving, mouse. Specific changes in synaptic function will be related to changes in the function of the visual cortex (vision) and hippocampus (spatial memory).

Intermediate term (3-6 years): Continued collaboration with pharmaceutical companies to investigate compounds that might block the pathological effects of neurodegenerative disease models on the function of neural circuits in the visual cortex and other brain areas. Potential identification of novel therapeutic targets and strategies.

Long term(> 6 yrs): Increased understanding of disease processes underlying Alzheimer's and other neurodenerative diseases will allow improved therapeutic strategies to combat these disorders.

How will you look to maximise the outputs of this work?

We will maximise outputs by dissemination of new knowledge at meetings and conferences, by publication of results in scientific journals and by collaborating with other research groups to investigate similar questions. We will also collaborate with colleagues at our establishment who study the visual system or particular behaviours in mice and promote the publications of our articles and datasets on social media channels like Twitter and via the media office of our establishment.

Species and numbers of animals expected to be used

- Mice: 2400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Brain architecture of mice and particularly the visuomotor system that we will study is very well conserved across mammals and is thus similar to that of humans. Our findings will thus have a high probability to generalise to other mammals and humans.

Mice use vision in their natural habitat and they can be trained on tasks that require vision. Using mice, we can study visual processing in the brain and how changes in this processing influence behavioural performance.

Many genetic tools exist for mice. These tools enable us to study specific cell types, and measure and manipulate neural activity.

Mice can be kept in animal facilities typically provided at a university setting under conditions that cater their well-being and health.

We will be using adult animals because we are studying fully developed brain function.
Typically, what will be done to an animal used in your project?

Almost all of our mice will be bred in the local animal facilities.

Mice that will be used in experiments (an estimated 20%) usually receive an implant attached to their skull so they can be head restraint. We will gain access to their brain by removing a small part of their skull (about 0.5 – 5 mm in diameter). In some mice, we will induce the genetic expression of certain molecules by injecting viral vectors into the brain

or the eye. We may also implant light guides (tens to hundreds of microns in diameter) to optically access deeper parts of the brain. These interventions are necessary to measure neural activity, identify certain cell types, or manipulate neural activity. These procedures are all performed under full anaesthesia and under aseptic conditions, and animals will be treated with analgesia during recovery from the surgery. Several surgeries may be necessary to accomplish our goals, for example if it is better for the animal's well-being to split one surgery into two or when genetic expression needs to be induced at certain time points after the animal has been trained, where training necessitates the head restraining implant. No animal will undergo more than 5 surgeries (each lasting more than 10 min).

Mice are then acclimated to head restraint and to being placed on a motorized treadmill (if used) over several days before we perform experiments to record neural activity. These experiments last at most 4 hours a day. Depending on the method of recording, the experiments continue for several days up to several months.

Some animals will be trained to perform a specific task, e.g. they have to choose one of two visual stimuli. To keep the mice motivated to learn and perform the task, their daily water intake will be restricted, and they will be rewarded with water when performing the task correctly. Animals are monitored every day for signs of dehydration, weight loss and abnormal behaviour, and their water intake will be adjusted accordingly.

At the end of the experiments, the animals will be culled or perfused for further histological processing of their brains.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will undergo surgery under general anaesthesia but are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. None of the surgical intervention, implants or viral injections is expected to lead to long-term harm.

Head restraint and placement on a motorized treadmill will cause stress to the animal but usually only during the first few sessions while the animal is acclimated. Once the animal is used to the head restraint, most of the time animals do not show signs of stress and behave normally, e.g. they run on a treadmill or they groom themselves.

In some experiments, in which neural activity is recorded, the insertion of the recording probe (a few microns in diameter) may cause temporary pain when the dura, i.e. the skin surrounding the brain, is penetrated.

Under water restriction, mice will most likely experience weight fluctuations and may show signs of dehydration. These effects will be monitored every day and provision of water will be increased as necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 95% of the animals (2,000 of 2,100) are expected to undergo Protocol 1 (Breeding) and will experience a severity category of mild.

20% of the animals (420 of 2,100) are expected to undergo Protocol 2 (Measurements and manipulation of neural activity during behaviour), and thus will experience a severity category of moderate.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will study how the brain processes visual input during different behaviours, and how this visual processing impacts decision making and motor output. No artificial or non-living biological model system can replace the animals we use to perform our studies as we do not know the neural architecture and function that performs visual processing and controls behaviour.

To investigate how circuits in the brain contribute to the processing of information (e.g visual information in the visual cortex), we will need to work in vivo. This is the essence of our approach: to use the actual, unperturbed, neural circuit as far as possible. Cultures of neurons cannot see or navigate in space or carry out behavioural tasks that reflect the normal functions of the brain, and are therefore not an adequate substitute to understand how the retina or brain works.

As the function of neural circuits is profoundly altered by anaesthesia, many experiments will study unanaesthetised animals. This is also required to study processes such as motivation states. We will always seek to minimise animal use, however, and to maximise the information gleaned from every animal used.

Which non-animal alternatives did you consider for use in this project?

Parts of the brain (e.g. brain slices) and the eye (in particular the retina) can be removed from a dead animal and kept under conditions that allow nerve cells to stay functional. Such experiments are termed “in vitro” studies. These model systems can be used to study circuits of nerve cells and to some degree their function, e.g. which nerve cells are active together.

Artificial neural networks offer the opportunity to simulate biological neural networks.

Why were they not suitable?

In vitro models of populations of living nerve cells lack the input from the rest of the brain and they cannot be studied in relation to the animal’s behaviour, which is an essential goal of this project.

Regarding artificial neural networks, we have too little information about the biological networks in order to reconstruct them artificially. More importantly, we do not understand how nerve cells react and interact during natural behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Using statistical methods, we have determined how many nerve cells we need to record to answer each of our scientific questions and to draw robust conclusions from our results. Based on our previous experience, we have estimated how many nerve cells we will record from each animal. Both numbers together, i.e. the number of necessary nerve cells and the number of nerve cells recorded per animal, provide an estimate of the number of animals we will need to use for this project.

Several factors complicate the estimation of the numbers of animals though. First, there are uncertainties on the actual number of nerve cells we can record from each animal, as this depends on the quality of the preparation and the recording, as well as individual differences across animals.

Second, although we have planned a number of specific experiments that we want to perform, the exploratory nature of our research demands some degree of flexibility in the planning of experiments. In the case of highly unexpected results from one experiment, we may adjust subsequent experiments, which may lead to different numbers of animals needed. In the case of inconsistent results from performed experiments, we will perform further experiments on other animals if it is likely that these experiments will lead to consistent and robust results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental technology yields a large number of nerve cells that we are able to record in each animal: (1) we use state-of-the-art technology that allows simultaneous recording of hundreds to thousands of nerve cells; (2) we can perform these recording sessions several times on the same animal, so that every session yields another population of recorded nerve cells.

Our longitudinal experiments on awake animals last from several days to a few months. To gather the largest possible amount of data from each animal, and thus reducing the total amount of animals, we need to pay particular attention to the health and well-being of each animal. Please, see Refinement for details on this.
Our measures to control animal behaviour leads to shorter experimental sessions and reduces the number of animals. To investigate the influence of running on neural activity, we are introducing motorized treadmills to control when the animal is still or running at a certain speed, instead of relying on the animal to spontaneously sit still or run. As we need

to collect enough data in each condition, the control of running minimizes the necessary time needed for data collection.

When we are investigating functional differences between specific types of nerve cells, we will use several methods of targeting several types within the same animal. For example, we can use a transgenic animal to target one genetically defined cell type. At the same time, we can define other cell types based on the anatomical connection to other brain areas by injecting tracers into several brain areas.

We will constantly review the methods we are employing by following published literature or receiving advice from other experienced researchers in order to increase the effectiveness of our methods. This will reduce the number of failures, for example in targeting specific cell types, and will increase the success rate of experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient use of animals bred both under this licence and under the authority of other licences within the establishment that allow for the breeding and maintenance of mice expressing genetically encoded reporters and effectors of neuronal activity. For example, we will avoid ordering additional wild type experimental animals whenever surplus mice can be obtained locally.

We will collect multiple data from each animal, thus minimising the number of animals required. For example, in vivo imaging data of neuronal and synaptic activity will be collected from many hundreds of neurons in the one animal, from several regions of the cortex or hippocampus. The numbers of animals to be tested will be the minimum number required to obtain statistically reliable results, based on previous experience in the laboratory, and from published findings. Where appropriate, power calculations will be used to estimate the appropriate numbers of animals on the basis of expected variability, and anticipated effect sizes. Where possible, we will use within-subject comparisons to increase the statistical power of the experiments, and to minimise the numbers of animals that are used.

The tasks that are described here produce quantitative data, which is, in general, suitable for standard parametric statistical analyses, though non-parametric analyses will be used where data does not meet the assumptions (e.g. homogeneity of variance) required for parametric analysis. We shall use randomised block designs, where possible, to eliminate non-experimental sources of error. We have considerable experience of the use of statistical testing so that most designs will not require additional advice, but if necessary we can consult a number of statistics experts in the School of Psychology.

Cryopreservation will be used to preserve important lines and remove the necessity to hold stock for extended periods. On occasion we may need to ensure that our protocols are optimised and this may require the re-implantation of un-manipulated oocytes, embryos or blastocysts. Cryopreservation of embryos will be used for long-term storage of genetically altered mouse lines and pedigree lines with in vivo viability assessed to ensure that lines can be re-established successfully. Rederivation will be undertaken should the health status of the animals be compromised in a way that would significantly affect the welfare of the animals or where the experimental results might be altered unduly.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In our experiments, we will use purpose bred mice, some of which are genetically altered so we can distinguish and target specific types of nerve cells. In comparison to many other mammals, particularly larger animals, mice can be kept in the laboratory under conditions that cater their health and wellbeing very well. The genetic modifications in the mice we are using are not expected to lead to pain or any harm for the mice. All animals will be co-housed with litter mates as mice are social animals. We will only make exceptions to this rule if the animal's health is impacted, e.g. when animals get injured by other cage mates or when animals are too vulnerable due to surgical implants or sutures.

We will perform surgeries to access parts of the animal's brain and to implant a plate that allows us to head restrain the animal. We always use appropriate anaesthetic and analgesic regimes for pain relief during surgery, and surgeries are performed under aseptical conditions. The implant weighs less than 1 g and does not affect behaviour of the animal in a negative way.

We will head restrain the animal during our experiments so we can reliably measure the activity of many neurons. At the same time, we will control the animal's sensory input, e.g. via visual displays, and its running speed (when placed on a motorized treadmill). We will acclimatize the animal being head restrained step by step, starting by simply handling the animal and then restraining it just for a few minutes. After a few days, the animal is getting used to the procedure and does not show signs of stress anymore.

To record and manipulate brain activity we will use methods of two-photon imaging, electrophysiology, opto- and chemogenetics. Two-photon imaging can be performed on awake animals on a daily basis for weeks and months without any invasive procedures in addition to the initial surgery. The same is true for the manipulation of activity via optogenetics. Manipulation of activity via chemogenetics requires the injection of specific drugs that then only act on previously targeted neurons that express receptors for these drugs. Electrophysiology necessitates the insertion of a probe into the brain to record electrical activity of the neurons. The recording probes we are using are only a few microns in diameter, much thinner than a human hair. The animal might feel mild pain when the probe penetrates the membrane surrounding the brain (the dura), but does not feel pain as the probe penetrates the brain itself as there are no pain receptors in the brain.

We will train some of our mice to perform a visual decision task where they have to choose the correct stimulus out of two presented stimuli. We do this to study how the brain processes visual input and it uses this information to make decisions. To keep mice motivated to learn and perform this task, we restrict their daily water intake as they are rewarded with water when they perform correctly. We monitor the animals every day for signs of dehydration and ill health and increase their water intake accordingly.

Our research depends on the mice being healthy, cooperative, and engaged in the tasks that we trained them to perform, so we have many reasons to avoid any suffering. The measures we take to avoid any unnecessary suffering work: the mice are cooperative and engaged.

Mice are the best experimental model for use in this project for a number of reasons. They share similar brain structures and functions with other mammals, including primates (but unlike non- mammalian vertebrates). Importantly for this project, a number of transgenic mouse lines are available, which will allow visualisation of specific cell types (e.g. Cre driver lines targeting different types of inhibitory interneuron), neuronal calcium reporters (e.g. GCaMP6/Thy1), reporters of synaptic activity (SyGCaMP or iGluSnFR) and manipulation of cellular function (e.g. APPSWE mice). Mice have been well-studied both in the fields of information processing within neural circuits and the disease models proposed here, so that these results will be readily integratable within the field and should prove more translatable to humans than studies using lower order vertebrates. Finally, the small size of mice means that more brain is accessible within the <1 mm imaging depth possible using the 2-photon imaging methods proposed here, than is possible in larger species.

Why can’t you use animals that are less sentient?

A major aim is to understand how cortical procesing of visual information is altered by changes in behavioral state of the animal. We decided to use mammals, in particular mice, rather than species of a different class that may be considered less sentient, because the brain structures we are studying (in particlar the cortex) are conserved within mammals including humans but are absent or show greater differences across animal classes such as fish or birds. We also cannot use aneasthetized animals because these do not produce behavioural responses modulated by vision. Anaesthesia also fundametally alters the function of the cortex and makes it abnormal.

The brain is still developing until early stages of adulthood. Our goal is study processes in a fully developed brain, and we therefore use adult animals. A further advantage of using adult animals is that they do not grow anymore; implants mounted on the head therefore do not need to be adjusted for changing sizes of the skull.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is monitored throughout the experiments, and animals are humanely killed where necessary.

Using a chronic cranial window for imaging involves surgery from which animals quickly recover, and then are stable for several months with usually no decrease in life expectancy or quality of life due to the surgery. After surgeries, the animals receive analgesic to minimize pain and are monitored closely for at least three days.
Animals are acclimatised to the head restraint for several days starting with a few minutes of restraint on the first day. Animals are taken off head restraint if they show high levels of stress, and acclimation is continued on a slower rate for these animals.

Animals under water restriction are closely monitored every day for changes in weight and signs of dehydration and illness. Water is given in higher amounts or ad libitum to restore full health.

Training of animals on decision tasks is performed step wise starting at an easy level and slowly introducing more difficult conditions. The time point of introducing more difficult conditions is based on the performance of each individual animal. In this way, the animals are learning the task in the shortest time possible.

Throughout the duration of this project, we will adapt all methods if better strategies become known and available.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continuously refine our training procedures to follow best practice in this area, which is a very active one at the moment; e.g., Guo et al (2014) Procedures for behavioral experiments in head-fixed mice. PLoS One 9: e88678.

Burgess et al (2017) High-Yield Methods for Accurate Two-Alternative Visual Psychophysics in Head- Fixed Mice. Cell Reports 20: 2513-2524.

Goltstein et al (2018) Food and water restriction lead to differential learning behaviors in a head-fixed two-choice visual discrimination task for mice. PLoS One 13: e0204066.

We regularly receive information from NC3Rs working groups that disseminate refinements developed by other researchers.

Surgical procedures will be carried out according to the published LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have regular discussions with the Named Persons and animal technicians at Sussex to review current approaches and whether there are any new 3Rs opportunities.

We receive the NC3Rs e-newsletter that provides updates on 3Rs events and publications.

We will attend relevant NC3Rs events and workshops and participate in the NC3Rs working group on 'high-yield rodent behaviour', through which we share best practice in this area;

We will attend relevant 3Rs symposia at our institution.

37. The Evaluation of Veterinary Medicinal Products

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Evaluation, Efficacy Studies, Vaccine, Medicinal

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to generate data to support the safety, quality and efficacy of veterinary medicinal products in regulatory applications.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This is a service licence that aims to provide an ongoing service to customers such as pharmaceutical companies and research agencies. It aims to provide supportive data for the safety, efficacy and quality of vaccines and similar therapeutic biologicals.
What outputs do you think you will see at the end of this project?

The work carried out under this licence aids the development and licensing of new medicinal products and improves currently licensed products, thereby contributing to improving animal and human health, food production and the control of infectious diseases. There is also an economic benefit to the consumer and farmers through more efficient production. These products are fundamental in controlling disease and the spread and effects of infectious pathogens in animals and humans.

Who or what will benefit from these outputs, and how?

The data generated from these studies is used by pharmaceutical companies to support applications for Marketing Authorisations for their vaccines or other veterinary medicinal products. The data also informs companies on the design of field trials and even whether to proceed with candidate vaccines. Batch release testing allows companies to sell their products in compliance with manufacturing requirements. Ultimately the work therefore ensures products released onto the market are safe and efficacious.

Profits from commercial work are reinvested to fund the development of other tests and research posts. This benefits the organisation as a whole, and therefore ultimately the animal health work we are engaged in.

How will you look to maximise the outputs of this work?

This is a service licence with outputs linked to demand from industry.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals selected have been proven to be the best model for the proposed testing and are specified by regulatory text of the European Pharmacopoeia.

Typically, what will be done to an animal used in your project?

Protocol 1 Avian Viral Vaccines: Test for Extraneous Agents in Seed Lots

For each test item, ten chickens at 14 d/o will be inoculated with the equivalent of 100 doses of the vaccine via i/m and the equivalent of 10 doses of the vaccine via eye drop. Inoculations are repeated 14 days later. Five weeks after first inoculations the chickens are bled to provide serum samples for serological analysis and euthanised.

A control group of five chickens are reared to 14 d/o, bled at the time of first inoculations to provide baseline serum samples and euthanised.

What are the expected impacts and/or adverse effects for the animals during your project?

As the inocula are vaccine seed lots, no adverse effects are anticipated beyond some transient localised swelling or inflammation around the i/m injection site.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Chicken - mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The response to inocula such as pathogenic organisms and vaccines is a very complex process and one that cannot be replicated in vitro and it is not possible to generate definitive safety and efficacy data without the use of animals. The design of many studies for safety and efficacy are specified in regulatory guidelines and by the Competent Authorities and specify animals as the detection system of choice. However, should alternative tests that are acceptable to the Regulatory Agencies become available, such as PCRs for the detection of viruses and whole genome sequencing techniques, then these will be used to replace animal tests.

Which non-animal alternatives did you consider for use in this project?

None, the use of animals is a regulatory requirement for the proposed work.

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used is specified in the regulatory guidelines so there is limited scope for reducing the number of animals. The overall numbers proposed are those for testing ten test items.

Ongoing results are monitored and when possible the knowledge used to reduce the numbers of animals in future tests. A reduction in the overall number of animals may be possible by using only the most susceptible species or stage of development or sharing control groups. New methods that further reduce numbers will be used, for example better inoculation regimes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Scientific expertise of the organisation, input from customers, discussion with regulators and statistical rigor ensures the number of animals used is minimised. Possible reduction is discussed with the Sponsor and adjusted according to the aims of the studies.

Ongoing results are monitored and when possible the knowledge used to reduce the numbers of animals in future tests, such as sharing control groups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

N/A

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal model and age is specified in the relevant European Pharmacopoeia monograph. Careful consideration is given to possible refinements on a case-by-case basis. In addition, data from companies and their communications with the regulatory authorities and feedback directly from the competent authorities may allow tests to be refined.

Why can’t you use animals that are less sentient?
The animal model and age is regulated in the relevant European Pharmacopoeia monograph and therefore cannot be altered.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Ethical husbandry techniques will be applied, as will environmental enrichment.

All plans undergo review by the Animal Welfare and Ethical Review Body. All require close monitoring of all animals used in Studies.

As well as pre-start meetings involving the NVS, NACWO and animal care staff to ensure current knowledge is brought to bear, projects are followed up by a wash up meeting. All aspects are discussed, was the project a success, what went well and if there was anything that could be done better. If there are any suggestions for refining the procedure they will be considered and if appropriate, incorporated into the protocol.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

HO The Harm–Benefit Analysis Process

HO Guidance to ASPA

HO Code of practice

RSPCA Guidance on Welfare of rabbits and chickens LASA Guidelines on substance administration NC3Rs web site

Agency Procedure - AP007: Code of good practice for the use of animals in scientific studies

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Contact with the NVS, NACWO and NIO through various forums and use of the library function which can scan for relevant publications.

38. Novel interventions for poultry red mite

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

parasite, vaccine, poultry, mite

Animal types	Life stages
Domestic geese (Anser anser domesticus)	adult
Domestic fowl (Gallus gallus domesticus)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will progress novel interventions for the control of poultry red mites and involves development of laboratory colonies of the parasite as well as testing new methods to control the parasite in the laboratory and in the field.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infestation of laying hen houses with poultry red mites (Dermanyssus gallinae) is a major problem for the egg-producing industry worldwide and costs the poultry industry in excess of £250 million per year in the EU alone. Current treatment options are limited and often ineffective. Poultry red mites are blood feeding (hence their colour) external parasites that

build up on the cages of birds kept for longer periods of time such as those found in egg laying operations (up to 60 weeks). Heavy infestations cause anaemia, increased irritation and restlessness, feather-pecking and an increased incidence of cannibalism. These behaviours have a considerable negative impact on both welfare and productivity. Poultry red mites have also been implicated as carriers for a number of important avian diseases (including avian influenza) and have recently been recommended to be listed as an occupational hazard for poultry workers on the basis of their allergenicity. The poultry red mite problem is likely to increase due to resistance developing to main chemical treatments and consumer demand (and legislation) driving reduced use of chemical treatments and enriched environments for birds (which results also in increased habitats for the red mites). We aim to control infection with poultry red mites by exploiting the host immune response to these organisms to induce immunity against the pathogen and investigate whether this induced immunity can form an element of integrated control strategies.

What outputs do you think you will see at the end of this project?

At the end of the project we will have generated new information on host:parasite interactions, laboratory culture and control of poultry red mite. We will disseminate this information through open- access publications and presentations.

Who or what will benefit from these outputs, and how?

This project is expected to provide data to support the development of novel interventions to control poultry red mite. In the short term, protection and vaccine efficacy data, and data supporting the immune correlates of vaccine-induced protection, for example, will be generated. These data will be generated from experimental in vitro and in vivo protection trials and from field-scale trials for effective prototypes and will benefit researchers investigating the mode of action and efficacy of these vaccines. In the medium to long term, these data will form the basis of the rational development of a novel intervention in the form of advanced prototype vaccines and integrated approaches. Successful vaccines would be developed further in partnership with commercial vaccine manufacturers to produce registered seed stocks of vaccine antigen which will then be used in the safety and efficacy trials required for product registration. Several animal health companies have registered an interest in this area and this will be of benefit to them in the development of a novel market for animal health and welfare vaccines. In the long term, the outputs of a vaccine development project will therefore benefit the animals (laying hens) through improved welfare and freedom from parasitism; egg producers through increased productivity and reduced usage of chemical acaricides; vaccine manufacturers and distributors through the ability to supply novel products to a market which does not have any competition from other vaccines for poultry red mite; consumers through freedom from chemical residues in eggs. The work will also provide outputs which will underpin the fundamental scientific knowledge for scientists working on vaccines to control ectoparasites in production animals.

How will you look to maximise the outputs of this work?

The results of our investigations will be published in open access journals appropriate for subject matter, 3Rs and scientific impact. All manuscripts will follow the ARRIVE guidelines [Kilkenny et al., 2010. PLoS Biol 8(6): e1000412] to promote accurate reporting appropriate for 3Rs initiatives.

Following the key project milestones we will attend international conferences (e.g. the World Association for the Advancement of Veterinary Parasitology Conference and the International Symposium of Parasite Infections in Poultry) to communicate progress and to emphasise the focus on refinement and reduction in this project, highlighting crossovers in

disciplines. We will attend the British Society for Parasitology Annual Spring meeting each year to communicate these aspects. We will interact with scientists on the Interreg Europe project MITECONTROL and the networks which remain from the EU COST Action FA1404 “COREMI” which promotes sustainable control of the poultry red mite through co-operation and multidisciplinary networking between scientists and stakeholders from member states. Through these networks we will make our technologies and findings, and thus the benefits of refinement and reduction in animal use, available to EU scientists.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 1100
- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Poultry red mites are obligate parasites - they can only survive if fed the blood from birds. In this project we will use adult birds as they are able to mount good immune responses to any vaccines that we are testing and, when we need to take blood samples from them, we can minimise the numbers of procedures required to obtain sufficient volumes of blood.

Typically, what will be done to an animal used in your project?

Birds will typically be injected with vaccines and blood taken from them to monitor their immune responses. Small areas of feathers may be plucked from the birds' legs to allow access to monitor vaccine efficacy. Experiments may typically last between 10 and 20 weeks and birds would typically receive 2 injections of vaccine during that period and have 5 blood samples taken.

What are the expected impacts and/or adverse effects for the animals during your project?

Injection may cause transient pain, though previous studies have indicated no or minimal reactions at the site of injection of red mite antigens. Vaccines will be prepared using sterile technique to avoid introduction of infection. Following feather plucking, mild transient discomfort may be caused. This will be mitigated by plucking small areas.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?
The expected severity for all procedures is expected to be mild, for all animals.

What will happen to animals at the end of this project?

- Killed
- Kept alive

- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Dermanyssus gallinae (poultry red mite) is an obligate but off-host parasite requiring to regularly feed on blood to complete its lifecycle, and has many similarities with ticks. The population of the poultry red mite is thus maintained through a complex interaction with the host.There is thus no practical alternative to the use of birds to test the efficacy of a vaccine to control this parasite. Searches for potential alternatives to the hen model using the current (24th August 2021) resources of the Fund for the Replacement of Animals in Medical Experiments (FRAME http://www.frame.org.uk) and the National Centre for the Replacement Refinement and Reduction of Animals in Research (NC3Rs http://www.nc3rs.org.uk) have not yielded any useful alternative models. Laboratory-based blood feeding techniques are available to test the immediate effects of specific antibodies, which are incorporated into the blood meal. In addition, an on-hen feeding device is available to ensure accurate assessment of the efficacy of the vaccines prior to field trial. Although both these technologies still rely on the use of birds, the numbers of both birds and procedures required are very low compared with other methods of vaccine testing.

Which non-animal alternatives did you consider for use in this project?

None are currently available.

Why were they not suitable?

None are currently available.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based on published data for the numbers of hens required for laboratory and field experiments to test a poultry red mite vaccine within the timescale of the licence and on the numbers of geese to be used as blood donors for parasite colony development in the same period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All animal studies have been, and will continue to be, planned in consultation with professional statisticians prior to submission to our local AWERB in order to provide

adequate group sizes for the most appropriate statistically robust analyses while minimising the number of experimental animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Analysis of efficacy and variability in our results will be used to inform a possible reduction in hen numbers in each treatment group in future experiments, with the proviso that reduction in numbers of experimental animals will have minimal impact of statistical significance of results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The poultry red mite is a specific problem for domesticated poultry which are, therefore, the only realistic choice of animal for these studies. The pathogens to be investigated in this project are obligate parasites and the model animals being used in this project are also the ultimate target species for any therapeutic emerging from the project. The models to be used include a mite challenge model where we test antibodies against mites in small-scale laboratory trials. While this requires a source of avian blood for the model, it reduces the numbers of animals required as a single blood sample can be used for testing antibodies (derived from eggs) against a range of antigens. To assess prototype vaccines in birds, we will also use a recently-published parasite feeding device in small scale trials involving only 5 birds per treatment group to remove sub-optimal vaccines. This technology was recently awarded the International 3Rs prize for it’s impact on both reduction and refinement of procedures.

Why can’t you use animals that are less sentient?

The parasite is specific for birds and terminal anaesthesia is not appropriate for procedures with a mild severity.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring post procedures will identify any areas which require refinement. For example, animals are closely monitored following vaccination and, if any of the compounds administered cause pain, appropriate analgesia will be administered

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where appropriate, the World Association for the Advancement of Veterinary Parasitology guidelines for best practise will be followed https://www.waavp.org. In addition, the

ARRIVE guidelines 2.0 and PREPARE guidelines will be followed to allow the experiments to be performed in the most refined way and the publication of the data in the most appropriate form. (https://arriveguidelines.org/ https://norecopa.no/prepare).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The host institution holds numerous NC3R research grants and has regular contacts with this body. In addition, we have an active 3Rs committee, which provides advice to project and personal licence holders. Any relevant advances in the 3Rs will be implemented into any of the protocols where appropriate.

39. New therapeutics for inflammatory bowel conditions

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Inflammation, Intestine, Therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to facilitate drug discovery and development for the treatment of inflammatory bowel diseases (IBD) in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The incidence of inflammatory bowel conditions, such as Crohn's disease and Ulcerative Colitis (UC), is increasing in the developing as well as the developed world. This increase may be driven by changes to the types of bacteria that live in the gut, as a result of the increasing amounts of processed foods that we eat, and other environmental factors that we are exposed to, such as chemicals. These changes may trigger an unwanted

inflammatory response in the bowel. An individual's genetic make- up is known to influence their risk of developing long-lasting inflammation.

Inflammatory bowel diseases can be socially-debilitating due to the discomfort, pain and diarrhoea that they can cause; they can also get worse with time and can lead sufferers to develop other life- threatening diseases, such as bowel cancers. As the disease gets worse, patients require more powerful drugs to keep their disease under control. The drugs themselves have unwanted side-effects, such as immunosuppression, leaving patients vulnerable to infection. As a result of damage caused by the inflammation, the bowel may become narrow or stick to itself, or stick to the inside of the body wall (adhesions). Narrowing of the bowel may result in blockage and the adhesions can results in holes forming between different parts of the bowel, or between the bowel and the outside of the body; these issues require patients to have surgery to have the damaged bowel removed.

There is, therefore, an unmet clinical need for new treatments which are more effective, with less side effects.

What outputs do you think you will see at the end of this project?

The principal output from the project will be decisions on the potential for new drugs to treat inflammatory bowel diseases in humans. The identification of new drug targets may also be possible.

Where appropriate and permissible, data will be shared with the wider scientific community, through presentation at relevant scientific meetings and publication in peer-reviewed, open-access journals.

Who or what will benefit from these outputs, and how?

Primarily, the scientists who have developed new therapeutic strategies and agents for IBD will benefit from being able to make decisions about research priorities. Other researchers pursuing similar goals may benefit from what we find out, by making appropriate choices of experimental models or therapeutic approaches; for example, based on findings that may be presented or published by ourselves or our collaborators. Ultimately (although not within the lifetime of the project), it is hoped that people suffering with inflammatory bowel diseases will directly benefit from the output of the studies that we have been part of, with the availability of new treatments.

How will you look to maximise the outputs of this work?

Work output is dependent on using personnel who are trained and competent in all the experimental techniques required to deliver the aims of the project.

Planning and management of the studies undertaken are also critically important, particularly with regard to the choice of the correct experimental model and design of experiments, so that studies are fit for purpose.

Finally, data must be analysed and communicated effectively in order to ensure that their meaning is fully appreciated and that appropriate conclusions are drawn, and decisions made.

Underpinning all of the above, is the maintenance of animal welfare and the application of humane endpoints, in order to maximise the quality of the data obtained from a study.

Species and numbers of animals expected to be used

- Mice: 3750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using young adult mice in this project. This reflects the age at which first diagnosis of IBD is most common in humans. Adult mice will have a fully mature gut, including the presence of established populations of microorganisms within the gut. The use of animals allows us to investigate whether drugs can prevent disease and reverse established disease. These models provide essential information for making important decisions during the drug development process. Mice are the animal of lowest sentience in which we can perform these investigations.

Typically, what will be done to an animal used in your project?

In this project, mice will develop colitis (inflammation of the large bowel), that is similar to Crohn's disease and ulcerative colitis in humans. Induction of colitis is achieved in one of three ways: a chemical may be used to cause the inflammation; the mice may have been bred to have a mutation which results in them spontaneously-developing intestinal inflammation; finally, inflammation can be induced in mice which lack a fully functional immune system by injecting them with certain types of white blood cell from a normal, healthy mouse. The mice with colitis will then be treated drugs to see if they can prevent the development of the disease, or if they can reverse the disease process. These drugs may be administered by injection or given by mouth; they can also be administered in the animals' food and drinking water. Sometimes it may be necessary to perform small studies so that we can gain better knowledge of how and when we should give the drug to treat the disease, and what dose of the drug we should use. Blood may be sampled during the study. Mice can be administered compounds, in addition to the candidate therapeutics being tested, in order to measure changes associated with inflammation; subsequently, these compounds may be measured in blood samples. At the end of the study, mice will be humanely killed and tissues and blood taken for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that most mice will develop diarrhoea (soft and unformed stool) to some extent, unless they are receiving a drug that prevents the disease. The diarrhoea may be associated with weight loss, or reduced weight gain relative to mice that do not have colitis. The diarrhoea can make the mice dehydrated; the chemicals used to induce the colitis may result in some blood being observed in the stool. It is expected that there will be some observable decrease in the overall body condition of the mouse. The mice can experience some discomfort because of the colitis and this may show in the way they move around. The mice can be less inclined to stand or climb to feed from their food

hopper, so food intake may be reduced. Very rarely, there is the risk that a mouse may develop a non-resolving rectal prolapse. Mice may be expected to show mild clinical symptoms for a few days to a couple of weeks in some studies. The implementation of humane endpoints will limit the duration of more severe symptoms.

During the study, repeat injections may cause local irritation at the site. Mice may be restrained for the purpose of blood sampling from the tail vein, which may cause transient distress. Minor pain/discomfort may be experienced when blood is sampled. Very rarely sites of injection/sampling may become inflamed or infected. Discomfort from these procedures should be transitory and last for less than a minute

Some strains of mice used are immunodeficient and so are more prone to developing infection, such as inner ear infection, although this is rare. Cells from a mouse with a normal immune system can be used to induce intestinal inflammation in the immunodeficient mice; very rarely, these cells may cause inflammation in another organ, such as the lungs. Symptoms of these adverse effects will be recognised in routine welfare checks and limited by the application of humane endpoints.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

mild or less: 20 % moderate: 80 %

severe: not expected

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The gastrointestinal tract is perhaps the most complex organ system in the body. It must provide a physical barrier and is responsible for processing food, absorbing nutrients and excreting waste – all of which are continuously trafficked through the gut. It can be regarded as the largest organ of the immune system and is a first line of defence for the body, against invasive microorganisms. It contains more than 100 million nerve cells. It is home to several hundred species of microorganism, of which not all have been identified; in addition, not all can be grown in a laboratory. Gut health depends on the complex interaction between the cells that line the gut (epithelial cells), the immune cells in the gut and the bacteria (the gut flora). Modelling the complex interactions between the intestine and its immune system and the microorganisms that live in the gut is very difficult; cell culture models are only able to partly recapitulate this. The mouse models of inflammatory bowel disease demonstrate similar features to the disease in humans, such as the dependence on gut bacteria, the types of immune cells involved and the response to a

range of therapeutic agents. The animal models of colitis can also be predictive of drug action in humans; we have observed this with respect to a range of new drugs that have recently been licenced for treatment of IBD in humans.

Which non-animal alternatives did you consider for use in this project?

Three dimensional cell culture models using human cells are currently being developed. Initially, the complexity of these models will be low, allowing only a direct assessment of how the intestinal epithelial cells (the cells that line the intestine, forming the physical barrier between the inside and the outside of the body) repair following injury and how experimental drugs can modulate the repair mechanism. Subsequently, it is hoped to introduce other components to the cultures, such as immune cells and bacteria (or molecules derived from bacteria). Other laboratories (both academic and commercial) are also developing similar models; we are collaborating with one such laboratory.

These culture models allow us to look at how molecules directly affect the intestinal epithelium, the single layer of cells that line the gut. For example, they can be used to determine if molecules have effects that may be beneficial to the regeneration of this epithelial cell layer, such as changes to how fast the cells divide, changes to the proportions of cells with different functions within this layer, and how good this layer of cells is in forming an effective barrier to microorganisms. The 3D cell cultures can also be used for toxicity screening, which can help in eliminating candidate therapeutics from a pre-clinical development programme.

There will be an initially slow, but progressive accumulation of data that will allow us to compare the outcomes we observe in the cell culture models to those we see in the animal models. The ultimate goal will be to replace, where possible, the need for animal studies.

Why were they not suitable?

The three-dimensional cell culture models currently lack the complexity required to allow any definitive determination of the effectiveness of new drugs to treat IBD in humans. As mentioned previously, we are looking to improve these models and have a programme of cell culture model development in place.

The development of non-animal models depends on the availability of human donor material. The prospective acquisition of such material requires ethical approval and patient availability and so is a slow process (made slower by the current pandemic).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals quoted is based on animal usage over the term of the current licence. The figure quoted is for the whole five year period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When determining the number of treatment groups (and, therefore, animals) required for a study looking at the effectiveness of a new treatment for IBD, the following groups must be considered are:

Untreated (non-disease, baseline) controls, a reference control (a drug known to reduce disease, which is used as a benchmark for the Test drug or drugs) and a relevant placebo control for the reference (e.g. an inactive molecule with a similar structure, or the medium in which the reference drug is formulated).

The remaining groups in the study will be for the Test drug and its placebo control. Careful consideration is given to the range of different doses of drug that may be used in order to reduce the number of treatment groups and, therefore, the number of animals. The range of drug concentrations used is often based on previous studies using the drug, either in another animal disease model or in cell culture experiments; this can also be based on results from studies using similar molecules. These studies may have been conducted by ourselves or others.

The size of the effect we are looking for in response to a drug will influence the number of animals that we use. This has to be realistic and can be based on previous work using similar drugs. The smaller the improvement in disease that we want to detect, then the more animals that need to be used. We commonly set a threshold for being able to detect a 25 % reduction in disease with reasonable certainty.

Testing more than one drug in a study is a good way of reducing the overall number of animals used. In this way, we can minimise the number of mice used for control groups, particularly if the drugs are administered in the same way and at the same frequency.

We continuously review the data that we obtain from our studies in order to monitor how our models and or reference drugs and controls are performing. These data reviewed by independentstatistical experts in order to inform us of the correct number of animals to place in treatment groups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We may perform small pilot studies in order to measure the concentration of drug that is achieved in the blood and in the intestinal tissue following its administration; this will be done with small numbers of mice per group (five or less), with one group per concentration of drug. Such studies can inform us of the most suitable concentrations to use in a bigger study to look at the effect of the drug on disease. The range of concentrations tested will be within the toxicity limits of drug; this will have been determined by previous work by other laboratories, based on animal studies and/or cell culture experiments.

We always seek to maximise the amount of information that we can obtain from each study. This is achieved by collecting clinical observations during the study and collecting as many tissue samples as possible, for analysis at the end of the study. We have available a wide range of analytical platforms to support our studies and give us access to multiple readouts that can inform us about different aspects of a drug's ability to suppress intestinal inflammation. In collecting as much data as possible from each study, we minimise the risk of having to run another study in order to gain further knowledge.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse models of inflammatory bowel disease. These models are well-characterised in terms of their biology and the onset of symptoms can be predicted and so a suitable frequency of monitoring animals for welfare purposes can be established and incorporated into study protocols. This also allows us to make informed decisions about when it is appropriate to end a study, according to the question we are trying to answer (by running the study). Humane endpoints are employed. All mice are humanely killed at the end of each protocol.

Why can’t you use animals that are less sentient?

Immature animals cannot be used as the intestine will not be fully mature and the population of microorganisms found in the intestine is also likely to be immature. These factors have a direct influence on immune responses in the intestine. The Zebrafish can be a useful model for studying genetic influences of intestinal inflammation, but testing candidate therapeutics can be challenging in such an organism and the skills and tools required to perform some of the analyses that are required are limiting. Our ultimate aim is to replace animal models where possible, so it is our opinion that our resources are best focused on this aim rather than establishing and validating another animal model. Mouse models are also the best-characterised and well-established models of IBD and employed by key opinion leaders in this field of research.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are monitored at least once daily and clinical observations are recorded. Data are reviewed daily in order to assess if any intervention is required. There are defined points in studies when mitigation such as mash food and increased frequency of observations are introduced. Appropriate guidelines will be followed with regard to best current practice for blood sampling and administration of substances to the mice.

During the project, we will operate a process of continuous review to ensure that the models we run are fit-for-purpose. This involves looking at all the data that we collect and seeing how it may change with time. We can then make appropriate changes to ensure that disease is not too severe, or that models run no longer than they have to.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will perform procedures according to our own standard operating procedures. We will also follow guidelines issues by the Joint Working Group for Refinement. *Lab Animals* (2001) doi: 0.1258/0023677011911345 and guidance from the NC3Rs, as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the 3Rs advances through attendance at lectures and seminars run locally, as part of a continuing professional development programme; through the 3Rs website; by keeping up with the latest scientific publications in the field.

40. Vaccination and Antibodies for Disease Protection

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Vaccines, Antibodies, Immunology, Disease Prevention, Therapeutics

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop and optimise vaccines or antibody-based interventions against disease targets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines are the pre-eminent cost-effective tool for reducing the burden of infectious disease, and it is the immune responses (especially antibodies) they induce that underpin their success. Indeed, in the past century, widespread vaccination campaigns led to the eradication of smallpox in humans and rinderpest in cattle, with polio also now on the brink; whilst most recently, the global success with new vaccines against Covid-19 has provided a route out of the pandemic. However, despite these great achievements, many difficult diseases remain against which highly effective antibody-mediated immunity fails to arise or for which effective vaccines have simply not been developed. In addition to the

known ‘big killers’ (malaria, tuberculosis and HIV), emergence and re-emergence of outbreak pathogens has become a serious threat to human health and the global economy, as exemplified by the SARS-CoV-2 pandemic and the previous 2015 Ebola virus epidemic. New approaches are also needed to tackle diseases in the ageing population.

In parallel to these advances in vaccines, antibodies have also made a huge impact in the field of biologics. Monoclonal antibodies (mAbs) have become essential treatments for inflammatory and autoimmune conditions, as well as cancer. With the more recent deployment of mAbs as treatment for Ebola virus and Covid-19, there is now renewed interest in the development of antibody-based biologics for other challenging infectious diseases.

The development and optimisation of new vaccines and antibodies against disease targets is thus critical to on-going efforts to improve global public health.

What outputs do you think you will see at the end of this project?

The below outputs are expected to arise by the end of this project:

- At least 10 peer-reviewed open-access scientific publications.
- At least 15 data presentations at scientific meetings or national / international conferences.
- At least 2 patent filings on arising intellectual property (IP).
- New information on vaccination strategies to achieve better immunity, prophylaxis or therapy for human malaria.
- New vaccine candidates and/or antibody biologics will be defined for human malaria that are ready to progress to clinical development.

Who or what will benefit from these outputs, and how?

- This project will mainly focus on the development of new vaccine and antibody candidates against the human malaria parasite. However, the technologies and approaches being used can be easily applied to other disease-causing pathogens, including viruses and bacteria, of humans and animals. We have a primary research interest in malaria parasites and vaccines, but also contribute our expertise to a number of other projects related to the prevention of human diseases such as Ebola, Covid-19, thalassaemia.

- We also work on vaccine platforms, i.e. new technologies that can be used to deliver vaccines. Typically we innovate in this area for malaria, because it is a very challenging disease target. However, often, the new vaccine platforms we develop can be easily transferred and used for other disease targets, e.g. pandemic viruses. In the medium/longer-term this means our outputs can find utility in a variety of different disease settings.

- The wider scientific community typically benefit from conference presentations (short-term) and publications (medium-term). New discoveries in malaria vaccine science are often broadly applicable across numerous disease areas (of humans and animals), meaning advances can be relatively quickly applied to other fields following presentation/publication of new knowledge.

- Arising IP for new malaria vaccines/biologics typically necessitates *in vivo* animal data. New patent filings bring benefit to the economy through licensing deals to companies

(can be short, medium or long-term dependent on the nature of the IP).

- New information on vaccination strategies and new vaccine/antibody candidates bring benefits to science and the economy in the short/medium term, as future clinical development projects are funded and undertaken. The ultimate beneficiaries of new vaccines/antibodies in the long-term are the public (human health) and/or animals (veterinary health) when new products are licensed to prevent and/or treat disease. The ultimate manufacturer of the biomedical product would also benefit financially and contribute to the long-term growth of the economy. In the case of malaria vaccines/antibodies, the ultimate beneficiaries of these products in the long-term are those individuals living in malaria-endemic countries (including those in Africa, Asia and South America).

How will you look to maximise the outputs of this work?

- We disseminate arising new knowledge by regular presentations at a wide variety of meetings/conferences (for scientists or relevant stakeholders / funders / health policymakers). We also publish arising data in peer-reviewed open-access scientific journals. We include all relevant data, regardless of whether the outcome would be deemed "successful or unsuccessful" in terms of vaccine improvement/development.

- We collaborate widely with numerous academic research groups and/or industry (biotech and pharma) at local, national and international level. Collaboration enables knowledge transfer andsharing of best practice.

- We participate in numerous national and international networks that are relevant to vaccine design, testing and development and enable sharing of new knowledge. New approaches/insights/breakthroughs in vaccines are typically transferrable to other disease targets in a short time frame.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use adult mice (from 6 weeks up to 15 months of age).

It is not possible to generate complex antibody responses outside of a functioning immune system in an animal. Mice represent the lowest order of species to enable us to meet the project's objectives.
The work is seeking to understand the immune response in an adult animal with a fully matured immune system, hence adult mice are used.

In some cases genetically modified mice will be required in order to understand the mechanisms by which we can develop improved vaccines and/or to enable specific types of antibody response to be induced. These genetically modified mice may also be bred for

use in this project.

Typically, what will be done to an animal used in your project?

The majority of mice will be vaccinated with a vaccine formulation intramuscularly on three separate occasions, typically at monthly intervals. Small blood samples will be taken from tail veins prior to each new vaccination to monitor antibody responses in the blood over time. Mice are typically killed 2-4 weeks after the last vaccination to measure systemic immune responses or to isolate antibodies from cells or serum. Most experiments are thus approximately 3-4 months' duration. If a longer experiment is required, mice will not be kept past 15 months of age.

Separately, genetically modified mice may also be bred for use in this project.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice may experience short-lived general malaise following vaccination, with mild symptoms persisting for 24 hours, just as occurs in humans.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 50% Sub-threshold, 45% Mild; 5% Moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune response to vaccination involves multiple, complex systems interacting in a physiological environment often involving antibodies, T cells and innate cells and therefore cannot be replicated in tissue culture. It is also not possible to generate complex antibody responses outside a functioning immune system in an animal.
Which non-animal alternatives did you consider for use in this project?
Wherever possible we replace the use of animals to study vaccines and/or generate antibodies.

We have developed a number of new *in vitro* assays that have allowed us to replace the need for animals to test the function of the antibodies that we induce by vaccination.

We use human cell samples from vaccine clinical trials to isolate antibodies *in vitro*.

We use *in silico* or *in vitro* methods to design/isolate antibody variants that could show improved potency.

Why were they not suitable?

In some cases it is simply not possible to answer scientific questions without vaccinating animals. However, we deploy a variety of state-of-the-art techniques that are highly complementary. As such, *in vivo* animal work provides a major avenue of scientific investigation, but it is one of many. We are thus able to use many other *in vitro*, *ex vivo* or *in silico* techniques to maximise knowledge gain first about vaccines and/or antibodies, and replace the need for animals wherever possible.

For example, it is not possible to fully optimise a new vaccine technology without confirming its ability to induce a physiological immune response. However, we use a variety of complementary scientific approaches to achieve this aim. Numerous analytical techniques are applied first *in vitro*, and only the most promising vaccine candidates are then assessed by *in vivo* immunisation.

Another example is the need for animal immunisation if no relevant human samples exist from which to isolate antibodies; these might include highly novel targets in a pathogen.

Similarly, *in silico* or *in vitro* methods rely on computational analysis or laboratory-based systems respectively which may not always be optimal, correct or able to out-perform nature's ability to improve or "mature" antibody potency by a functioning immune response.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

These numbers are based on prior experience and equate to 1800 mice per annum for 5 years. This includes:

- Breeding of 1200 mice per year (or 6000 in total for 5 years); and

- Experiments, whereby a single researcher may typically undertake an experiment with 30-36 mice; assuming 6 test groups of group size = 5-6. Three experiments of this typical size per year, would be 100 mice per researcher. Based on experience, with six research scientists working on the project, this would total 600 mice per year; 3000 in total for 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Throughout the project we will employ several strategies to reduce the number of animals used:

Prior to experimental work, statistical power calculations will be performed allowing use of

the smallest number of animals needed to provide satisfactory analysis of the data. We will also conduct our experiments so that we comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines) when we publish the results. We will also continuously evaluate and update our statistical approaches and group sizes, and make routine use of the NC3R's Experimental Design Assistant (www.nc3rs.org.uk/experimental-design-assistant-eda) and PREPARE guidelines (https://norecopa.no/prepare).

Past experience and/or new knowledge enables selection of experimental time-points that maximise the amount of data while using the minimum number of time-points.

Many experiments necessitate the inclusion of control groups to enable the comparison of new vaccines to a gold standard or most-promising vaccine to date. To minimise the repeated use of control groups, as many test conditions as possible will be included in an experiment. However the overall size of experiments will be limited as far as may be possible without compromising their scientific integrity. We will also aim to show statistical reproducibility of results with repeat control groups (e.g. those receiving a gold-standard vaccine), which would also allow for use of one control group across multiple future experiments.

Vaccine dosing experiments have provided us with reference data that allows us to select optimal antigen doses for investigation of immunogenicity. This has led to a reduction in the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible the data from each individual animal will be maximised through the collection of multiple tissue samples at endpoints and/or sequential sampling from the same animals across a time course, e.g. blood sampling during a vaccination time course.

The number of excess mice generated through breeding will be minimised by constant and careful monitoring of breeding programmes.

We are continuously refining/improving our antibody isolation methods, meaning fewer animals are needed to isolate rare/potent antibody clones of interest.

When testing new / exploratory vaccine technologies or approaches, pilot studies in a small number of mice will be performed to confirm viability of the approach (e.g. that an appropriate immune response is definitely observed and that there is no unexpected reactogenicity) prior to initiating larger experiments to test more variables.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

During the project we will vaccinate adult mice, and assess the immune responses. Blood samples may be taken to monitor responses over time. We continuously investigate ways to refine our techniques to minimise animal suffering.

Most vaccines used in humans cause transient local and/or systemic general malaise. This resolves within 24 hours. Some humans experience no side effects, whereas others experience some. It is not possible to predict. Consequently, it is necessary and inevitable that some animals may experience the same transient moderate general malaise when receiving clinically-relevant vaccine formulations.

Our previous experience ensures we can reduce the number of blood samples to only the key time- points post-vaccination. As the primary focus of our programme is clinical deployment, we primarily use vaccine delivery platforms that have been approved for use in humans and have minimal side-effects.

We also select routes of immunisation based on clinical relevance (e.g. intramuscular route will be the most commonly used route given that most human vaccines are delivered by this route, or alternative routes will be assessed if clinically relevant to the specific type of vaccine under study, e.g. the intranasal route would be used to assess delivery of a vaccine against a respiratory pathogen to the lungs).

Why can’t you use animals that are less sentient?

Mice represent the lowest order of species which will achieve the objectives of this project. Despite extensive efforts in the fields of immunology and vaccine development, there is no available alternative *in vitro* to using animals for the faithful induction of immune responses associated with vaccination. We have chosen adult mice for these studies since they are the most characterised species for detailed immunological analysis. Mice have proved to be excellent indicators of immunogenicity enabling the clear assessment of novel vaccines and vaccination regimens for improvements.

Mice also have the ability to raise highly effective and functional antibodies, many of which have ultimately led to licensed biologicals for human disease. Because of the numerous different immunological tools available, mice can also be used for detailed characterisation which is not possible in higher organisms and they also provide the unique opportunity to study the role of particular genes in the induction of an immune response by using genetically modified mice with defined gene modifications.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Routine vaccination requires use of needle and syringe as there is no alternative. Some needle-free technologies are in development by others, but remain highly specialised, in development, not easily accessed and not applicable to routine use. Chosen routes of administration are determined by clinical relevance and/or scientific experience. To minimise distress due to administration of substances, guidelines on volume limits are followed and the smallest needles possible will be used.

Blood sampling is performed from a superficial vessel in the mouse tail. Monitoring of immune responses in the blood is necessary, routine and clinically-relevant. From our past experience characterising the kinetics of the immune response, we are able to minimise the number of blood samples such that blood is taken at the most informative time points

post-vaccination depending on the type of immune response we are measuring.

When using a new type of vaccine, small pilot studies will be performed and mice will be checked at least once per day for at least 5 days and monitored for signs of general malaise.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All researchers will routinely discuss their techniques with the NVS and NACWO to get advice on refinement.

All researchers will regularly review websites with 3Rs information to monitor for potential refinements including:

www.nc3rs.org.uk https://norecopa.no https://www.lasa.co.uk

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use local and national resources:

- All researchers will attend regular University/internal meetings where best practice on the 3Rs is shared.

- All researchers will regularly review websites with 3Rs information, including www.nc3rs.org.uk and https://science.rspca.org.uk.

41. Regulation of normal and malignant haematopoiesis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Blood lineage specification, Blood stem cells, Leukaemia, T-cell therapy

Animal types	Life stages
Mice	embryo, juvenile, adult, pregnant, neonate
Xenopus laevis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our main aim is to understand how blood cells are formed throughout life and the processes that convert normal cells into diseased cells with a focus on how aggressive leukaemia develops. This will guide efforts at understanding how to make blood cells to treat patients and to improve treatment of blood diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood cells are vital for oxygen and nutrient transport and to fight infections. When production of blood cells (haematopoiesis) is altered, leukaemia develops from rare cells

known as leukaemic stem cells (LSCs) that proliferate aberrantly and do not make normal blood cells. Understanding how blood cells are produced throughout life will help design methods to support to make blood for patients and identify novel therapeutic targets for treatment of blood malignancies and cancers and improve human health.

What outputs do you think you will see at the end of this project?

The specific outputs will be:

Refinement/establishment of new protocols for *in vitro* production of Haematopoietic Stem Cells (HSCs) from pluripotent stem cells or patient-specific cells.

Improvement of bone marrow transplantation technology and stem cell therapy through better ability to maintain, expand or direct the differentiation of HSCs.

Insight into the molecular and cellular processes by which normal blood stem/progenitor cells are transformed into leukaemic stem cells.

Development of less toxic and more effective rational combination therapies to eliminate leukaemic stem cells.

Development of sensitive tools to monitor residual leukaemic stem cells that could give rise to relapsed disease.

Who or what will benefit from these outputs, and how?

Short-term benefits: Mechanistic studies of blood production during embryogenesis will benefit developmental haematologists and, more broadly, developmental biologists as these will generate general principles. Molecular studies of production of normal adult cells and of leukaemia initiation and relapse will be of interest to the researchers studying both normal and malignant haematopoiesis as this will provide insights into fundamental oncogenic mechanisms. In leukaemia, identification of new therapeutic targets will be the first step towards development of new drugs. This will be of interest to the pharmaceutical industry.

Medium-term benefits: The ability to maintain, expand or direct the differentiation of HSCs will directly benefit clinical practices and patients requiring blood stem cell transplantations, by reducing transplant-related toxicity and death (currently, 5-10%). Newly designed therapies (for example human T cell therapies or combined therapies) will offer major improvements in the treatment and management of patients with leukaemia (acute myeloid and other types).

Long-term benefits: Patients with single gene blood disorders are currently treated with HSCs from donors (allo-HSC transplantation) with major issues due to lack of suitable donors and, when a donor is found, up to 40% mortality rate due to rejection of the graft. The ability to generate blood stem cells *in vitro* from patient-specific cells (auto-HSC transplantation) will benefit many haematology cell-based therapies. This would increase the survival rate currently achieved through allo-transplantation.

How will you look to maximise the outputs of this work?
We will disseminate our results at scientific conferences and in publications (choosing open access and general, rather than specialised, journals for broader dissemination), as well as through public engagement and engagement with patient groups. We will make

any new genetic tools and mouse models available to the scientific community through collaborations and deposition in appropriate public repositories for mouse strains. We will engage with clinical scientists and industry to translate therapeutic strategies towards clinical use.

Species and numbers of animals expected to be used

- Mice: 16300
- Xenopus laevis: 40

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Justification of species: Our studies ultimately aim at dissecting the regulatory mechanisms supporting production of human blood stem cells and at understanding how blood malignancies develop. Some of this work will be performed *in vivo* and we have chosen to work with mice, the lowest vertebrate species with similar physiological characteristics to humans. Mice are also the model of choice for genetic modifications of genes of interest for functional studies. In addition, the mouse is sufficiently similar to humans to allow human cells to be propagated *in vivo* using xenografting of immune-deficient animals. Lower vertebrate species such as frogs share key regulatory mechanisms with mammals and we also use this model organism for specific aspects of our studies.

Justification of life stages: Development of the blood lineage initiates at around day 7 to day 8 of mouse embryonic development (days E7-E8) and the first blood stem cells emerge at day E10. We will therefore focus our studies of developmental haematopoiesis around these stages and the corresponding stages of frog embryo development. In mice, the hematopoietic system reaches its adult state around weeks 4 to 5 after birth. We will use juvenile and adult mice to study normal haematopoiesis and how malignant haematopoiesis emerges and develops.

Typically, what will be done to an animal used in your project?

The majority of mice (60-70%) will be involved in breeding and maintenance only and will not experience any procedures. Moreover, a proportion of our work involves the study of embryonic stages before day 14 of embryonic development prior to protection under ASPA.

Experimental mice will undergo the following typical experiences:

Induction of gene expression in pregnant mouse females by substance administration (up to 3 times by intra-peritoneal injection), followed by humane killing and embryo harvesting.

Transplantation of blood cells into mouse tail vein or the femur following sub-lethal irradiation; administration of substances into the peritoneal cavity once a day for up to 28 days; blood sampling; bone marrow sampling (up to four times in total). Mice will be humanely killed.

Subcutaneous injection (up to 4) of primary human mesenchymal stromal cells by surgery; administration of human recombinant parathyroid hormone by subcutaneous injection daily for up to 28 days; transplantation of human blood cells transcutanouesly into the newly generated ossicles; administration of substances into the peritoneal cavity (once a day for up to 28 days) or into the ossicles (twice a day on a single day or once a day for up to 7 days); blood sampling; bone marrow sampling (up to four times in total). Mice will be humanely killed.

Subcutaneous injection of hormone into female Xenopus to induce super-ovulation; Humane killing.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts include transient discomfort or pain when substances are administered, when cells are injected, blood or bone marrow samples taken, and after surgery.

Development of hematological malignancy can be associated with fatigue due to anaemia. Rarely, the animal can experience more than moderate anaemia and show additional clinical signs, such as weight loss or not grooming appropriately. As soon as these signs appear, the experiment will be terminated.

Irradiation prior to bone marrow transplantation can cause transient mild anaemia for a few days.

Surgical procedures may rarely be associated with skin infection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse:

Sub-threshold severity: 65%

Mild severity: 5%

Moderate severity: 30%

Xenopus

Mild severity: 100%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This programme investigates blood formation during early embryonic development, the adult bone marrow and leukaemia initiation and propagation in the marrow and throughout the blood. All of these biological processes happen in a highly complex environment. In development, blood formation occurs at a time of active cell migration through numerous cellular niches. In adults, the bone marrow is a highly complex tissue composed of many cell types. All of these processes occur in the setting of whole animal physiology, with metabolic changes and changing responses to multiple environmental challenges. Today, we do not have enough information to accurately model these processes *in vitro.* Moreover, *in vitro* studies do not mimic the metabolism, the complexity of engagement of the drug with different targets and the animal's and disease response to therapy. For obvious reasons, we cannot study the impact of untested therapies directly in patients. Therefore, *in vivo* models are required for our work.

Which non-animal alternatives did you consider for use in this project?

We have used and are still extensively using embryonic stem cells as well as haematopoietic cell lines than can grow using *in vitro* culturing methods as they allow some mechanistic insight and generate preliminary data.

Some aspects of blood cell differentiation and both normal and malignant stem cell maintenance can be mimicked *in vitro*, and we pursue these as methodologies when the question can be appropriately answered by *in vitro* techniques. In particular, we have considered the use of *in vitro* cultures for the maintenance and differentiation of haematopoietic stem cells, and for maintenance and screening of malignancy-propagating cells.

We are currently generating *in vivo* models of transplantation with more efficient engraftment of human samples by creating humanised bone marrow ossicles. Going forward, this will help define the physiological conditions necessary for the maintenance and proliferation of normal and malignant human haemopoietic cells, therefore leading to the development of *in vitro* assays in replacement of *in vivo* xeno-transplantation assays.

Why were they not suitable?

Despite the improvement of *in vitro* culture systems over the past decade, these models only partially recapitulate the 3D organisation of the embryo and provide information outside a physiological context, thus limiting the type of experiments that can be performed.

While *in vitro* colony forming assays can reveal progenitor lineage potentials, they do not read out fate.

We have been able to propagate some malignancy-propagating cells *ex vivo*; however, they rapidly lose their malignant properties, emphasising the need for a better understanding of the environment that sustains them. While we will continue to explore the methodologies mentioned above, they currently do not adequately replace *in vivo* experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experiments planned for this license are similar in nature to experiments we are currently performing, and animal numbers have been calculated based on the number of projects currently ongoing and planned, and our long-standing experience with this type of research, assuming that the number of PILs working on the new license will be similar.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Breeding strategies have been designed to minimise the number of non-experimental mice generated (e.g. by generating homozygous lines where possible without generating adverse phenotypes). Once work is completed, unused colonies are frozen down promptly. We source wild-type and common reporter mice from central colonies to avoid redundant breeding.

Transplantations: the number of animals used in experiments are calculated to ensure meaningful data can be obtained in experiments whilst keeping surplus animals to a minimum. We generated a database of available human samples in our biobank that have been transplanted into mice before, with information on engraftment for each sample analysed. This way researchers can select from those samples to address specific questions and don't have to test a number of new samples by transplantation into mice to find a suitable sample. We use our transplantation models to address different research questions in the same experiments. This reduces the total number of transplantation experiments that have to be performed. We routinely use intra-osseous injection (as opposed to tail vein injection) to minimize the number of injected cells that are lost in circulation and improve engraftment of small and rare populations of haemopoietic cells. This will result in a reduction of the total number of mice used in xenotransplantation experiments. Moreover, new mouse strains for transplantation of human cells have been established. These strains enable engraftment of a higher number of samples and higher levels of engraftment, thus reducing the number of mice needed to answer a specific question, as more transplanted mice will be suitable for analysis and the obtained cell numbers will be higher. We continuously look for novel mouse strains to improve transplantation efficiencies of human cells. Finally, the use of ossicles and scaffolds to generate an *in vivo* xenotransplantation model are being tested to achieve even more efficient engraftment of human samples, therefore overall reducing the total number of animals used.

Xenopus: We purchase wild type frogs from stock centres. As these are established lines, we only maintain minimal numbers. We have reduced the number of animals used by carrying out in vitro fertilisation enabling multiple females to be fertilised by a single male. We reduce the number of frogs used by buying testes rather than live animals.

Downstream experimental techniques have been optimised on low cell numbers to reduce the number of mice needed for adequate data collection.

We regularly consult Norecopa.no and NC3Rs websites for advice on experimental design. We will be conducting our experiments according to the ARRIVE guidelines when we prepare for publications.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding strategy: Genotyping of transgenic animal is done promptly to keep colony size to a minimum. When possible, we breed either wild-type mice, or heterozygous and homozygous mutant mice together to produce the genotype needed (for experimental and control mice) and, consequently, minimise the number of mice to genotype. The colonies are only expanded at times of experimental need. We will plan experiments within the lab, and where relevant across labs, share tissues and cells from mice.

We always set up pilot experiments when implementing new cellular/molecular assays in order to optimise our protocols on low cell numbers and to use the minimum number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice: The use of bone marrow transplantation represents the most refined methodology for the identification and characterization of hematopoietic stem cells and haematological disease-propagating cells under physiological conditions. When required, irradiation is used for ablation of the endogenous hematopoietic cells. In many cases, this is a prerequisite for the transplanted cells to engraft. Irradiation is associated with transient discomfort. However, we will always use the least harmful methodology for transplantations, using sublethal or no irradiation where possible. When transplanting human cells, conditioning of haematopoietic cell transplant recipients with split radiation dosage to reduce morbidity and mortality to very low levels. We are also using immunodeficient mouse strains that allow for transplantation of human cells without irradiation conditioning. This reduces irradiation-related morbidity.

We avoid invasive techniques when administering drugs whenever possible by providing them in diet or drinking water rather than intraperitoneal injection. When required, invasive procedures are performed under general inhalation anaesthetic, and the animals are closely monitored after the procedure to ensure that normal function and behaviour is restored. Humane end points are refined during experiments to avoid unnecessary suffering of animals.

Xenopus: Haematopoietic development in Xenopus embryos shares many key regulatory pathways with higher vertebrates. Xenopus embryos are easily accessible and amenable to gene expression studies and genetic manipulations and are, therefore, an appropriate experimental model. To produce eggs for *in vitro* fertilisation, female frogs are injected with hormone by subcutaneous injection. This is the most refined and painless method to induce super-ovulation. To prevent the unnecessary use of animals, frogs that produce low quality eggs in two consecutive rounds of induction are humanely killed.

Why can't you use animals that are less sentient?

The mouse is the least sentient model with a haematopoietic system that sufficiently resembles the human haematopoietic system for the study of normal and malignant haematopoiesis to be relevant to human health.

The haematopoietic system only reaches its mature state 5 weeks after birth. To obtain results relevant to adult haematopoiesis, we therefore need to use adult mice. In addition, the vast majority of haematological cancers occur in adults, and their development occurs over an extended period of time, precluding the use of immature life stages and anaesthetised animals.**How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?**

Where required, local and systemic analgesia is administered immediately after a procedure. Mice are monitored once daily and up to 7 days, depending on the procedure, for signs of pain or adverse effects. Examples of post-operative care are provision of more analgesia for pain management, prophylactic antibiotics to prevent infections or palatable food at cage floor level in case of weight loss.

For mouse transplantation, we will use the least harmful methodology, using sublethal or no irradiation where possible, based on pilot experiments testing the feasibility of doing so.

For intravital imaging, we will seek the advice and training from researchers experienced in this technique (e.g. imaging facility of the MRC Weatherall Institute for Molecular Medicine or external experts) in order to ensure that no adverse effects result from terminal imaging.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgery will be performed following LASA aseptic surgery guidelines. We will use the NC3Rs Experimental Design Assistant (EDA) online tool or similar softwares to design experiments. We will conduct and report our experiments for publication according to ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All research staff working under this license will be encouraged to attend the annual institutional 3Rs day. We will consult the NC3R regional manager when necessary and relevant websites (NC3R, RSPCA Science group).

42. In situ molecular structures of the mammalian brain

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
Synapses, Memory, Alzheimer's disease, Advanced pathology, In situ structural biology

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of our research is to understand the structural basis of memory in the mammalian brain and how it is lost in Alzheimer's disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A key property of memory is that it is acquired within milliseconds yet retained for hours, days, months or even our entire lives. Importantly, long-term memory is not stored by on-going activity in the brain. Rather it is encoded by molecular and cellular structures. Therefore, investigating these molecular structures may give us insight into the mechanism of memory and how it is lost in neurodegenerative diseases of the nervous system.

Synapses are thought to be the molecular ‘microprocessors’ of the brain, mediate the correct ‘wiring’ of neuronal circuits, and mechanisms that are thought to be important for encoding memory.

My research exploits mouse genetic reagents and recent advances in cryo-electron microscopy to obtain in situ molecular structures of the mammalian brain, with a particular focus on synapses and neurodegenerative disease.

We use engineered mutant mice into which we have inserted genetic tags encoding fluorescent proteins. These tags are designed to label particular molecular structures within the brain and leave the healthy function of the mouse brain unimpaired. We also use fluorescent pharmacological labels where available. To investigate structures associated with neurodegenerative disease we use mouse models of Alzheimer’s disease. Of the existing models in vertebrate and invertebrate species, mouse models recapitulate the human diseases the closest.

Tissue samples collected from these labeled mice are frozen in vitrified state and imaged by cryo- fluorescent microscopy, wherein fluorescently tagged locations within the cells of the tissue are identified. We then image these samples on cryo-electron microscopy and map the locations. Next, we collect high-resolution images of the fluorescent locations as it is incrementally tilted in the microscope giving us different views. Finally, these views are computationally reconstructed to the in situ 3- dimensional structure. These experiments exploit advances in cryo-electron microscopy awarded the Nobel Prize in Chemistry 2017.

What outputs do you think you will see at the end of this project?

The major outputs of the research project:

Genetically altered mice

In situ structures of the mammalian brain.

Peer-reviewed scientific articles.

Who or what will benefit from these outputs, and how?

The mutant mice that we generate and use will provide a key resource for investigating molecular mechanisms of the mammalian brain and in the long term will contribute to devising mechanism-based therapies to treat diseases of the nervous system. These experiments will benefit the postgraduate students and postdoctoral research associates in training them in cutting-edge mouse genetic and in situ structural biology techniques. The in situ structures of brain that we acquire and insights gained from this information will be reported in peer-reviewed scientific articles benefiting the global neuroscience and Alzheimer's disease research community. The raw structural data and molecular models will be deposited in public databases, providing a resource for the scientific research community and pharmaceutical industry in perpetuity.

How will you look to maximise the outputs of this work?
I will maximise the outputs of this research by:

public engagement of the scientific discovery that we make.

I will promote the discoveries published from this project via press releases and social media announcements.

I will disseminate the research at international conferences, for example Gordon Research Conference 3DEM and AD/PD.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For several reasons, the project will use mice.

There is extensive knowledge of their neuroanatomy, physiology, and genome.

They have a similar genetic mark up to humans, sharing all but ~1% of each other's genes. The ability to manipulate the mouse genome permits the introduction of genetic alterations pertaining to human nervous disorders.

Typically, what will be done to an animal used in your project?

Mice will be housed and bred in a social environment whenever possible and provided with environmental enrichment such as chew sticks, fun tubes, nesting material, and platforms. Some mice will be left to age up to 15 months to allow development of the neurodegeneration which causes weight loss and progressive hind limb impairment. In some mice administer substances by a variety of routes, choosing the most suitable and least invasive route possible. Some of the routes will be non-invasive such as food or water. Other routes such as injection (under the skin, into the peritoneal cavity, into a vein, into a muscle), gavage, inhalation, intranasal will cause mice transient pain and/or transient stress. Some mice may receive surgical injections into defined areas of the brain: mice will be anaesthetised and a small hole will be drilled into the skull at the site of injection. Surgery mice will be given pain relief prior to recovery from anaesthesia and whenever necessary to alleviate pain as advised by the veterinarian. Following the administration of substances mice will be most often culled within 24 hours, whereas a minority of mice will be aged and to observe the possible development of neurodegeneration in brain and spinal cord, in which case these mice will experience weight loss and pain due to progressive hind limb impairment. At the end of experiments, mice will be humanely killed and samples collected for analysis. The mice may be killed under terminal anaesthesia by exsanguination to collect sufficient blood for protein.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of genetically altered and wiltype mice bred for use in procedures in this project will not experience adverse effects (subthreshold or mild severity). A small number of mice that carry a human mutation causing the accumulation of amyloid aggregates in

the spinal cord will experience hindlimb paralysis, mice do not suffer pain as this disease progresses (moderate severity). A small number of mice will experience transient pain that is not long-lasting through surgery with anaestetics or by the administration of substances to trigger neuronal activity (moderate severity).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Mild: 70%

Moderate: 30%

Severe: 0%

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The brain structure of all mammals is similar and so the mouse is best suited for this work since, of all existing models, mouse models are the closest to the human diseases.

We developing our cryoCLEM approach to work with ES cell-derived neurons. However, so far, we have found these cells do not develop to form mature synapses as found in adult mouse brain.
Additionally, cells do not provide physiological conditions, the complex interactions amongst different cell types, nor develop the anatomical specializations found in tissue.

Existing animal models of common neurodegenerative diseases exhibit the essential features of the human diseases, a necessary prerequisite for the identification and evaluation of disease modifiers. As such, they are true models of at least some of the molecular and cellular features of the human diseases. At present, no valid alternative model exists.

Which non-animal alternatives did you consider for use in this project?

We are collaborating with colleagues generating neurons from induced pluripotent stem cells grown in the laboratory. This would enable the use of neurons derived from skin cells to be grown into nerve cells.

Why were they not suitable?

While this is ongoing research, currently we have been unable to produce cells and synapses comparable to those in the mature mammalian brain. The development of 3D organoids by colleagues in my field may also contribute to generating 'lab-grown' mini-brains. Currently, we do not have available protocols to develop these tissues to maturity, which is necessary for studying memory and modeling neurodegenerative disease. In the long term, this approach may be a viable alternative to using mice.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The following considerations have influenced our estimate of the number of mice used:

The number of different genetically altered mouse strains.

The length of the project provided by grant funding.

The number of mice needed for each experiment that will answer our research questions with a high degree of confidence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Mouse breeding will be carefully monitored to ensure that surplus animals are not generated. We will use the minimum number of animals needed to give a statistically significant result. A statistical expert will be consulted regarding experimental design and the most appropriate statistical analysis. Prior experiments and expertise with the animal model used will be considered when deciding on the number of animals needed for an experiment. Cryopreservation is being used routinely to preserve important mouse lines and to remove the need to breed mice only to maintain a given line.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have performed pilots of our breeding strategy and established all the work-flows for obtaining high- quality in situ structures from mouse brains. Therefore, we have high confidence in the optimal number of mice needed for all our experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Existing animal models of common neurodegenerative diseases exhibit the essential features of the human diseases, a necessary prerequisite for the identification and evaluation of disease modifiers. As such, they are true models of at least some of the molecular and cellular features of the human diseases. At present, no valid alternative model exists. Only mice used in experimental studies will be allowed to develop neurodegeneration. Otherwise, only young mice will be kept.

Genotyping will be undertaken from ear biopsies except in those rare cases where more DNA is required when a tail biopsy will used.

When new lines are generated and bred for the first time, animal technicians will be specifically informed and the first litters carefully monitored. Any untoward phenotype will be discussed with the NACWO, veterinarian and if appropriate, the Home Office inspector.

The surgery will be carried out following "Guiding principles for preparing for and undertaking aseptic surgery" (2010) as closely as possible. Mice will be given analgesia prior to recovery from anaesthesia and whenever necessary to alleviate pain as advised by the veterinarian.

Why can’t you use animals that are less sentient?

We are investigating a key attribute of sentient animals, the structural basis of how memories are encoded in the mammalian brain. Therefore, less sentient animals at an immature life stage for example would prevent us from addressing this important fundamental question. Similarly, we are investigating the structural basis of Alzheimer's disease, in which patients' sentient attributes are eroded and lost, including memory. Thus, to model this disease in animals at a less sentient stage would not provide the best possible model of Alzheimer's disease. Alas, non-mice models, including invertibrates (eg. Drosophila fruit flies) do not have a nervous system sufficiently similar to that in mammals. Wherever possible we will use terminal anesthesia to perform experiments in animals that are less sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
Good handling and injection technique will minimise any minor/brief distress associated with the systemic administration of test substances. Where multiple daily injections are given, the injection site will be changed to minimise pain and potential inflammation.

For surgical procedures, suitable anaesthesia and analgesia will be administered in consultation with the NVS and any sign of suffering will be discussed with the NVS for immediate advice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure experiments are conducted in the most refined way, best practice guidance in the following publications will be followed:

Handbook of Laboratory Animal Management and Welfare, Third Edition. September 2003. S. Wolfensohn & M. Lloyd. Blackwell Publishing Ltd. https://onlinelibrary.wiley.com/doi/book/10.1002/9780470751077

Guiding Principles for Behavioural Laboratory Animal Science. Edition One: November 2013. LASA. https://www.lasa.co.uk/wp-content/uploads/2018/05/LASA_BAP_BNA_ESSWAP_GP_Behavioural_LAS_Nov13.pdf

The Design and Statistical Analysis of Animal Experiments. March 2014. S.T. Bate & R.A. Clark. Cambridge University Press. https://doi.org/10.1017/CBO9781139344319

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To stay informed about new advances in 3Rs relevant to this project, I regularly perform literature searches, visit the NC3Rs website and receive NC3Rs email updates to ensure I am abreast of new research and procedures that will improve animal welfare. For all refinements, I will work with our Named Veterinary Surgeon (NVS), NACWOs, and academic colleagues to pilot improvements to animal welfare.

43. Investigation of the faecal phenotypes of ruminants - sheep model

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Proteomics, Metabolomics, Metagenomics, Faecal biomarkers, Animal nutrition

Animal types	Life stages
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This work will apply advanced molecular biological techniques to identify proteins or other molecules that can be used to develop non-invasive tests to monitor the health of sheep, when they are fed on specific diets. Here we aim to use sheep as a model for ruminants in general.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A high proportion of British sheep and cattle is finished (fattened) in indoor fattening units

on high or *ad libitum* cereal diets. These diets are largely composed of barley, oats and maize, which contain somewhere in the range of 70 – 80% dry matter (DM) as rapidly fermentable starch. In general, high starch diets result in high rates of bodyweight gain and improved financial performance. However, as with most dietary inputs, there is an ideal rate at which cereals can be included, beyond which any increase results in reduced performance. Excessive starch supplementation results in increased loss in the faeces and contributes to digestive diseases, ruminal indigestion, which can result in a reduction in efficiency of production of meat of milk. There is an unmet need for farmers to be able to determine in real time whether their starch inputs are within an optimum band for maximal feed-use efficiency.

Existing guidelines for optimal feeding rates of starch in rations are not precise enough to account for variation in animal genetic and nutritional background, and there is wide variation in the amount and availability of starch in commonly used concentrate feeds. It is possible to measure faecal starch concentration in sheep and cattle, however the assay is cumbersome and expensive, and only a few laboratories undertake it. The characterisation of cattle and sheep faecal proteins has been limited. Work to date has looked at composite samples of faeces from animals on varied diets and at varying stages of production. It should be possible to develop a rapid, pen-side assay on faeces to determine if starch supplementation is within an optimal band. The faecal concentration of host (cattle or sheep) proteins appears to vary with diet, and we know that starch varies and can be measured. To identify the most effective markers of sufficiency of starch supplementation, further information is needed regarding the biochemical differences in faeces of animals fed differing diets when total intake, age and stage of production have been controlled.

The detailed characterisation of the biochemistry of faecal samples (ie the phenotype referred to in the title) using advanced molecular biology methods is intended to lead to easier, less invasive methods for assessing the health and production status of animals on diverse diets.

What outputs do you think you will see at the end of this project?

The new information that we hope to derive is the identification of proteins or metabolites in the faeces, which, alone or together, indicate the inflammatory, metabolic, and nutritional state of the animal.

It is expected that the study results will be published in peer reviewed publications. We aim to generate sufficient information for at least 3 publications.

Agricultural scientists, farm animal nutritionists and veterinarians will apply the methods to further explore the use of faecal markers in the study of animal nutrition.

If we can identify promising markers, then it is likely that our industry partner will invest in the development of a commercial tool for pen-side or laboratory use.

It is proposed that the techniques arising from these studies will lead to models of animal (nutritional) experimentation of higher welfare, and to improved dietary/rationing control, enabling real-time ration formulation and / or ration adjustment. More efficient rationing should result in reduced cost of production and lower environmental impact of production.

Who or what will benefit from these outputs, and how?

Farmers, agricultural nutritionists, animal scientists and veterinarians should all benefit

from this information.

The data collected in the course of this work may be used for the development of new products.

How will you look to maximise the outputs of this work?

Results of the study and new knowledge will be disseminated via publications printed and online. The results will be presented in national and international conferences. Our industry partner will promote the results of the study. If we are successful in identifying markers of efficiency, then we expect that this might be commercialisable IP of interest to our industry partner.

Species and numbers of animals expected to be used

- Sheep: 90

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The stage of interest to us is the late growing and finishing or fattening stage of life – sub-adult male animals that represent the majority type of animal that is fed on cereal in conventional agricultural practice.

Ultimately we aim to develop tools for application to all ruminants. We have selected sheep as a model in this study because of the reduced cost and increased ease of handling and experimentation at all stages. In animal nutrition science, sheep are a generally accepted, close model for cattle.

Typically, what will be done to an animal used in your project?

Sheep will be treated for internal parasites on arrival, by one-off administration of a de-worming drug (orally or by injection). On a subsequent single occasion, a small probe (ruminal pH bolus) will be administered orally to a proportion of sheep. Sheep will be subject to handling on several occasions (i.e., held by a trained and experienced stock-worker). On each occasion, when handled, a small blood sample and a small faecal sample will be obtained from each sheep, and the sheep will be weighed.
Sheep might be penned in individual pens for between 10 and 49 days. When penned individually, all sheep will have nose to nose contact with other sheep in the group. Sheep might wear a harness that collects all faecal output for a small number of 24-hour periods. All sheep will be offered differing diets and all diets will meet the sheep's nutritional requirements. However, some sheep will be offered diets without an initial transitioning period, and this might cause indigestion. These sheep will only be offered this diet for a period of 48 hours.

What are the expected impacts and/or adverse effects for the animals during your project?

It is possible that a small number of sheep (fewer than 15 individuals) will suffer from moderate signs of indigestion. This could include diarrhoea and loss of appetite. These signs are unlikely to persist for more than 48 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity: It is possible that 15 sheep out of a possible 90 sheep enrolled in the study would experience this severity

Mild severity: All other animals are expected to experience a mild severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of the study is to assess the effect of starch-containing diets on the faecal phenotype (metabolome, proteome, and chemical profile) of sheep. This requires experimentation on sheep as the relevant target species. Consequently, alternatives to using ruminants have not been considered.

Which non-animal alternatives did you consider for use in this project?

In vitro ruminal fermentation is widely used to characterise digestive processes in sheep and cattle but these methods are not suitable for our study.

Why were they not suitable?

We are interested in faeces as our end sample, and the relationship between ruminal fluid and faecal composition has not been effectively characterised. We expect that much of the variation in patterns of biochemical composition that we will see are likely to be driven largely by distal gastrointestinal modifications, particularly in the caecum and colon.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number used reflects the different types of studies in the project overall. We need a relatively small number of sheep in the pilot study, in which we intend to apply most strongly contrasting dietary treatments. In the second sheep study, we need more sheep to deal with the increased number of treatments. It is possible that if the initial work suggests only small effects of dietary treatment on proteome and metabolome, we might need to reduce the number of treatments used for and increase the number ofanimals per treatment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Selection of numbers is based on what we consider to be the combined effects of the expected effect size and the experimental aims. The number of animals is the minimum number expected to provide sufficient empirical strength to disprove our hypotheses if they are not true.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have preliminary data that suggests it is reasonable to expect measurable effects with the proposed scale. The initial experiments are the pilot studies for the work. They will later inform the design of further studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This work is directed at the development of proteomic based assays on faecal samples to quantify the efficiency of feeding starch-based concentrates to sheep. Two experimental methods have been developed to achieve this objective:

Feeding a high and low volume of starch-based concentrates to sheep without a transition period: As refinement, here we reduce the time of the challenge and use the smallest challenge expected to address the experimental requirements, although individually housed, all sheep will have direct nose-to-nose contact with one or two other sheep, all diets offered will be of a formulation that is commercially available, and we minimise handling stress by synchronously collecting samples, as infrequently as we can.

Feeding differing volumes of a starch-based concentrates to sheep with a transition period: As refinement, here we minimise handling stress by sample collection synchronously and as infrequently as we can, and all diets offered will be of a formulation that is commercially available.

Why can’t you use animals that are less sentient?

There is no relevant model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have selected interventions specifically to minimise welfare costs. We will apply a high level of monitoring of animals on the study at all times. We are using a short challenge period and a dosage that we expect will not result in any discomfort. All diets offered will be of a formulation that is commercially available. We minimise handling stress by synchronously collecting samples, as infrequently as we can, and where individually housed, all sheep will have direct nose-to-nose contact with one or two other sheep.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There is no specific guideline that is relevant for this study. The most useful document is the "Welfare of sheep: code of practice."

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The researchers involved subscribe to online notifications, receive institutional 3Rs information and are aware of the regular symposia that are organised on the subject. There is also collegial group membership of the institution’s welfare committee. Regular dialogue will ensure awareness of important developments.

44. Generation and breeding of genetically altered rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
Transgenic, Generation, Mouse, Breeding

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project licence are:

To generate mice with germ line genetic alterations and initiate their breeding in order to supply them to either the Establishment Breeding Maintenance Licence**,** research groups at our Establishment or to other establishments working in collaboration with us.

To rederive new lines imported from external sources with unknown health status for introduction into barrier accommodation and maintenance at a high health status in optimum environmental conditions.

To cryopreserve gametes/embryos to protect against genetic drift and in the event of unexpected disaster (eg. Infection in the animal unit). Archiving of lines will also avoid wastage from the need to maintain colonies by continuous breeding.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Generating new mouse lines will allow researchers to answer key questions related to understanding the function of genes and pathways in a wide variety of biological, physiological and pathological processes involved in cancers.

When mouse lines exist elsewhere, they will be imported into the Institute and will usually need to be rederived into the breeding unit. This allows researchers to share Genetically Altered Animals (GAAs) and for them to be used to answer different scientific questions.

Cryopreservation is a very important aspect when working with mouse strains. It not only serves to safely archive strains in case of disasters, but also slows down genetic drift, reduces the wastage of animals during continuous breeding and avoids the need to transport live animals, by shipping frozen material instead.

What outputs do you think you will see at the end of this project?

Newly generated, genetically modified mouse models will be embedded in projects from different research groups at the Establishment. The generation of new mouse strains is crucial for the development of research projects aiming at understanding the function of genes and pathways in a wide variety of biological, physiological and pathological processes (Khaled and Liu, 2014).

Once a particular mouse model is generated, it will constitute a fundamental tool that can be used by many research groups. Depending on the versatility of the genetic modification, many aspects of cancer research will benefit from the existence of these GAAs. For example, conditional gene activation and introduction of specific point mutations have been widely used to unravel gene function in different types of tumours.

Under the previous licence there has been a proven record of efficient generation and breeding of new mouse strains and this new PPL will continue and improve the provision of high quality animals to the researchers.

Khaled WT and Liu P. Cancer mouse models: Past, present and future. Seminars in Cell & Developmental Biology 27 (2014) 54–60.

Who or what will benefit from these outputs, and how?

This project aims to generate, breed and supply GAAs for the benefit of research groups at the Establishment and for those at other establishments working in collaboration with us.

There are around 14 groups at the Establishment using mouse models who will benefit immediately from the newly generated GAAs to fulfil their scientific questions.

How will you look to maximise the outputs of this work?

Once new mouse lines are generated they will be transferred to the researchers to perform all the required experiments. Within their research framework, all the results will be published accordingly.

Species and numbers of animals expected to be used

- Mice: 11,950

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Researchers have studied laboratory mice as models of human cancer for many years. Their use as cancer models has provided exceptional insight into the biology and genetics of this human disorder. There are standard protocols, methods and reagents used that have been optimised for manipulation of genes in this species and their acknowledged benefits for use.

Early embryonic stages will be use to introduce the genetic modifications required. Depending on the approach, 1-cell stage embryos or blastocysts will be used. Also, females around 3-4 weeks of age and 7-8 week of age will be used for superovulation protocols and as embryo recipients respectively. Vasectomies will be performed in males around 7-8 weeks of age.

Typically, what will be done to an animal used in your project?

GAAs will be created under this licence in order to understand further different processes associate with cancer. The various steps involved will be:

1: Injection of hormones to increase embryo production in female mice.
2: Female mice may have embryos implanted.
3: Vasectomy of male mice to allow them to be used to make females have phantom pregnancies and make them ready for receiving the test-tube generated embryos.

New mouse strains will be created by manipulation of the embryo using standard gene targeting methods. Each new strain will have a very well described, expected phenotype. However, animals will be monitored for unpredicted adverse effects. Surgical Procedures will be performed under anaesthesia and using pain relief and following aseptic methods to minimise risk of post-surgical complications. Anaesthesia will be carefully and regularly monitored to ensure that an adequate depth is maintained throughout any surgical procedure. Mice will be monitored regularly for their health status throughout all procedures. All procedures will be undertaken by trained, competent people.

What are the expected impacts and/or adverse effects for the animals during your project?

After surgeries animals will be closely monitored to assess their recovery. Analgesia will be provided before the surgery and after if required. Within these standard surgical procedures, it is estimated that any type discomfort will be transient.

When new mouse lines are generated, founders carrying genetic modification will be closely monitored for unexpected adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on Returns over the last four years we anticipate ~12% Unclassified; 67% Mild; 21% Moderate; 0.3% Severe. There have been no “Unclassified" since 2017 however.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of the Licence is to generate transgenic mice for research purposes.

New technologies are improving the field of animal transgenesis and they will allow bespoke new mouse models to be applied in biomedical research. Although the very first steps in a scientific project will involve in vitro approaches, the final characterisations and implications will required the use of GAAs. The different animal models will integrate the complete range of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal biological processes.

Prior to creating a new strain, consideration will be given to the scientific evidence gathered from in vitro data. The breeding method and proportion of affected animals produced will also be considered and discussed with the researcher and the NVS as required. This information will be included in the Transgenic Mouse New Line Creation Justification Form (Appendix 1).

Which non-animal alternatives did you consider for use in this project?

Not applicable here given the Licence purpose.

Why were they not suitable?

Not applicable here given the Licence purpose.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is estimated on the basis of yearly generation of 15 new mouse lines, perform 80 cryopreservations, importing 10 new mouse lines from external providers and perform 7 embryonic stem cell projects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To avoid generation of already existing GAAs, all databases and cryopreservation banks will be interrogated. Examples of resources available include:

Jackson laboratory: https://www.jax.org/jax-mice-and-services/find-and-order-jax-mice International Mouse Strain Resource (IMSR): http://www.findmice.org/index International Mouse Phenotyping Consortium: http://www.mousephenotype.org
The genetic background of the strain used to generate a new GAA will be carefully considered and discussed with the user to avoid producing unwanted mice.

A full list will be maintained for all existing strains created and existing in CRUK MI. This comprehensive record will detail the nature of the mutation, any known adverse phenotypes, breeding and husbandry requirements. A full Mouse Passport will be maintained in house for all lines as a transgenic register providing husbandry and welfare information (Appendix 2).

Some reagents design to generate the genetic modification will be tested in vitro before using them in the embryos.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cryopreservation of gametes/embryos and sperm will be carried as routine. This methodology will protect against genetic drift and in the event of unexpected disaster. Archiving of lines will avoid wastage from the need to maintain colonies by continuous breeding.

Super-ovulation using inhibin antiserum and equine chorionic gonadotropin increases the number of ovulated oocytes. This will result in enhanced production of embryos per mouse, therefore reducing the number of mice required to provide embryos for microinjection or cryopreservation of transgenic lines (Takeo et al., 2015).

Takeo T & Nakagata N. Superovulation using the combined administration of inhibin antiserum and equine chorionic gonadotropin increases the number of ovulated oocytes in C57Bl/6 female mice. PLoS One 10(5): e0128330 (2015).

The implementation of iGonad protocol aims to reduce the number of animals required to generate new mouse lines. The traditional procedure implies harvesting embryos from super- ovulated females (females group 1), injecting / electroporating them and afterwards, transferring them into foster mice (females group 2). In the iGonad protocol only one group of females will be used as embryos will be electroporated in vivo and the oviduct will be carefully returned to the body cavity.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Researchers have used laboratory mice as models of human cancer for many years. There are several reasons that make this rodent the best model to use: the mouse has a short reproductive cycle, large litter sizes, is easy to maintain and can be readily shipped from breeding facilities to research locations. The breeding methods we use will be undertaken under general anaesthesia where there is a risk of pain, suffering, distress or lasting harm.

The welfare of newly established and imported genetically altered animals will be assessed following the principle guidelines and recommendations provided by the report of the GAA welfare assessment working group (Wells et al., 2006).

Wells DJ, Playle LC, Enser WEJ, Flecknell PA, Gardiner MA, Holland J, Howard BR, Hubrecht R, Humphreys KR, Jackson IJ, Lane N, Maconochie M, Mason G, Morton DB, Raymond R, Robinson V, Smith JA and Watt N. Assessing the welfare of genetically altered mice. Laboratory Animals (2006) 40, 111–114.

Why can’t you use animals that are less sentient?

Researchers have studied laboratory mice as models of human cancer for many years. Their use as cancer models has provided exceptional insight into the biology and genetics of human disorders. The generation of new mouse strains is crucial for the development of research projects aiming at understanding the function of genes and pathways in a wide variety of biological, physiological and pathological processes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be given adequate analgesia and be closely monitored after surgical procedures. We use a document, that needs to be completed with daily observations, associated with each mouse that have undergone a procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Manipulating the Mouse Embryo. A laboratory Manual. CSH Laboratory press.
Reproductive Engineering Techniques in Mice. Naomi Nakagata.
Breeding and Colony Management Best Practices:

https://www.nc3rs.org.uk/sharing-archiving-genetically-altered-mice-opportunities-reduction-and- refinement

https://www.nc3rs.org.uk/breeding-and-colony-management

Wells DJ, Playle LC, Enser WEJ, Flecknell PA, Gardiner MA, Holland J, Howard BR, Hubrecht R, Humphreys KR, Jackson IJ, Lane N, Maconochie M, Mason G, Morton DB, Raymond R, Robinson V, Smith JA and Watt N. Assessing the welfare of genetically altered mice. Laboratory Animals (2006) 40, 111–114.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Every year our Establishment organises events where we can present and discuss new approaches related to the 3Rs. Also, I am a part of a working group in the NC3Rs that meet regularly to generate online resources about colony management and archiving.

45. Studies on immune regulation and tolerance

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Tolerance, Immune regulation, Transplantation, Autoimmunity, Cellular therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, adult, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to examine the mechanisms that are responsible for immune tolerance, and to further develop existing therapies or identify new therapeutic targets that promote tolerance for pathologies such as autoimmunity and transplant rejection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system plays a central role in maintaining human health. When dysfunctional, the consequences can result in serious and life-threatening diseases. In autoimmunity, the

immune system is unable to maintain tolerance to 'self' and therefore can attack and destroy cells and tissues. Identifying methods to prevent this from happening has implications for a number of diseases including diabetes, inflammatory bowel disease, and psoriasis. In transplant rejection, the immune system is functioning normally and detecting the transplant as 'foreign', therefore initiating a destructive immune response against the transplant which can result in graft loss, organ failure, and patient death.

In both autoimmunity and transplant rejection, regulating and controlling immune responses is key. The immune system has inherent regulatory mechanisms that normally function to restrain its activity and prevent an overshoot of immune responses. Over the past decade or two, we have identified methods to harness these physiological mechanisms to control immune responses therapeutically, with some of these therapies successfully translated from animal models to human clinical trials. Specifically, we have identified and developed cellular therapies ("living drugs") which exploit the immune system's regulatory circuits and started to test these in humans. This project aims to continue this important work to further develop these therapies for eventual translation to clinical trials for patient benefit.

What outputs do you think you will see at the end of this project?

The main outputs of the project will be:

Supporting data for clinical trials. We expect to provide the preclinical data required to allow us to progress next-generation immune regulatory therapeutics to phase I trials.

Open access peer-reviewed publications and pre-prints. Here we will share our findings with the academic community.

Datasets. The data underpinning the publications will be shared openly and freely in relevant data repositories such as the Gene Expression Omnibus (GEO).
Animal models. We will continue to refine our experimental models and share these protocols within publications.

Who or what will benefit from these outputs, and how?

This project aims to both advance our basic science understanding of immune regulation as well as to provide the preclinical data required to translate cellular therapies and other immune regulatory therapies (biologics, small molecules) to clinical trials. The specific benefits are:

Benefit to patients: To develop and evaluate cellular immune regulatory therapies, biologics, and small molecules that promote immune tolerance. A specific focus will be on regulatory cellular therapies such as regulatory T cells with the aim of assessing next-generation cell products that are genetically modified to enhance their functionality. The data generated under this authority will provide the preclinical data required for MHRA approval for phase I/II trials. We have a proven track record in this regard with therapies developed under our PPLs progressing to three separate clinical trials.

Benefit to scientific community: We aim further characterise the physiological mechanisms that maintain immune tolerance. It is anticipated that this knowledge will contribute to the immunology with possible future opportunities for therapeutic development. Contribution to the field will be through publications and presentations, with the aim of 2-3 per year over the course of the lifetime of the PPL.

Benefit to 3Rs and patients: Our work on humanised mouse models for the evaluation of cellular therapies has formed the foundation for successful application to the MHRA in the UK and the FDA in the USA for progression of therapies to clinical trials. This therefore allows the acceleration of successful therapies to phase I trials without the need for assessment in non-human primates or other large animals.

How will you look to maximise the outputs of this work?

We will ensure maximum benefit by sharing all our findings, whether they are negative or positive, both in conference with publication of abstracts, and through peer-reviewed publications. Our methodologies for producing new experimental models, particularly humanised immune system mice, will be shared freely within our publications.

Our team has a strong record of collaboration across research groups, disciplines, and institutions and we believe that this is crucial to scientific advancement. We aim to continue this through our ongoing collaborations within academia within our institution, the UK, and internationally.

Our research has direct clinical relevance, and we will maintain our dissemination activities to the public and key stakeholders through press releases and patient and public engagement activities.

Species and numbers of animals expected to be used

- Mice: 30000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The least sentient mammalian species that is appropriate for this work, namely mice and rats, will be used for this project. The availability of gene knockout and transgenic animals, that are absolutely central to the success of this project, means that the mouse is the preferred species to use for this work. Rats will be used for specific experiments related to vascularised transplants, where surgery is challenging in mice due to their size. Our mouse and rat experimental models are advanced enough that they have facilitated the direct translation of therapies from mouse to human, and have formed the basis of successful FDA and MHRA applications for advanced therapeutic approvals. For the majority of experiments, adult mice and rats will be used to allow for the transplants to be technically successful, however for a very small number of experiments where engraftment of mice with cells is more successful at a younger age, experiments will start with neonatal mice that are then transplanted with tissues as adults.

Typically, what will be done to an animal used in your project?

Well-characterised inbred and genetically modified mouse and rat strains will be used to allow the impact of specific genes on rejection, immunisation, infection and tumour

development to be determined. Both wild type and genetically modified animals will be bred and subsequently undergo a variety of transplantation procedures. All transplants will be performed in a dedicated operating suite by fully-trained personal licence holders. Anaesthetic, analgesia and post-operative protocols have been developed with the institutional veterinary service and represent current best-practice. Recovery from surgery is closely monitored and animals return to normal behavior (movement, feeding, drinking) within twelve hours. All other non-surgical procedures (such as immunisation) are performed in a dedicated procedure room under aseptic conditions, with animals monitored frequently post-procedure. Some procedures may be performed using human cells or tissue to emulate human immune responses. The surgical transplantation models used in this Project are the most advanced available and the result of decades of experience with their use by our group. Viral infection models are performed in dedicated areas in order to protect other mice. Occasionally, mice are irradiated in order to reconstitute their haematopoietic system with other genetic strains. Group sizes depend on the number of experimental groups and range between 4-10 mice depending on the type of experiment.

Typically, animals are prepared for donation of serum, cells, tissues or organs. This will involve intravenous or intraperitoneal injections. Animals receiving cell transplants will receive these through the intravenous or intraperitoneal route. In some cases these mice may also receive an injection of tumour cells or be irradiated before cell injection. Cell injection is sometimes performed to model graft- versus-host disease. Mice or rats receiving skin transplants will have a general anaesthetic for the procedure and have a patch of their skin replaced with donor skin from a different mouse or human.

Some mice may have their immune systems modified using a virus before skin transplantation, while others may be irradiated before transplantation to provide an environment for cell engraftment. Animals may be treated before or after skin or cell transplantation with agents that modify immune responses by topical, subcutaneous, intravenous, or intraperitoneal routes. Monitoring of transplant survival requires simple visual inspection (skin grafts) or tail bleeding to determine cellular phenotype and serum levels of therapeutic molecules, or an assessment of weight loss over time. To model the changes in blood flow that happen in transplantation, in some animals the kidney vessels may be clamped for a short period of time. Tumour monitoring is performed visually and by measurement of subcutaneous growth. At the end of the experiment (which is at the time of complete rejection or up to 100 days after transplantation) the animals will be humanely killed and transplants and other tissues recovered for histological, cellular,molecular and genetic analyses.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts
The procedures in this project are safe and have been optimised over a number of years with veterinary input. Intravenous, intraperitoneal, and subcuticular injection is transiently painful but mice are normal shortly after the procedure. Skin transplantation is performed under general anaesthetic. Postoperative pain is possible but controlled with analgesia. Reduced mobility over the first 1-2 weeks after skin transplantation is possible as a result of the bandaging but this is temporary. Weight loss is also possible due to the bandaging, but this resolves soon after bandage removal. During the skin rejection process a local inflammatory response at the site of the transplant will occur, however animals do not generally become unwell with this.

Adverse effects
A number of very uncommon adverse effects may develop in animals as a result of surgery, immunisation, irradiation, infection, tumour implantation, or administration of drugs. However these adverse events will be recognised early before the animal is in significant distress and steps taken to prevent any suffering. Injection of virus may be associated with a short-term systemic illness characterised by slight listlessness for a period not exceeding 48 hours. The administration of immune cells may result in the development of autoimmunity or graft-versus-host disease that results in weight loss, hair loss, pallor, or hunching. Treatment of animals with drugs or antibodies to modulate immune responses is generally safe. Very rarely there is a risk of toxicity that may result in weight loss, hunching, and reduced mobility. There is a small risk of injury to the pharynx, oesophagus or larynx/trachea with oral gavage which may include inadvertent injection of substances into the lungs. However this is extremely rare (under 0.1% of animals). Very rarely (under 0.1% of animals), an air embolus may propagate after intravenous injection. Our experience of intraperitoneal and subcutaneous injections is that these techniques are not typically associated with any adverse effects. After skin transplantation and in typically less than 5% of cases, wound dehiscence may occur prior to healing. If this occurs, the recipient will be re-sutured if uninfected once under general anaesthesia. In our experience wound infection after surgery is very rare and has no cases have been observed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Subthreshold: 43%

Mild: 31%

Moderate: 26%

What will happen to animals at the end of this project?

- Killed

Replacement

**State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?**

The use of animals will allow us to study how the immune system reacts to foreign cells and tissues. The immune system is complex with many arms that act together as a system throughout many organs and thus its entire function cannot be recapitulated outside of an animal. For example, it is not possible to recreate the dynamic migration of cells between lymph nodes, the blood, and transplanted tissues in vitro. Studying immune responses in animals systems would facilitate an understanding of how the immune system behaves normally, how rejection takes place, and how it can be regulated therapeutically. Additionally, because the genetic makeup of rodents is very well characterised, it is possible to recreate very specific transplantation models in order to reduce confounding

factors. The availability of genetically modified animals allows the assessment of how changing only a single factor modifies the immune response.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we avoid the use of animals and prefer to analyse human tissues, for example using our new spatial genomic approaches which facilitate the analysis of archival human tissue biopsies. We have developed methodology to generate cellular therapies in vitro, and use in vitro techniques to explore specific elements of immune function such as cell migration and proliferation. We are also moving to expand our use of humanised mouse models to replace and reduce our reliance on pure mouse models. We are working on developing ‘organoid’ models which can recreate some elements of a whole organ system in the lab using cells from human donors.

In an effort to both improve the translatability of our research and replace animals, we have developed humanised mouse models. Here, immunodeficient mice and rats can be engrafted with human cells to allow the study of human immune responses without the need for larger animal models. Using these techniques, we have replaced the requirement for mice to provide donor organs with tissues obtained from discarded human tissue (obtained with full ethical approval and patient consent).

Why were they not suitable?

To date, it has not possible to recreate in vitro the complex micro and macroenvironments that are present within a transplanted organ in the context of a whole animal or replicate the communication that occurs in vivo between the transplant and the lymphoid system. Our in vitro systems allow the interrogation and assessment of only a small number of dimensions related to the immune response and cannot recapitulate both the innate and adaptive responses. Our in vitro migration assays can only assess migration of cells between two areas, and not the entire circuits present in vivo. Our 'organ on a chip' techniques provide the ability to assess some immune responses in the context of a section of human tissue but cannot yet provide the whole spectrum of immune responses over time with all the input from other lymphoid tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are estimated based on our knowledge of how many animals have been used in our previous experiments/PPL and the planned experiments to be performed on this PPL according to the projects that have received peer-reviewed funding.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the majority of experiments, inbred strains of mice will be used and the strain combinations selected to allow a high chance of success. Experiments are designed to include clear objectives and rationale, appropriate controls, single variables in experimental groups, and observer blinding. The NC3Rs EDA is used where possible to help in experimental design. Control groups are often shared across multiple contemporaneous assays in order to reduce the number of mice required.

Where possible, we are moving towards in vivo assays where transplant rejection data may be qualitative rather than quantitative, therefore reducing group sizes. For example, the degree of rejection may be assessed in a single mouse based on in depth histological analysis of the tissue e.g. evaluation of the cellular infiltrate at a given time point rather than through obtaining transplant loss data. These qualitative methodologies are being optimised in a view to reducing our reliance on the use of large groups of mice in which transplant loss is the measurable end point. Similarly, we now use serial non- invasive in vivo imaging whenever possible in order to reduce the number of animals per experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Good colony management ensures that only those animals required for experiments are produced. A database is used to provide data for any breeding calculations.
We follow best practice in project organisation, management and data analysis helps us to keep the number of animals to a minimum. Where possible, we perform smaller pilot studies to confirm that our methodology is feasible before embarking on larger studies that may risk experimental failure.

We ensure good sharing of animals across our research group so that numerous organs can be harvested post mortem, resulting in fewer animals being needed by the group. For example, when skin is retrieved for transplantation, the blood or other organs removed as part of the retrieval process can be used to pre-treat another group of recipient mice and the spleens used for in vitro assays.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and rats will be used for this project. These are the least sentient mammalian species that is appropriate for this work as the transplantation and experimental procedures require an animal of a certain size for technical success. While our previous work included heart, vessel and islet transplants, we have now refined our techniques to allow for cell or skin transplant models to provide as much information as possible through new in-depth analysis techniques including spatial transcriptomic profiling. Skin transplantation is the least painful of all the tissue transplantation techniques we have used in the past. We have also eliminated double transplantation with heart and skin, as we are now able to gain the required data from skin transplants alone.

Rats are up to ten times larger than mice, providing an advantage for technically demanding surgical studies. In particular, their size facilitates the transplantation of human grafts that require immediate vascularization, such as human skin. The use of these animals in transplantation studies is therefore a step closer towards clinical translation, allowing the evaluation of novel therapeutics in a unique vascularised human transplant context and therefore with the potential to obviate the need for non- human primate studies (such as those of kidney transplantation).

The ability to recreate a human immune system within immunodeficient mice and rats is a powerful steppingstone towards translation of therapies, evidenced by our ability to progress directly from mouse experiments to a clinical trial without experimentation on larger animal species (e.g. cynomolgus kidney transplantation).

Why can't you use animals that are less sentient?

A mammal is required to ensure a whole functional immune system is studied. Animals smaller than mice do not allow for the transplantation surgical procedures required to be performed. Immature or terminally anaesthetised animals do not allow for the important time course analyses, including transplant survival and graft-versus-host disease development.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We ensure that animals are handled with care to ensure minimal distress, using polycarbonate handling tubes. Our routes of administration are those which cause the least pain or distress but still achieve our scientific aims. We no longer utilise footpad injections for immunisation. When an extended period of injections are required, we will make use of implanted pumps to reduce the stress from repeated handling and injections. Irradiation, performed to deplete the immune system, is always delivered using split dosage to minimise distress and side effects. For our skin transplantation, we have developed flexible bandaging techniques that eliminate the need for immobilisation of the animal. Pain is monitored post-operatively using the NC3Rs Grimace Scale and adequate analgesia provided as and when required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance is collected from the NC3Rs (www.nc3rs.org.uk), LASA (www.lasa.co.uk), and Norecopa (norecopa.no). The establishment's Named Information Officer ensures that current guidance is disseminated to researchers. The NC3Rs has a webinar on 'Systematic reviews of animal studies' which provides an overview of the tools available such as the Systematic Review Facility (SyRF) which can help support meta-analysis of animal studies. The NC3Rs website provides many resources to help with further refinement such as advice and guidance on common procedures such as blood sampling and the evidence base to support the single use of needles (which we have always ensured is standard of care in our experiments). The NC3Rs also has information relating to non-aversive mouse handling, bleeding, genetically altered mouse breeding, and grimace scales which are helpful for all the experiments we perform.

By keeping up to date with the NC3Rs through their newsletter and website, I ensure that any new e- learning resources are disseminated to my research group. I also follow the

NC3Rs/LASA training material on the Procedures with Care which covers the administration of substances to mice and rats and aseptic technique in surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Members of the group are encouraged to attend seminars hosted by the establishment where new and refined developments are disseminated. Researchers are also required to stay up to date with the literature in order to learn of new scientific techniques that may replace animal work, and also keep an eye on the NC3Rs website for any new findings or advice as well as events, also subscribing to their newsletter. Regular discussion with animal care staff as well as the NC3Rs Regional Programme Manager complement the other sources of information.

46. Mechanisms of Acute and Chronic Inflammation

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Inflammation, Lungs, Infection, Asthma, Fibrosis

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall objective of our investigations is to identify molecules and mechanisms that start, progress and end the inflammatory response in acute and chronic lung diseases/respiratory conditions (such as asthma, chronic obstructive pulmonary disease, lung fibrosis and respiratory tract infections).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The inflammatory response involves directing specific white blood cells to sites of disease and damage, where they interact with other cells and release substances which allow the surrounding cells to divide and fight the disease and/or repair the damaged tissue. However, how the cells are directed to and function at sites of disease and damage are not well understood.

Inflammation is a normal biological process that the body uses to protect itself against diseases and for restoring damaged tissues back to normal functions. However, when inflammatory processes are poorly controlled or directed against normal bodily functions,

they are harmful to the affected individual and result in diseases such as Asthma, Lung Fibrosis and Chronic obstructive pulmonary disease.

Understanding the mechanisms involved in the inflammatory response is fundamental to analysing the processes of infectious disease control on the one hand and inflammatory diseases on the other. This understanding is critical for the design of new drugs for common inflammatory diseases for which there are currently few effective treatments

What outputs do you think you will see at the end of this project?

This work is expected to provide new information about mechanism of inflammation in lung diseases and how these can be manipulated for benefit.

The expected primary benefit is the publication of high-impact scientific papers about inflammatory mechanisms in lung diseases and information that will impact clinical management of such diseases.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will improve our understanding of mechanisms of inflammation in airway diseases and how they can be manipulated to promote lung repair rather than further damage and thus restore normal lung function. We will also promote and publish any refinements or best practice we identify during this project. We will make post-mortem tissue available to collaborators.

In the medium term, the clinic will benefit from the identification of markers to allow better identification of patient subgroups, while the pharmaceutical industry will be interested in potential novel therapeutic targets we identify.

The long-term benefits of this study are that data generated will have far-reaching implications for the treatment of respiratory diseases, benefitting patients and clinicians by contributing to the development of novel treatments for acute and chronic inflammatory diseases, and new preventative strategies for childhood disease such as asthma, which will ultimately reduce the economic and health burden caused by such diseases.

How will you look to maximise the outputs of this work?

Findings will be made available to other scientists through publication in open-access journals and presentations at scientific conferences and meetings.

Additionally, we will take as many tissues as possible at post-mortem and will make them available to other researchers immediately or in future by biobanking them.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is critical to perform these studies in mammals since there are significant differences between the biological systems of frogs and fish to that of humans. Mice are the least sentient animal that display many of the important features seen in human diseases. Furthermore, for genes which instruct the cell how to make proteins, mice and human are on average 85% similar. Therefore, we will also use genetically altered mice, as well established and sophisticated techniques exist that allows us to switch genes on and off and in specific cells. This enables us to examine the role of genetic defects too. Additionally, conditions like asthma and respiratory infections which occur in both children and adults present differently in these age groups and have different underlying mechanisms, which are also observed in mice. Therefore, we will use neonatal (new-born) and adult mice in our studies as it is important that we use age appropriate mice to address our research questions.

Typically, what will be done to an animal used in your project?

Most animals will be exposed via the nose to either an allergen (3 or 5 times weekly for up to 5 weeks) or a pathogen (on one or two occasions) or an agent that causes lung fibrosis (on one occasion), along with an additional substance which will alter the development of the disease. Disease progression and animal welfare will be monitored at least once daily and will include weighing, and assessment of body condition and behavior, until satisfied that there are no welfare concerns, then checks will be reduced to not less than twice weekly. At critical time points, under general anesthesia without recovery, the animals' lungs and/or blood vessels will be imaged, or lung function measured, before cells and tissues are collected. For animals exposed to an allergen the experimental duration will either be 3 or 5 weeks; for those exposed to a pathogen 10 days; and those exposed to an agent that causes lung fibrosis 7, 21 or 42 days.

Prior to the above, some animals will undergo removal of bone marrow cells and subsequent replacement of such cells (bone marrow ablation and reconstitution), or surgical removal of the spleen, to modify their immune systems.

What are the expected impacts and/or adverse effects for the animals during your project?

The following procedures are expected to cause some moderated discomfort, that animals will fully recover from quickly. They will be given painkillers and post-procedural treatments and checks just like people are; bone marrow ablation and reconstitution (tiredness and reduced appetite), removal of the spleen (pain) and pathogen exposure or lung fibrosis (weight loss). Other procedures, such as administration of allergen or substances, are expected to cause minimal but transient discomfort with no lasting harm. During procedures under general anaesthesia without recovery, the depth of anaesthesia will be sufficiently deep that the animal will feel no pain. We do not anticipate any severe adverse events.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

5% Non-recovery

45% mild

50% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals in our project because lung diseases and inflammation are complex processes that involve many different tissues and cells working together, which cannot be adequately or fully modelled by computational or in vitro (non-animal) studies alone. We do not fully understand these multifaceted processes or how the complex interactions between different parts of the body, cells, tissues and the environment cooperate, so unless we study animals as a whole, we cannot learn how to prevent and treat these conditions.

Which non-animal alternatives did you consider for use in this project?

In our work we use many different types of techniques and experiments to answer our scientific questions. Throughout the project, where possible, we will complement the in vivo (live animal) work with ex vivo (non-live animal) techniques such as precision cut lung slices, and mouse or human derived cell and tissue culture systems. When suitable non-animal experimentation using in vitro and in silico (computer) techniques will be used including;

Cell culture - submerged, air-liquid interface cultures and co-cultures of primary isolated human cells and cell lines.

lung-on-a chip - using primary isolated human cells and cell lines human samples databases and data sets

However, these are not adequate to fully replace all animal experimentation.

Why were they not suitable?
Such methods do not consider complex interactions that occur between integrated biological systems (for example respiratory, vascular and immune systems) and the external environment in the way that a fully intact organism does. Different cell types require different growth conditions some of which are incompatible with each, rendering full modelling impossible. Technologies to model pressure, and air and blood flow are still in development are not currently robust enough to meet needs. We will continue to monitor the field for novel techniques using non-animal materials and will implement them, where appropriate, as they arise.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The projected number of animals reflect the number necessary to achieve the scientific objectives outlined in the programme of work described in this application. We have estimated mice based on the anticipated numbers of experiments, the numbers of experimental groups and the numbers of mice in each group. The estimates are based on similar studies we have conducted in the past using similar protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant and consult with the college Statistical Service to design experiments with the fewest animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Genetically modified mice will only be maintained whilst there is a justified use for their continued breeding. We will breed in ways that minimise waste and ensure the majority of animals can be used in experiments.

We are now using the Precision Cut Lung Slice technique, an ex-vivo technique which allows imaging of live viable lungs (up to 7 days from removal). This results in a reduction as multiple slices can be obtained from a single mouse.

We have refined our assays such that we can measure multiple parameters in each animal, thus maximising the information gained from each experimental group. Combining tests in the same mice allows the interpretation of data to be correlated directly, rather than inferred. This allows us to carry out more advanced statistical analysis to detect correlated trends between assays. Directly correlated effects have a greater sensitivity as the major source of variance (between mice) is removed. We will also collect tissues from all our animals, and share with other researchers, to perform experiments in the laboratory so no additional animals are required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen the smallest animal possible to represent human disease. While the model chosen closely represents the important features of the human disease in the treated animals, they are the least severe and do not promote undue distress to the mice. Where possible, we administer substances locally rather than systemically (through the entire body) to restrict systemic side effects. We constantly monitor animals for signs of ill health and work closely with animal care staff and veterinary surgeons to ensure the best possible husbandry and welfare for mice under procedure. Anaesthesia and analgesia (pain relief) are used routinely in all animals when required and appropriate. Suffering is minimised by procedures being carried out by highly skilled and experienced scientists.

Why can’t you use animals that are less sentient?

It is critical to perform these studies in mammals since there are significant differences between the physiological systems of frogs and fish to that of humans. The mouse is the lowest mammalian species in which the full range of genetic and physiological manipulations necessary for the investigation of lung disease and inflammation can be achieved.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

While the model chosen closely represents the features of the human disease in the treated animals, they are the least severe and do not promote undue distress to the mice. We will frequently monitor animals for signs of ill health and work closely with the NACWO and veterinary surgeon to ensure the best possible husbandry and welfare for mice under procedure. Refinement measures carried out in this project will include: use of anaesthesia and analgesia whenever possible as well as enrichment of the animal's environment. We will increase monitoring if any adverse effect occurs and consult the NACWO and veterinary surgeon and offer pain relief, treatment, stop the experiment or humanely kill animals as appropriate. Through the project we will continue to look for new ways to refine our experimental protocols and make animals more comfortable. This could include when appropriate milder models (effects or earlier end-points) along with milder administration routes, lower administration volumes and/or reduces administration frequencies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Frequent communications (newsletters and meetings) are produced within the institution on the advances in the 3Rs and their implementation. All staff working under this licence will be signed up to receive these. Advice regarding the well-being of animals will be sought from the vets and animal care staff regularly.

We will follow external sources including National Centre for Replacement Refinement and Reduction of Animals in Research resources (website https://www.nc3rs.org.uk/).

47. Understanding Common Human Neurodegenerative Diseases

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

mechanisms of neurodegeneration, propagation of protein aggregates, Alzheimer's disease, Parkinson's disease

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to understand more about the mechanisms of neurodegenerative diseases, in order to finding new targets which could lead to the development of mechanism-based therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodegenerative diseases, such as Alzheimer's and Parkinson's diseases are among the most common age-related human diseases. Alzheimer's disease is characterized by dementia, whereas Parkinson's disease is primarily a movement disorder. Existing treatments only treat disease symptoms without modifying the underlying disease process.

What outputs do you think you will see at the end of this project?

The assembly of a small number of proteins into insoluble filaments is the gain-of-toxic function mechanism that underlies age-related neurodegenerative diseases. These filaments are not just clumps of unfolded proteins. Our on-going electron cryo-microscopy studies have shown that individual molecules form specific contacts to give rise to long helical filaments. Tau filaments are associated with several diseases, including Alzheimer's disease, and the types of contacts they make are characteristic of particular types of disease. Another protein, alpha-synuclein, also forms inclusions in brain cells and is associated with diseases, such as Parkinson's disease and multiple system atrophy. It also forms filament structures that are specific for each pathology.

We are now developing methods by which to assemble recombinant tau and alpha-synuclein into filaments with structures like those of filaments from human brain. Depending on the conditions, we have shown that recombinant tau (297-391) can assemble into filaments identical to those of the paired helical filaments of Alzheimer's disease or type II filaments of chronic traumatic encephalopathy. We are developing methods for reproducing other folds.

This work opens the way to producing transgenic mouse models with filament structures like those from human brain. None of the existing mouse models have developed such filaments. This may explain why mouse lines have been imperfect models of human disease. The new possibilities provide a substantial refinement. We are launching an ambitious and extensive programme of research along these lines. At present, we are in the lead worldwide as far as high-resolution structure determination of disease filaments goes. We will extend this lead to the generation and characterisation of transgenic mouse models of a number of human neurodegenerative diseases.

Therefore our outputs will be new improved mouse models of human disease which have filament structures like those found in human brain. All new information will be disseminated in peer-reviewed open access publications and at presentations at scientific meetings.

Who or what will benefit from these outputs, and how?

All new information generated during our project will be made available to the scientific community and will benefit all researchers with an interest in human degenerative diseases especially tauopathies and synucleinopathies and in protein aggregation in general.

Once published, we will make the new mouse lines available to academic and pharmaceutical laboratories. These new improved mouse models will be used for the testing of novel biomarkers and mechanism-based treatments of neurodegenerative diseases. In the short term it will impact research and development in the field and in the long term this knowledge will guide the development of novel biomarkers and mechanism-based therapies.

How will you look to maximise the outputs of this work?

By publishing in high-impact journals, by talking about this work in scientific meetings and by collaborating with others. In addition, we will make these lines freely available, without requiring authorship.

Species and numbers of animals expected to be used

- Mice: 45,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Human neurodegenerative diseases are diseases of the central nervous system. Mice have a central nervous structure that is comparable to that of humans. They are open to genetic manipulation and their generation time is reasonable.

The majority of mice used will be adults mice and aged mice to study disease progression. We will also maintain breeding colonies and making new transgenic lines and cryopreserving existing transgenic lines which means that all life stages will be used in this project.

Typically, what will be done to an animal used in your project?

Mice will be housed in a social environment whenever possible and provided with environmental enrichment such as chew sticks, fun tubes, nesting material and platforms.

Some mice will aged to allow development of the neurodegeneration. These mice may experience weight loss and hind limb impairment as the disease progresses.

Some mice will undergo behavioural tests to check for neurodegeneration such as motor function or memory tests. These tests are non-invasive and there are no expected adverse effects.

We may administer substances by a variety of routes, choosing the most suitable and least invasive route possible. Some of the routes will be non-invasive such as food or water. Other routes such as injection (under the skin, into the peritoneal cavity, into a vein, into a muscle) or gavage will cause mice transient pain and/or transient stress.

Some mice may receive surgical injections into defined areas of the brain. Surgery mice will be given pain relief prior to recovery from anaesthesia and whenever necessary to alleviate pain as advised by the veterinarian. Following the administration of substances mice will be aged to observe the possible development of neurodegeneration in brain and spinal cord, in which case these mice will experience weight loss and pain due to progressive hind limb impairment.

At the end of experiments, mice will be humanely killed and samples collected for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Some mice will develop symptoms of neurodegenerative disease, which may manifest themselves by weight loss, muscle weakness and mobility problems. Ageing mice may experience pain due to age- related diseases such as neoplastic and chronic degenerative non-neoplastic diseases.

Mice will experience transient pain post injection. They will experience stress and post-operative pain due to surgery. Post surgical pain is limited up to 24/48 hours and pain relief is given to the mice.

We have monitoring programmes in place for all animals to assess health status in order to avoid animals experiencing unnecessary adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

60% of mice will not experience any pain and are classed as sub-threshold severity.

10% of the animals will experience some pain which will be mild severity such as an injection.

30% of animals will experience pain such as progressive back leg disability and are classed as moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The identification and evaluation of genetic and pharmacological modifiers of neurodegeneration requires the use of experimental animal models.

The brain structure of all mammals is similar and so the mouse is best suited for this work since, of all existing models of neurodegeneration, mouse models are the closest to the human diseases.

Which non-animal alternatives did you consider for use in this project?

We are studying the structures of tau and alpha-synuclein filaments made in the test tube by electron microscopy to obtain high resolution images. We have established cell assays to study mechanisms of uptake and cell-to-cell propagation of tau and alpha-synuclein assemblies of defined structure in vitro. These data are taken into account when designing animal experiments.

Why were they not suitable?

We do carry out experiments in cell lines in our laboratory, but whilst this will provide some information, cultured cells do not provide physiological conditions or the complex

interactions amongst different cell types. Tissues can also be used but only provide an isolated response, which is not completely representative of in vivo responses, because inducers and modifiers of pathology often involve metabolism and interplay among different tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on past experience we estimate that we will need around 8,000 mice by year. We maintain around 25 transgenic colonies. Our transgenic lines express one of three proteins (beta-amyloid, tau and alpha-synuclein) in a wild-type, mutant or truncated form. In other lines, the function of a mouse gene may be disrupted by gene knockout or modified by gene knockin. Some of these lines will be crossed with transgenic lines expressing putative modifiers of disease such as genes involved in inflammation or knockout or knockin transgenic lines.

Some mice will be used for breeding to maintain the colony. Some mice will be bred for tissue collection for ex vivo work. Some mice (in groups of 8 to 12) will be aged to allow neuropathology to develop prior to tissue analysis of a time course which will usually have four to eight time points. Some mice will be given pharmacological modifiers (groups of 8 to 12) and tissues collected for analysis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All animal work is preceded by detailed studies in test tubes and cells. We will use the minimum number of animals needed to give a statistically significant result. A statistical expert will be consulted regarding experimental design and the most appropriate statistical analysis. Prior experiments and expertise with the animal model used will be taken into account when deciding on the number of animals needed for an experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mouse breeding will be carefully monitored to ensure that surplus animals are not generated. Wherever we use a new substance in mice we will conduct a small, time-limited pilot study.

Cryopreservation is used routinely to preserve important mouse lines and to remove the need to breed mice only to maintain a given line.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models of common neurodegenerative diseases such as Alzheimer's and Parkinson's diseases, which we use express the human proteins known to be involved in the human diseases (beta-amyloid, tau and alpha-synuclein) and exhibit the essential features of the human diseases and as such they are the best models available for our studies.

We have a monitoring programme in place for all our animals to assess health status in order to avoid animals experiencing unnecessary adverse effects. There is an enhanced monitoring programme for older animals and animals which may develop weight loss and/or hind limb impairment to minimise suffering.

When new lines are generated and bred for the first time, animal technicians will be specifically informed and the first litters carefully monitored. Any untoward phenotype will be discussed with the NACWO, veterinarian and if appropriate, the Home Office inspector.

The surgery will be carried out under asepsic conditions and we will aim to follow "Guiding principles for preparing for and undertaking aseptic surgery" (2010) as closely as possible. Mice will be given analgesia prior to recovery from anaesthesia and whenever necessary to alleviate pain as advised by the veterinarian.

All animal experimentation conducted under this project licence will comply with the document entitled "Animal Usage Guidelines". This document has been adopted by the local Ethical Review Process in order to inform researchers of the bounds within which their animal work should be conducted, and to provide practical recommendations on various aspects of animal experimentation.

Why can't you use animals that are less sentient?

Mice are the least sentient representative species we can use: we need to use a mammalian species because it has a central nervous system comparable to ours and mice are a suitable model because we have the ability to manipulate mice using genetic means. The greatest risk factor for neurodegenerative diseases is ageing so mouse models will be aged to investigate the contribution of the ageing process in neurodegenerative disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Some of our mice develop motor impairment as they age and these mice will be closely monitored for difficulty satisfying hunger and thirst and for weight loss. Where appropriate food and drink will be provided on the cage floor.

In view of the progressive decline associated with ageing there will be increased vigilance both in monitoring indices of general health (weight, grooming, reactivity) and additional observations designed to detect specific problems such as the development of tumours.

For administration of a substance the route of administration will depend on the solubility and bioavailability of the compound and the least invasive route that is suitable will be chosen.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We use the NC3R website to ensure that we follow best practice. We use The Experimental Design Assistant (eda.nc3rs.org.uk) on the NC3R website to to check the design of our animal experiments and ensure that we have robust and reproducible data.

We follow the PREPARE (norecopa.no/prepare) planning guidelines and the checklist of the ARRIVE (arriveguidelines.org) guidelines to maximise the quality and reliability of our publications.

We also follow best practice for our surgery experiments as laid out in the LASA guidelines (lasa.co.uk/PDF/LASA_Guiding_Principles_Aseptic_Surgery_2010.2.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We keep up to date with the current literature and subscribe to the NC3Rs newsletter to get the latest updates. We attend seminars and conferences where the 3Rs are discussed. We encourage the sharing of best practice between animal technicians.

All animal welfare issues are addressed and solutions implemented following discussions between the animal technicians, the NACWOs, the veterinarian and PIL holders.

48. Elucidating sources of contrast in quantitative brain MRI

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Magnetic Resonance Imaging, brain, histology, multiple sclerosis

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how different components of the brain tissue contribute to the observed contrast in magnetic resonance images.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Magnetic Resonance Imaging (MRI) is a type of scan that uses strong magnetic fields and radio waves to produce detailed images of the inside of the body. It is for example routinely applied to image the brain of healthy people and of patients. The characterization of one particular type of tissue in the brain, i.e. the white matter, is important for diagnosing disease (such as for example Multiple Sclerosis). While MRI is very good in depicting

lesions in the brain ("qualitative assessment"), clinicians are now interested in quantitative information such as length or volume of brain cells to provide a more refined diagnosis. The structure of white matter, however, is complex, which makes it challenging to interpret the MRI images in an accurate and quantitative manner. We therefore need to study the relationship between imaging findings and anatomical features in an animal model such as the mouse, where we can easily compare our MRI findings with histology. This would not be possible in humans. Histology can then be related to the MR images in a novel way by spanning a range from nanometer to millimeter.

What outputs do you think you will see at the end of this project?

To date, quantitative readouts ('imaging biomarkers') from MRI are indirect, meaning we are measuring physical properties (such as relaxation times or diffusion parameters etc.) from which we infer physiological or anatomical properties. The estimated parameters will be affected by tissue properties AND potentially by the experimental configuration. It is therefore important to understand the influence and contribution of both parts. This process becomes a fundamental aspect for developing these imaging biomarkers and it will be ultimately essential for their application on patients in the clinics. The output of this project will therefore lay the foundation for answering major open questions in multi-scale imaging (i.e. covering resolution from µm- to mm-range) and in MRI.

Who or what will benefit from these outputs, and how?

The proposed experimental design (i.e. manipulation with the cuprizone model) together with the cutting edge MRI and electron-microscopy technologies used in the present study will generate an extremely valuable multimodal dataset. We expect the outputs of our study to be beneficial on both short and long terms. Initially, throughout the duration of the research project, methods, analyses and findings will be presented internally and externally trough conference reports for the benefit of the scientific community to support collaboration and design of new research studies. Furthermore, we will use a combination of approaches providing complementary information to gain a deeper understanding of the biophysical origins of differences in the estimated MRI parameters thus enhancing the interpretation of quantitative MRI. Hence, on the long term, we hope outputs from the present study will help devising biophysical models capable of achieving a better biological accuracy and perhaps, enhanced diagnostic power boosting MRI clinical utility.

How will you look to maximise the outputs of this work?

Throughout the duration of the research project, study results will be reported using peer reviewed journals and conference reports. Where possible original, peer-reviewed research publications will be made freely available and open access to research data will be supported. Furthermore, collaboration among research groups will be promoted. Data analysis will be reported and made available to enhance reproducibility and replicability. Finally, the PhD thesis will be made freely available from the EThOS repository

Species and numbers of animals expected to be used

- Mice: 70

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.
The project will use adult wild type C57Bl/6 mice as they are one of the predominantly used species in biomedical research. Furthermore, C57Bl/6 is the strain where cuprizone induced demyelination has been consistently reported. It is therefore the most utilized strain in studies using the cuprizone diet.

Typically, what will be done to an animal used in your project?

The project will use two groups of mice, only one of which will be fed with a Cuprizone supplemented diet for a duration of six weeks. Both groups however will be subjected to two MRI scans, six weeks apart, typically lasting 2-3h. In rare circumstances, due to technical difficulties with equipment, a third MRI scan may be performed. In either case, the second or third scanning session will be performed under terminal anaesthesia. A clinically approved MRI contrast agent might be given during the imaging session.

What are the expected impacts and/or adverse effects for the animals during your project?

Cuprizone feeding has been associated with weight loss. This is expected to happen especially in the first two weeks of diet followed then by a gradual increase in body weight, which however remains below the baseline. Behavioural phenotype associated to cuprizone feeding include motor limitations such as tremors, abnormal walking and reduced coordination, spatial memory, reduction in social interaction with peers, environment exploration and spontaneous motility. Administration of cuprizone supplemented diet will be limited to a short period of time therefore preventing permanent damage.

MR imaging is performed under general anaesthesia. While the adverse effects of general anaesthesia are rare, the mice will typically undergo two MRI sessions six weeks apart under general anaesthesia. The animals will not be recovered after the second imaging session. If for technical reasons a third scan is required, it will be conducted under terminal anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for all animals will be *moderate*.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are essential to understand the observed imaging contrast under in vivo conditions as mimicks the clinical scenario. Furthermore, the ability to compare the in vivo measurements with histological “ground truth” analyses in a controlled setting is a fundamental aspect and would not be possible or ethical to perform in humans.

Which non-animal alternatives did you consider for use in this project?

We will always make use of non-sentient phantoms and/or cadavers and ex vivo tissue in the first phase of the development.

Why were they not suitable?

None of these alternative settings reflect the complexity of the in vivo situation (as also found in patients), where there is interplay between motion (i.e. cardiac and respiratory motion, blood flow) and complex (magnetic) properties associated to living brain tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Authority is being sought for a defined study, for which the number of required animals was determined using power calculations (n=20). An additional group (n=20) has been added for validation after the developmental phase on non-sentient phantoms / under ex vivo conditions.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Minimizing the number of animals will be achieved by moving to in vivo testing / validation only once all imaging sequence are fully tested on non-sentient phantoms / under ex vivo conditions. We will adhere to a strict workflow to achieve our scientific goals while minimizing animal usage. The NC3R's Experimental Design Assistant has been used to design the study while minimizing the total number of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As mentioned before, we will always make use of non-sentient phantoms and/or cadavers and ex vivo tissue to ensure that all imaging techniques are working before the in vivo application.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice because this species provides sufficient similarity in health and disease to man. The proposed in vivo imaging is non-invasive in nature but requires for the animal to be anaesthetized. The dietary intervention is required to generate the disease model but will be limited to a short period of time therefore preventing permanent damage.

Why can’t you use animals that are less sentient?

Mice are the mainstay of biomedical research. In order to elucidate the imaging contrast observed in MRI and to perform histological validation, these models are essential.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As mentioned, the proposed in vivo imaging is non-invasive in nature, but requires for the animal to be anaesthetized. All animals will receive additional heat and fluid support during and after the imaging examination to aid recovery from anaesthesia and will be closely monitored until fully recovered. During imaging sessions, ECG, respiration and body temperature are continuously monitored. All cages include environmental enrichment and animals are kept in social groups whenever this is compatible with our objective. Cuprizone feeding has been associated with weight loss. This is expected to happen especially in the first two weeks of diet followed then by a gradual increase of body weight, which however remains below the baseline. We will therefore weigh the animals at least three times a week and document it.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3Rs website has a repository on topic-specific resources, including anaesthesia and analgesia, which are the most relevant topics. In addition, regular updates on training and best practice guidance is disseminated via the mailing lists mentioned above.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have university-wide mailing lists informing on advances in the 3Rs and on new training opportunities in this area. Furthermore, we are in close and regular contact with the University Veterinary Officer, with whom we regularly review our procedures. This represents an effective mechanism to convey and translate any new advances into code of practice.

49. Delivery, efficacy, and safety of nucleic acid therapeutics

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph

Key words

small interfering RNA (siRNA), antisense oligonucleotide (ASO), gene therapy, nucleic acid chemistry, nucleic acid therapy

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Determine the effectiveness of delivery, tissue / cell distribution, efficacy and safety of nucleic acid therapeutics with different chemical modifications, formulations and routes of administration

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Nucleic acid (RNA and DNA) therapeutics are a promising, relatively new class of medications offering the advantages of highly precise effects, rapid development time,

broad target range, and durable action. Several nucleic acid therapeutics have received regulatory approval and offer unparalleled therapeutic effects. However, enabling the application of nucleic acid therapeutics to a broader class of diseases requires understanding of how nucleic acid chemistry, formulation, and route of administration affect delivery and efficacy. Thus, this work seeks to characterise the effects of nucleic acid characteristics on these outcomes.

What outputs do you think you will see at the end of this project?

- Delivery of nucleic acid therapeutics to a range of tissues, such as CNS, kidney and heart
- Identification of novel nucleic acid chemical modifications or delivery methods that enhance the tissue/cell type specificity of delivery
- Identification of novel nucleic acid chemical modifications or delivery methods that augment the efficacy of genetic targeting
- Establish the feasibility of modulating specific disease-relevant target gene

Who or what will benefit from these outputs, and how?

Ultimately, human patients with diseases which could be treated by nucleic acid therapies will benefit by our demonstration of safe, effective therapeutic delivery. Our projects are prioritised to maximise the real clinical benefit. In the intermediate term, collaboration partners (academic institutions and biotech companies) will benefit from our research on how to improve the delivery, precision, effectiveness and safety of therapeutics. Concretely, we expect to identify specific nucleic acid chemical modifications, conjugated molecules, formulations, and delivery routes that improve the specific delivery (target organ/cell type compared to off-target), require less nucleic acid therapeutic compound to be delivered, or compound to be delivered less frequently (due to improved stability, or more specific distribution, or more potent genetic effects), and/or have an improved safety profile (e.g. reduced immune response), compared to existing therapeutic options. Furthermore, we expect to establish the feasibility of modulating specific disease-relevant target genes for future therapeutic development and application.

How will you look to maximise the outputs of this work?

- Our central mission is to accelerate the development and implementation of nucleic acid therapeutics. We will achieve this goal by:
- Disseminating our results to collaboration partners (academic, clinical, industrial, and charity) and the scientific community
- Organising conferences to exchange ideas and disseminate findings
- Utilising social media and other public relations channels to publicise our research and results Publication of results in peer-reviewed scientific journals

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The primary endpoints of the work are:

- to determine the distribution of nucleic acid-based compounds in different organs and cell types to determine the effectiveness of gene modulation in target organs and cell types
- to determine whether the compounds cause adverse effects

Each of these endpoints requires intact physiology, including functioning circulation, immune system, and organ systems. The distribution of compounds depends largely on route of delivery, physiological processes (e.g. liver metabolism and kidney excretion), chemical modifications enhancing stability and cell uptake, minimising protein interactions and immune response), and formulation (e.g. linking to other molecules to improve distribution). We will investigate different chemical modifications and formulations to promote delivery to target organs and cell types.Our aim in this Project is not to carry out dose-escalation studies specifically designed to ascertain toxicity of a compound in vivo.

The ultimate purpose of the work is to develop therapies for use in humans. With that in mind, mice offer several advantages over other species:

- Physiology and organ systems are closer to humans than, for example, fish or flies
- Mice are well established for routes of delivery applicable to humans, such as intravenous, subcutaneous and intrathecal injections

We will primarily use adult mice (age 2-6 months), to avoid confounding effects of development on physiology. In cases where the target gene is relevant in the context of early onset disease, we may use juvenile mice (3-8 weeks) for delivery outside of the nervous system.

Typically, what will be done to an animal used in your project?

Typically, an animal will receive a single dose of a double-stranded nucleic acid (e.g. siRNA), or four doses of a single stranded nucleic acid (e.g. ASO) 1 week apart. Compounds will only be delivered after extensive purification, chemical quality control, and testing in lab-grown cells to ensure effectiveness, precision, and minimal toxicity. The route of administration could be subcutaneous (s.c., under the skin), intravenous (i.v., into the vein), intraperitoneal (i.p., into the abdomen), intramuscular (i.m., into the muscle), intrathecal (into the spinal fluid), or intracerebroventricular (i.c.v., into the brain fluid), but each animal will only receive a single compound through one route. For intrathecal and i.c.v. administration, animals will be sedated or anesthetised to enable accurate administration. Immediately following administration, animals will typically be housed in metabolic cages. Blood and urine will be sampled to establish the pharmacokinetic profile of the compound. Subsequently, blood will be sampled weekly to monitor immune response and liver and kidney toxicity. Dependant on observed adverse effects and/or selected gene(s) to be targeted, following sufficient incubation time (for example, 2 weeks to 6 months), animals will be euthanised for examination of their tissues for gene expression and pathology, including quantifying biodistribution of the compound.

What are the expected impacts and/or adverse effects for the animals during your project?

Nucleic acid compounds with established chemical structures, formulations, and delivery routes are likely to cause few adverse effects. The administration itself will likely cause mild transient distress due to handling and injection, as well as sedation/anaesthesia where required. Novel chemical structures, formulations, and administration routes may cause unexpected adverse effects, but the likelihood is low because of the well-understood mechanisms of action. The most likely adverse effects are liver or kidney toxicity (the sites of compound metabolism and excretion respectively) or inflammation. Adverse effects may also occur as a result of modulation of the target gene, but this is also unlikely since genetic targets are chosen based on the expected beneficial effects of their modulation. Adverse effects could occur via off-target control of unexpected genes; yet this is also unlikely as extensive investigation of this phenomenon will be carried out (e.g. using transcriptomics) in cell lines. Blood sampling will cause transient discomfort, but no lasting harm is expected.

Repeated blood sampling may in rare cases (<1%) cause soreness around the site of collection on the tail. Intrathecal and intracerebroventricular administration may cause death from over dose of anaesthesia (<1%), death because of a failure to recover from anaesthesia (<1%), procedure- associated infections (this is anticipated to be extremely rare, <1%). For mice receiving intrathecal/i.c.v. injections, there is a possibility of wound infection (<1%) or wound reopening (anticipated to occur in <5% of animals). Accidental damage to the nervous tissues during substance administration may lead to temporary or permanent nervous signs post-procedure (<2%). In some cases an adverse response to the substance may occur. This may include inflammation, altered behaviour, or seizures. Adverse reactions to substances are anticipated to occur in less than 5% of animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate (all animals)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The work aims to determine the distribution of compounds among organs and cell types, their efficacy, and their potential adverse effects. Each of these requires an intact mammalian physiology including circulation, immune system and organ system that are analogous to humans.

Which non-animal alternatives did you consider for use in this project?

All nucleic acid-based compounds will first be extensively tested in lab-grown cells to ensure their genetic precision and effectiveness and to predict their safety as much as possible based on markers of cellular stress and toxicity. Specifically, compounds will be introduced into one or more human cell lines at a range of doses. We will measure expression of the target gene (compared to non-targeting control) and also ultimately the entire transcriptome to evaluate specificity. We will also evaluate markers of cellular toxicity and death. We also considered lab-grown tissues derived from human stem cells.

These can replicate aspects of organ formation and have been investigated in the context of different organs including forebrain, kidney, and liver. They contain authentic cell types and replicate some aspects of physiology, such as kidney filtration, but not others, such as immune responses.

Why were they not suitable?

Lab-grown cells and tissues will be used to test compounds with respect to genetic efficacy and specificity, but cannot be used to assess compound distribution in the context of intact circulation, immune system, and inter-organ communication. For example, compounds cannot penetrate the interior of lab-grown tissues (e.g. organoids) due to a lack of circulation. Lab-grown tissues also have no utility in predicting physiological adverse effects (e.g. inflammatory response).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will, using extensive targeting and toxicology testing in immortalised and primary cells lines, prioritize compounds for evaluation in mice. In similar studies, statistically significant effects can be observed with 6-8 mice. We plan to administer up to 15 compounds per year (9 given systemically, 6 delivered to the CNS) at up to typically three dose levels, plus up to two negative controls (for example, receiving a non-targeting sequence with and/or without specific chemical modifications) on each occasion. More than one compound may be used to investigate the same genetic target. Both sexes will be used.

Thus, up to 5 treatment groups per compound x 8 replicates = 40 x 15 compounds = 600 mice x 2 sexes
= 1200 mice x 5 years = 6000 mice total

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used the LASA/NC3Rs “Guidance on dose level selection for regulatory general toxicology studies for pharmaceuticals”. For initial screening studies, three compounds is the minimum to provide sufficient diversity and buffer and reduce the risk of failure. For dose-finding studies, three doses (low, medium, and high, based on established dose guidelines for the class of compound and route of administration, as well as effective dose in lab-grown cells) is the minimum number to determine the therapeutic window in which a

beneficial effect is observed with minimal adverse effects. Based on similar studies in the literature, 6-8 mice per group is the minimum required to obtain interpretable results, given the typical effect sizes and variances observed in previous studies of this type. We will use both sexes. Experimental design will be reconsidered for every compound/route and the required sample number calculated based on appropriate statistical tools and using current data on variability and effect size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- We will minimise variability, and therefore number of animals required to obtain interpretable results, by using inbred strains and ensuring good animal health and minimum stress. We will use animals of the same age and strain for each study. We will use small-scale initial pilot studies to determine the viability and best dose of lead compounds for each genetic target.

- We will avoid having to repeat experiments for additional data collection by collecting a wide range of tissues at the time of euthanasia

- We will avoid repeating experiments in cases where the effects of compounds with similar chemical structures have already been well characterised by us or others

- We will strive to disseminate negative results from our studies (i.e. cases where compounds were not effective or not well tolerated), to inform other groups and prevent them needlessly repeating studies with ineffective compounds

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use wild-type (non-genetically modified) mice, primarily of the C57BL/6J strain to ascertain compound efficacy. Typically, mice will receive one dose of a double-stranded nucleic acid (e.g. siRNA) or up to 4 doses of single-stranded nucleic acid (e.g. ASO) through the subcutaneous (s.c.), intravenous (i.v.), intraperitoneal (i.p.), intrathecal, intramuscular, or intracerebroventricular route. Mice will be euthanised after a suitable incubation period (2 weeks to 6 months).

The number of doses is the minimum to deliver sufficient compound (a single dose of double-stranded nucleic acid (e.g. siRNA) is adequate typically; up to 4 doses of single-stranded nucleic acid (e.g. ASO) may be the minimum necessary to attain sufficient levels to achieve the desired targeting effect). The routes of administration are the least invasive possible to achieve the necessary delivery (for example, where compounds administered s.c./i.p./i.v. do not reach the central nervous system in adequate quantities, this

necessitates intrathecal or intracerebroventricular administration). Wherever feasible, less invasive routes (s.c./i.p./i.v.) will be used.

Before planning studies with a given genetic target, we will scrutinise the literature for reports of effects on animals of genetic or molecular targeting of the same gene/protein, and of similar chemical structures being administered to mice. If targeting the gene/protein in different ways, or use of similar chemical structure and delivery route, is well-tolerated in the same species, it is highly unlikely that a nucleic acid compound will cause sequence-specific adverse effects.

Why can't you use animals that are less sentient?

The next less sentient viable animal model would be fish. These are not suitable for investigating organ distribution, since their organs are too different from humans (e.g. no lungs). Fish are also not suitable for investigating routes of administration, since many of these are not established or feasible in fish (e.g. intrathecal or intravenous injection). We cannot use mice under terminal anaesthesia due to the incubation times of 2 weeks minimum.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Comprehensive monitoring and welfare assessment (including Home Cage Monitoring Systems for new compounds), with use of analgesics or euthanasia if indicated

Minimize the dosing volumes Minimize the number of doses

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines

NC3Rs (National Centre for the Replacement, Refinement, and Reduction of Animals in Research) resources

LASA (Laboratory Animal Science Association) dosing guides

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

- Keep up to date with new literature in the field Attend international conferences
- Seek information on technical refinements from collaborators and colleagues Regular communication with local named persons
- Participate in discussions and attend seminars on 3R topics at the Harwell Research Campus
- Communication with the Medicines and Healthcare Regulatory Agency about optimal study design for translational projects aimed at bringing products to the therapeutic market

50. The evolution of the placenta across vertebrates

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

placenta, pregnancy, evolution, placenta development, pregnancy immunology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Poeciliidae	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how new organs originate and how they subsequently change in form and function across species using the placenta as a model. The placenta has evolved multiple times independently across vertebrates and we study its biology, development, and evolution in mammals and fish.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The placenta is responsible for transferring nutrients, oxygen, waste, and hormones between the mother and her embryo(s). Without the placenta, none of us would be here. Despite its crucial role, the placenta is one of the most poorly understood organs, and as a consequence, so are many pregnancy complications. An example is pre-eclampsia, a condition associated with maternal high blood pressure that can impact as many as 1 in 12 pregnancies and is a leading cause of maternal ill-health. This project aims to bring much-needed insight into the placenta, how it develops across different mammals, and how it

evolves across species. One of our focuses is on one of the most fascinating aspects of pregnancy - the mother's tolerance to the direct contact between her own cells and those of her foetus. We study how maternal immune systems have evolved different solutions in different mammals (including in humans) to deal with the challenges of the foetus on the mother's immune system.

The placenta is not, however, exclusive to mammals. Placentas have evolved more than 100 times independently across different vertebrates (for example, in some lizards, snakes, amphibians and fish). This makes the placenta an exceptional organ in which to study how organs originate and how they subsequently change in form and function across species. One family of small neotropical fishes (Poeciliidae) is exceptional from this point of view. Within this fish family (which includes guppies and mollies), placentas have evolved independently multiple times. We study this unique fish family to identify general principles (or rules) guiding the evolution of new organs.

What outputs do you think you will see at the end of this project?

There will be three main overarching outputs. One output will be a better understanding of the evolution of the mammalian placenta from a maternal perspective. Across mammals, maternal immune systems have evolved a variety of solutions to deal with the challenges of pregnancy. Identifying and understanding these solutions will shed new light on the evolution of the placenta. It will also contribute to our understanding of pregnancy complications, and it can potentially teach us about the immune rejection of transplants.

A second main output will be a description of how novel complex organs can evolve from scratch. Among Poeciliids, a placenta has evolved independently multiple times, and although sharing many features, the placentas from different species also show distinct morphologies. We aim to identify general principles underlying the formation of a new organ.

A third main output will be the identification of animal models that best mimic different aspects of the human placenta. Because the placentas of different species differ greatly, there is not a single best species that can serve as a proxy for the human placenta. By understanding the similarities and differences among placentas of different mammals, we will be able to identify the animal models that best resemble the human placenta.

We will share these outputs through publications in scientific journals and communications in scientific conferences and the press to quickly and freely disseminate our results to the general public and the scientific community.

We will also create a user-friendly (and freely available) database that compares placenta development across species. This database will allow the scientific community to access our data quickly and easily, maximizing its impact. It will also help in the choice of species and developmental stages for studying specific aspects of human placenta development.

Who or what will benefit from these outputs, and how?

The primary beneficiaries of these outputs will be other research groups that study the human placenta (in health and disease) and that of other species. We expect our novel findings to start being disseminated in scientific publications and conference communications two thirds into this project and continue for the ensuing years.

An output of this project will be a database, which will be available to all, describing (at the molecular level) placenta development across many species. These data will eliminate the need for smaller, targeted studies of individual species and/or developmental stages and serve as a resource for the scientific community. In the long run, it will reduce the number of animals used for these purposes. We anticipate making most of these data available before the completion of this project.

By comparing placenta development across multiple species, we will create a resource that will aid in choosing the most appropriate species to study different features of the human placenta. We anticipate that this will have a significant impact on the placenta biology community.

How will you look to maximise the outputs of this work?

We will create a database to make our data easily accessible to all researchers. We will produce the data in an unbiased and systematic manner to serve as a community resource. We expect our database to eliminate the need for smaller, targeted studies of individual species and developmental stages and hence, the number of animals involved.

We will disseminate the results from our work in multiple scientific publications. These peer-reviewed publications will be open access, that is, freely available to all. We will also disseminate our results through scientific conferences, national and international. To make our work accessible to the general public, we will write summaries for a lay audience and disseminate them in suitable outlets (general press).

This research involves collaborations with research groups from the UK, Europe, and the USA.

Species and numbers of animals expected to be used

- Mice: 4800
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The development of the placenta depends on an active collaboration between the mother and the embryo. There are currently no *in vitro* systems that can model this process properly. Our mammalian work will be primarily based on a collection of frozen tissues (placentas) obtained before the start of this project from several mammals (including humans, marmosets, mice, rats, rabbits, guinea pigs, horses, sheep, bats, and opossums). We acquired these frozen samples through multiple national and international collaborations. However, to study specific aspects of placenta development and function, we must work with genetically altered mice. We will work with two groups of genetically altered mice.

One group of mice have modifications that allow us to visualize under the microscope the cells where specific genes are active, which is key to understanding placenta

development. The other group comprises mice with genetic modifications that may impact the placenta, such as the maternal immune response to pregnancy. We are asking for permission to breed these mice in our animal facility to study their placentas. The placenta is an embryonic tissue that is only present before birth. Therefore, our work will focus on embryos and fetuses of both sexes and pregnant female adults.

The family of fish Poeciliidae (that includes guppies) is an exceptional model to study how placentas evolve from scratch because, within this family, placentas evolved independently multiple times. This means that we can study closely related species with and without a placenta, something not possible in mammals. Like in mammals, the fish placenta is an active collaboration between the mother and embryo and only exists before birth. Hence, our fish work will also be based on embryos of both sexes and adult pregnant females.

Typically, what will be done to an animal used in your project?

Mice: We are asking to breed genetically altered mice so that we can collect placental tissues from pregnant females. The tissues will only be collected after the animals are humanely killed using Schedule 1 approved methods.

Some mice will have genetic modifications that need to be activated by giving the pregnant female an activating substance. We will only use activating substances that do not produce adverse effects beyond their administration's mild and transient discomfort (e.g. oral gavage) or that cause adverse effects that can be counteracted by administrating other substances. For example, the adverse effects of tamoxifen, an activating substance, can be counteracted by the administration of progesterone. The activating substances will only be administered once per individual. We will collect placental tissues after the pregnant females are humanely killed using Schedule 1 approved methods.

Fish: We will humanely kill fish using approved methods. In addition to collecting placentas, we will also collect other organs/tissues (e.g. brain, ovary) to create a tissue biobank that we and others can use for future work, thus eliminating the need for further animal use.

Following veterinary advice, we may use hormones to induce some fish species to mate in case of low performance. The hormones will be added to the water in concentrations that will not adversely affect the fish. We will only use hormones if all other methods available fail (e.g. changes in nutrition, water temperature, environment enrichment) and if there are no known adverse effects associated with these hormones.

What are the expected impacts and/or adverse effects for the animals during your project?

Most genetic alterations in the mice that we will breed and maintain either have no impact on the animals or only have mild effects that do not impact their life quality in a laboratory setting.
Some genetic alterations may be associated with some embryo loss during early to mid-gestation or with difficulties in embryo implantation in the uterus. The latter is not expected to lead to adverse effects on the pregnant female, and the embryos are lost at a very early stage of development.

The administration of activating substances produces mild and transient discomfort. We will only use activating substances that do not have significant adverse effects or whose

adverse effects can be alleviated using other substances (e.g. progesterone in the case of tamoxifen).

No adverse effects are expected for the fish. We will only use hormones if they do not have side effects and are approved by the veterinarian.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of all protocols is set at mild, but the expected severity for the fish is sub-threshold.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development of the placenta is a cooperative process between the embryo (from which the placenta originates) and the mother. There is a special tissue that forms during pregnancy in the uterus, called decidua, which works together with the placenta to provide the developing embryo with the nutrients and everything else it needs to grow. It is the placenta and decidua combined that is the functional unit that allows animals to grow in their mother's womb. Pregnancy is also a process that differs in many essential details between species. For both these reasons, we cannot study placenta development using *in vitro* (cell culture) systems. We also know so little about this system that we do not know how to approximate *in silico* these complex interactions between the mother and the embryo, and so no realistic *in silico* models exist yet (but we hope our research will ultimately help make these models possible). The placenta needs to be studied in its native complex context, and we can only understand the diversity of placenta forms and functions between species by studying those species.

Which non-animal alternatives did you consider for use in this project?
Because the development of the placenta depends on both the embryo and the mother and the complex interactions between them, it cannot be understood outside its native (animal) context. The existing *in vitro* models of embryo development do not include the placenta. Even if they did it, the critical maternal contribution, the decidua, would still be missing. However, we have tried to minimise as much as possible the use of animals. Most of this project is based on placenta tissue samples that we acquired through multiple national and international collaborations. However, to study some aspects of placenta development and function, we must work with genetically altered mice.

Why were they not suitable?

There are no feasible alternatives to studying the placenta outside its native (animal) context because we know too little about this system to approximate it using other ways. The development of the placenta is one of the most complex biological systems as it requires tight cooperation between two distinct individuals, the mother and the embryo. By studying the development of the placenta and its evolution across species, we aim to generate knowledge that will inform future studies and allow the development of *in vitro* and *in silico* models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We are aiming to breed 12 genetically altered strains of mice. We will breed these mice to maintain the strains in our animal facility, and we will set up specific matings within and between these strains to collect the placenta tissues (the pregnant females will be humanely killed). We estimated the total number of mice by multiplying the number of strains (12) by the number of mice that historically were required in projects with similar goals per year (80) times the 5 years (4800 mice).

We are aiming to maintain 10 species of Poeciliids. Of these, we estimate that we will need to administer hormones to promote matings to a maximum of 5 species. If we administer hormones to 40 females in each species per year, that will lead to 5 species x 40 females x 5 years, which is 1000.

We will also create a tissue biobank for the 10 species of Poeciliids. This means that in addition to collecting the maternal-fetal interface (i.e., the placenta in species that have this organ), we will also collect other tissues (e.g., brain tissues, kidneys, ovaries). Across the 10 species, we estimate that we will humanely kill and then harvest tissues for 500 individuals (50 per species) in order to cover both sexes and main developmental stages.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?
We established national and international collaborations to create a tissue biobank of hundreds of placentas from multiple species and developmental stages. The placentas were not collected specifically for this project. Through this step, we dramatically reduced the number of animals to be used in this project. We will keep using this strategy of collaborating with others to minimize animal use whenever possible. Additionally, to reduce the use of the Poeciliidae fish in future studies, we will collect tissues (in addition to the placenta) from humanely killed animals and create a tissue biobank.

We consulted with the staff at our animal facility, including veterinarians, to estimate the minimum number of animals needed to maintain genetically altered strains. We strive to use and maintain low numbers of animals by sharing lines and tissues from genetically altered mice with other labs and freezing embryos, tissues, and gametes whenever

possible. Because our work focuses on prenatal development, when we humanely kill a female mouse (or administer a substance), we can obtain tissues from the entire litter of embryos. Each embryo is a data point. Together, this strategy will reduce the overall number of mice used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever possible, we will obtain tissues (placentas) through collaborations. We have done this successfully for animals from multiple species that are not genetically altered, and we will aim to do the same for genetically altered mice strains. We will only breed them ourselves when this cannot be done through collaboration.

Breeding will be carefully controlled to avoid surplus animals, and when animals do have to be sacrificed, we will aim to collect as many tissues from as many animals as possible (after they are humanely killed). We will build tissue biobanks for the different strains that we and others can use in future work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will work with two groups of genetically modified mice. One group of mice have modifications that need to be activated using gene activating substances (e.g. hormones). Some of these mice will allow us to visualise under the microscope (e.g., using fluorescence) the cells where specific genes are active, which is key to understanding placenta development and function. These genetic alterations do not cause any harm to the animals before and after activation. Other mice will allow us to understand the consequences of altering gene function in restricted physiological contexts, for example, in specific cell types and/or developmental stages. We will use these conditional alterations so that the modifications will only be active in a restricted group of cells and/or stages to minimise the negative effects on the animals. To activate the genetic alterations, we will give the animals the gene activating substances using methods (like oral gavage) that only cause mild discomfort and for a very limited time.

The other group comprises mice carrying genetic modifications with the potential to impact the development or function of the placenta, such as the maternal immune response to pregnancy. We will breed these mice and examine the placentas after the animals have been humanely killed. We can breed these mice because although the genetic alterations they carry may impact the placenta, they have restricted effects allowing for successful pregnancies.

For the fish species, the use of hormones to encourage breeding are not expected to have any negative impact, including pain or suffering.

Why can’t you use animals that are less sentient?

The mammalian placenta is an organ exclusive of mammals and can only be studied in mammalian species. However, because the placenta is only present before birth, most of the animals used will be at an embryonic or fetal stage of development. We will sacrifice the minimum number possible of pregnant females. Whenever possible, we will focus on embryos during the first two-thirds of gestation.

The Poeciliidae fish family is unique among animals because a placenta evolved independently nine times (for example, the mammalian placenta evolved only once, so all mammals share the same placenta). This means that uniquely in Poeciliids, we can compare multiple pairs of closely related species where one species has a placenta and the other does not. The Poeciliidae is a unique natural system that cannot be replicated with other species. We will study the fish before they are born, and we will sacrifice the minimum number possible of pregnant females.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The mice that we will breed will be monitored by highly trained animal technicians. There are ongoing efforts in our animal facility to test different bedding materials and shelters to identify those that maximise the animal's wellbeing. Different strains can have different preferences. We will apply the insights from these efforts to our mice to maximise their environmental enrichment. The mice that will be administered gene activating substances will undergo increased monitoring after the procedure. We will work together with fish specialists to maximise the environmental enrichment of our fish. If hormones need to be administered to encourage matings, we will precisely follow the instructions from the fish specialists and veterinarians and monitor these fish closely for the hours following the hormone administration.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow ARRIVE 2.0, PREPARE and NC3Rs guidelines. The NC3Rs monthly newsletter will keep us abreast of new developments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed through the NC3Rs monthly newsletter to which we are subscribers and through in-person training provided by our institution. Advances in the 3Rs are also shared internally at our institution via AWERB and NIO.

51. Towards a better understanding of pathological mechanisms of muscular dystrophy

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Duchenne muscular dystrophy, mdx mouse, purinergic signalling, inflammation, gene therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to fully understand the pathological mechanisms behind the most common and highly debilitating muscular dystrophy and to use this knowledge to develop new and more effective therapies for this incurable disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Amongst over forty muscular dystrophies, Duchenne muscular dystrophy (DMD) is the most common and lethal inherited muscle disease. Affected boys demonstrate their first clinical symptoms in early childhood, develop progressive muscle weakness and wasting leading to a severe disability in their early teens and die at the age of 20-30. The physical symptoms can be exacerbated by a cognitive and behavioural impairment. Despite decades of research, no cure is available and treatments are symptomatic only. Recent data, including that from our laboratory, indicate that the understanding of the DMD pathology is incomplete and this hampers the development of effective therapies. It is

imperative that the disease processes are fully investigated, as the new knowledge gained should lead to more effective treatments.

What outputs do you think you will see at the end of this project?

New knowledge on molecular disease pathways will be obtained. In addition, mechanisms preventing and promoting dystrophic muscle regeneration will be described. This information will help to identify potential new therapeutic targets and also provide tools for monitoring the effectiveness of therapies. All the results will be published in medical journals to inform the researchers and clinicians, with whom we already collaborate. Key findings will be presented as press releases and information outlets aimed at the DMD community and the general public. Ultimately, some of these findings might lead to clinical trials and be translated into viable treatments.

Who or what will benefit from these outputs, and how?

Patients, patients' families and clinicians (and in the longer term the health care system) will benefit from the outputs generated under this project. In the short-term, findings released as quickly as possible shall lead to improved understanding of this pathology. Moreover, such findings should inform novel therapeutic approaches. Some of these, involving the re-purposing of existing medicines, could be implemented quickly and inform the course of this project. Completely novel treatments would be expected to enter clinical practice after completion of extensive clinical trials. Ultimately, the successful completion of this project should result in better treatments for this highly debilitating and ultimately lethal disease. Beyond the DMD, these findings may find application in other areas of biomedicine by increasing our knowledge of the basic biology of the cells involved.

How will you look to maximise the outputs of this work?

Our research is highly collaborative, both nationally and internationally, which leads to widespread dissemination of data, including the negative results (to avoid unnecessary repetitions), through collaborative meetings and seminars. Moreover, we attempt to publish all the results, whether proving or disproving the research hypotheses, in high impact scientific journals and present these at conferences. We make all our research data freely available to other researchers and value their scrutiny and critical comments. Furthermore, we work with parents' groups and keep them informed about any new and relevant developments.

Species and numbers of animals expected to be used

- Mice: 5200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.
The mouse models of DMD are considered the most appropriate and efficacious for pre-clinical testing. Their use is the norm for making comparisons of the efficacy of any new method to previous approaches. We will be using two DMD mouse models, differing in the type of mutation and which we demonstrated to differ in specific aspects of the pathology.

Young adult mice, which show symptoms of the disease and also young pups to investigate the early, pre-symptomatic stages of this disease, will be used. Investigation of the latter life stage is important as we know that abnormalities are already occurring but the repair mechanisms are not fully operational yet. Therefore, the molecular pathways involved in damage and repair can be dissected. Furthermore, treatment at the early stages of this disease is expected to produce better results. Finally, older mice will be used to identify the long-lasting repair mechanisms. In addition to DMD mouse models, we will use mouse strains lacking specific proteins, which we discovered in earlier studies to be involved in the dystrophic pathology and which we aim to exploit as targets for developing novel, improved treatments. Genetically matched normal mouse strains will be used as controls in some experiments.

Typically, what will be done to an animal used in your project?

Mice will be bred to maintain the specific colonies and to generate new lines, which are dystrophic but lacking specific proteins that have been identified as important for the disease process. For breeding of genetically modified strains, the total of 5200 mice across five disease models will be used over the 5- year period. For the treatment, male mice will be handled, anaesthetised as appropriate, and the administration procedure undertaken. These could involve intramuscular or intraperitoneal injection or oral drug and/or gene therapeutic construct administration over a period of up to four weeks. For longer treatments drugs will be administered in drinking water, wherever possible, or implanted in a slow release form. 2000 mice will be used over the 5-year period. Some treated and control dystrophic mice will be tested for muscle strength and endurance and for their cognitive and behavioural functions using approved tests. 600 animals will be tested over the 5-year period. All animals will be killed at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

The DMD models to be used in this project show pathological symptoms akin to those in patients but these are transient (from 2 to 12 weeks of age), do not affect their mobility and do not lead to premature deaths. Mice genetically modified to lack specific proteins found by us to be involved in the dystrophic pathology have milder phenotypes than the original model and do not show any symptoms. Treated animals will experience a transient discomfort from the handling and the administration procedure. Bruising at the site of injection lasting for hours and exceptionally for a day may rarely occur. Weight loss associated with corticosteroid treatment may happen but will never be allowed to exceed 20% of body mass.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding of genetically modified mice severity is mild (5200 mice). The severity level of drug administration in drinking water is sub-threshold (50% of treated mice). The injection or oral drug administration and gene therapy treatments' severity level is mild (50% of treated mice).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are essential for this project as the dystrophic pathology results from a complex interplay between muscle degeneration and regeneration and immune and inflammatory responses, which contribute to both muscle damage and repair. Therefore, after completing all the possible in vitro tests, we cannot continue analysing these complex interactions and the efficacy of new treatments resulting from these new findings in an in vitro system. Tissue-specific ablation of the p2rx7 gene will explain the tissue- and cell-specific mechanism behind the therapeutic effect of p2rx7 ablation or inhibition that we previously identified. Moreover, we cannot study the functional efficacy of the purinergic blockade, which is under development as a DMD therapy as a result of our work under a previous licence, without pre-clinical testing in an animal model.

We have the zebrafish model of Duchenne muscular dystrophy (sapje) but while it replicates some of the key symptoms observed in patients and is being used by us for some applications. However, aspects of the fish disease relevant to this project are different and therefore the mouse models still need to be used.

Which non-animal alternatives did you consider for use in this project?

We use standard cell culture approaches, iPSCs differentiated into muscle cells, established muscle cell lines, muscle and macrophage cell co-culture system, and 3D muscle cell differentiation systems for some of our basic research.

Why were they not suitable?

The dystrophic pathology results from a complex interplay between muscle development and growth, muscle degeneration and regeneration and immune and inflammatory responses, which all contribute to both muscle damage and repair. The current co-culture systems cannot substitute for such a complex environment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will keep the numbers of mice used to the minimum, consistent with the aims and the predicted numbers have been calculated based on our previous experiences with these specific experimental designs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In all our experimental designs we have been following the ARRIVE guidelines, as demonstrated in Sinadinos et al., 2015 and the TREAT-NMD guidelines (https://treat-nmd.org/research-overview/).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever feasible, material from individual animals will be used for multiple analyses e.g. serum for creatine kinase assays, diaphragms for organ bath analyses and leg muscles for other analyses. Much of the work will involve histological sections. These will allow for a number of different analyses to be made in each individual animal (e.g. muscle morphometry and immunological infiltration analyses).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

There are several mammalian models of DMD: mouse strains, two dog, one pig and one cat models. The characteristics of each phenotype and pathology have been analysed for pathological similarities to the human disease and costs of the maintenance. There is a consensus amongst experts that the most appropriate model to test efficacy for DMD are the mdx mouse and the golden retriever muscular dystrophy (GRMD) dog model. Mouse models replicate the symptoms of human disease between 2 and 12 weeks of age but these are transient, not reducing animal mobility and not causing premature deaths. This transitional nature will be exploited to identify mechanisms that limit disease progression, as these could potentially be exploited for the treatment of dystrophic patients. Moreover, mouse has been chosen as it allows comparing the results of medicines administration with those obtained in double knockout studies and to compare efficacy of new treatments to other therapeutic modalities already described using this model. All the treatments are tested in 2-12 week-old animals.
The tests to be used in this study are based on specific guidelines provided by TREAT-NMD (*https://treat-nmd.org/*), designed specifically to standardize experimental protocols that are used as efficacy readouts to allow comparisons of parallel efforts. Following an extensive consultation process TREAT-NMD identified a limited number of experimental protocols, which are appropriate for use in preclinical work and accelerate the development of new therapeutic modalities.

Importantly, in this study pain or distress are not a necessary concomitant to the validity of the experimental outcome. Therefore, animals will be observed and scored according to the checklist established in the initial experiment. Following administration, any animals

showing signs of unwanted effects other than those resulting from injection itself would be killed by Schedule 1 method and if multiple animals display such symptoms the experiment with the particular drug will be terminated.

Why can't you use animals that are less sentient?

We are using *sapje* dystrophic zebrafish, where possible. But this model does not reproduce the aspects of the human pathology that we wish to study under this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mouse colonies are monitored regularly for any signs of distress. Mice post-procedures involving anaesthesia are placed in the recovery chamber and monitored constantly until they fully recover. For the treadmill test animals are trained and the test is done under a constant supervision to prevent any signs of exhaustion.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animals in Science Regulation Unit (ASRU) Guidance and regulatory advice, TREAT-NMD for best practice in animal research in dystrophic conditions (https://treat-nmd.org/research-overview/preclinical- research/animal-model-choice-for-dmd/) and ARRIVE for publication guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular updates from the NACWO and NIO and attend refresher courses. In addition, web- based resources such as the NC3Rs (nc3rs.org.uk/), will be consulted. All the advances applicable to this project will be implemented immediately.

52. Novel therapies for inflammatory joint disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Inflammation, Oxidative stress, Rheumatic disease, Arthritis, Therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to improve our understanding of sterile inflammation and to develop new therapies for joint disease. Many joint diseases such as Rheumatoid arthritis, gout and osteoarthritis have a sterile inflammatory component that is an important part of the pathology. Inflammation is also closely associated with increases in oxidative stress and this work aims to develop novel therapies that target these responses as a means by which to treat these diseases. Osteoarthritis, in particular, is a growing problem worldwide as a result of the aging population so that improved treatments would contribute significantly to patient mortality and morbidity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work so that potential new therapeutics can be developed for the treatment of human diseases. In some cases (e.g. osteoarthritis) there is a significant unmet medical need for new treatments as there are no existing therapies that

prevent disease progression. The work described in this licence will also deepen our understanding of inflammatory mechanisms, how these are regulated in vivo and how they might be pharmacologically controlled. This research will also inform our understanding of how oxidative stress influences inflammatory responses with a view to developing new ways of treating inflammation.

What outputs do you think you will see at the end of this project?

Outputs from this project will include new information on novel candidate therapies for joint disease and better understanding of the relationship between inflammation and oxidative stress. This new information will be published in the academic literature. In the long term, the outputs of this project may contribute to the development of new treatments for joint disease.

Who or what will benefit from these outputs, and how?

The short-term benefits (3-5 years) of these outputs are for the scientific community, particularly those involved in the fields of inflammation and oxidative stress. In the longer term (5-10 years), the pharmaceutical industry may benefit from the knowledge gained by this work. In the very long term (10- 25 years), patients and the NHS may benefit from new and better treatments for joint disease.

How will you look to maximise the outputs of this work?

There are already a number of collaborations in place to ensure sharing of knowledge and experimental approaches. New knowledge will also be disseminated via publication in the academic literature. Information regarding unsuccessful approaches will be disseminated via publication and/or attendance at academic meetings.

Species and numbers of animals expected to be used

- Mice: 2100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The molecules tested in the animal models detailed in this project will have already been tested in cells in vitro and in ex vivo tissue and now need to be tested in vivo. This is particularly important as one of the major aims of this work is to test delivery of therapeutic molecules to sites of disease when injected systemically. This can only be tested using an in vivo model system.

Typically, what will be done to an animal used in your project?

Animals in this project will be treated to induce inflammation or a specific joint disease. Disease induction will be via injection of immunogenic antigens or via surgical procedure. Animals will then be treated with a therapeutic molecule which may be a protein or a nucleic acid. Treatment will usually consist of an injection administered intravenously or intraperitoneally and would normally be repeated three times per week. Some experiments

will be of short duration e.g. up to 48 hours while others will be much longer e.g. up to 20 weeks. The number of procedures that each animal will be subjected to will depend upon the particular protocol in use. Each protocol is related to a particular joint disease, with the exception of Protocol 1 which is designed to test the pharmacokinetics of new therapeutic molecules.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected adverse effects include discomfort or pain at site(s) of injection which is expected to be mild and transient (all protocols). In some cases, (Protocol 5) surgery may induce pain/discomfort which will be controlled by the use of analgesia. Some protocols will cause inflammation at specific sites (Protocols 3, 4 and 5) with moderate severity. The estimated duration of these effects is between 48 hours and 8 weeks depending on the experimental protocol. All animals will be humanely killed at the end of each experiment/protocol and every attempt will be made to set early humane end-points.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All protocols have a 'moderate' expected severity. Therefore, all animals under this licence are expected to experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The molecules tested in the animal models included in this project have already been tested in cells in vitro and via ex vivo tissue culture. These molecules now need to be tested for therapeutic effects in vivo. This is particularly important as one of the major aims of this work is to test delivery of therapeutic molecules to sites of disease when injected systemically. This can only be tested using an in vivo model system.
Which non-animal alternatives did you consider for use in this project?

All of the development and preliminary testing of anti-inflammatory molecules has been performed in vitro using cultured cells or ex vivo tissue. There are no non-animal alternatives that are appropriate for the next stage of testing of these molecules for therapeutic efficacy.

Why were they not suitable?

A major aim of this work is to test the delivery of molecules to sites of disease in the body

when administered systemically. Therefore, an in vivo system is essential and cannot be replicated using other approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A statistician has been consulted so that the experiments designed have sufficient power to detect biological changes but will use the minimum numbers of animals per group. In addition, multiple parameters will be measured in each animal after death so that as much data as possible is obtained from each experiment thus avoiding the need to repeat experiments. This will not impact on the welfare of the animals while alive. Experimental bias will be reduced by use of randomisation when assigning animals to treatment groups and blinding of researchers to treatments received when analysing results.

I am wholly committed to publishing all data obtained in accordance with the NC3Rs ARRIVE Guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal usage will be reduced where possible. Some protocols have been specifically designed (Protocols 3 and 5) to induce disease in one limb so that the contralateral limb can be used as an internal control, so limiting the use of specific control animals. In order to reduce animal usage we will endeavour to gain as much information as possible from each experimental animal. Multiple samples will be collected when animals are terminated including blood, lymph nodes and inflamed tissue for fixation and subsequent histological examination. With Luminex and array technology it is now possible to sequentially measure levels of multiple mediators or their encoding RNA in small sample (50 µL) volumes through specific antibody or oligonucleotide interactions. This technology is available in our department and can further expand the information that can be assimilated from each animal where previously samples from several animals would have been required. The experimental designs detailed in this licence are based on the results of previous experiments performed previously in our lab and by our collaborators in other institutions. However, the NC3Rs Experimental Design Assistant will be routinely used to constantly monitor the numbers of animals used in our experiments based on new and emerging experimental data to ensure that animal numbers are reduced further if effect sizes allow. This will ensure that animal numbers are kept to the absolute minimum, while still obtaining robust scientific data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As mentioned above, wherever possible we will collect multiple data points from a single animal to increase data yield. Before any new study is conducted, we will conduct a range of in vitro and ex vivo experiments to enable us to provide reliable pilot data and thus allow

us to optimise dosing with test therapies. We will also make use of small-scale pilot studies in vivo to investigate observed effect sizes to determine whether an experiment can be completed with a reasonable sample size. If this is not the case, we will not proceed with that experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Each of the mouse models of disease detailed in this licence are well characterised in terms of their relevance to human disease. In addition, I have carefully considered the mouse strain used in each protocol so that the severity of the procedure can be minimised as much as possible. General measures taken to minimise welfare costs to animals include ensuring that all procedures are undertaken by suitably trained personnel and by ensuring that animals are inspected at least once daily during protocols so that unnecessary suffering is avoided. Pain relief will be provided where appropriate.

Animals will be caught prior to handling by methods such as catching and restraining using cupped hands or tunnels to decrease the stress and anxiety associated with catching mice by the tail.

Two protocols (Protocol 4 and Protocol 5) included in this licence are chronic in nature and painful and/or distressing for the mice. Therefore, there are specific refinements that will be applied when these protocols are used. The collagen-induced arthritis (CIA) model is useful for testing novel drug therapies because it mirrors the complexity of human RA in that both cellular and humoral immunity is invoked. At present, there is no spontaneous model in a GAA strain that resembles RA. The CIA model will be refined in a number of ways. To reduce the risk of ulceration at the site of injection of immunogen/adjuvant, a subcutaneous, rather than intradermal, injection will be given and the immunogen will be administered not at the base of the tail, but along the flank or back, where the skin is less prone to ulceration. Analgesics must be used with caution in animal models of arthritis because their anti-inflammatory activity tends to inhibit arthritis development in models of autoimmune arthritis.

However, dipyrone may be used as an analgesic as it does not inhibit disease progression or immune cell function when administered in the drinking water or by intraperitoneal injection. Analgesics will therefore routinely be administered prior to onset of arthritis and we will continue to optimise the dosing schedule and to evaluate alternative analgesics. Analgesics will be withheld if we suspect a pharmacological interaction with the drug under test. Additional husbandry support such as easier access to food (e.g. pellets placed at floor level) and supplemental bedding will be provided. General husbandry refinements for all protocols inducing chronic disease will include soft litter, nesting material, environmental enrichment and an appropriate number of cage-mates.

An important refinement is to limit the length of time that arthritis is present to the shortest possible time required to answer a given experimental question. Hence, mice with collagen-induced arthritis will normally be kept alive for a maximum of 21 days. For all dosing, the smallest needle diameter which allows rapid injection of the substance will be used, the smallest possible volume of substance will be administered and aseptic technique will be used. Where multiple injections are required, the most refined route of administration will be used, including slow release pellets or osmotic pumps. The use of humane endpoints, detailed in each protocol, will also ensure that no animal suffers unduly.

The model of osteoarthritis chosen is the destabilization of the medial meniscus (DMM) model that is the most refined of the OA models. Although this is a surgical model, it is minimally traumatic for the mice, leading to a slower progressing disease compared with those involving chemical induction or cruciate ligament transection. As described for the CIA model of arthritis, an important refinement is to limit the length of time that animals are in pain. The time-points chosen for analyses are 8 weeks, 12 and 20 weeks post-surgery to minimise the discomfort experienced by the mice while still achieving the scientific aims. Analgesia will also be administered just prior to surgery to minimise any pain induced by the DMM surgery.

Why can’t you use animals that are less sentient?

Experimental models of human disease are important for the development of new disease treatments. However, the challenge is to utilise experimental models that most closely mirror the human disease so that effective therapies in these models are likely to translate to novel treatments in the clinic. Mice are the lowest vertebrate group on which well-established models of disease have been developed. In this regard I will endeavour to refine our research strategy so that initial experiments are undertaken in the shorter models of disease and only the most effective therapies are examined in models requiring longer duration.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will continue to refine our methods to improve the well-being of animals, both by the updates provided by organisations such as LASA and NC3Rs and by contact with other research groups doing similar work.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to regularly update our knowledge on refinement using peer-reviewed, academic papers that use similar experimental methods. An important resource is the RSPCA resources on reducing severe suffering in animal research (https://science.rspca.org.uk/-/severe-suffering), with many of our refinements, particularly for the rheumatoid arthritis model, referenced on this site. We will also refer to resources, such as webinars and publications from organisations such as LASA and NC3Rs, including the LASA report on avoiding animal mortality, LASA guide to aseptic techniques, and NC3Rs newsletters.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular updates from The Laboratory Animal Science Association (LASA) and the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs). These organisations often provide educational material on how to improve animal well-being and minimise harm, and my laboratory members are encouraged to attend webinars hosted by NC3Rs. I also have regular meetings with my laboratory members to critically examine if any of these good practices can be adapted without altering our experimental outcomes.

53. Mechanisms and functions of sleep

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

sleep, torpor, brain, mice, hamsters

Animal types	Life stages
Mice	juvenile, adult, neonate, embryo, pregnant, aged
Siberian hamster	adult, juvenile, neonate, embryo, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Sleep is a vital process, necessary for well-being. The aim of this project is to obtain better understanding of the effects of sleep deprivation on the brain and the body, and of the benefits of sleep for metabolic regulation and cognitive functions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will have high impact for society, the economy and well-being because it will lead to a greater understanding of the mechanisms which regulate circadian entrainment, sleep/wake timing and sleep quality. Circadian rhythms and sleep/wake timing are

commonly disturbed by social and lifestyle factors, such as jet lag and shift work. Poor sleep is among the most prevalent complaints observed in many epidemiological studies, and the second most common overall complaint reported in primary care settings after pain. Disturbances in circadian rhythms and sleep/wake timing have a major impact on quality of life, resulting in impaired cognitive performance, increased risk of accidents as well as effects on immune function, hormone levels and cardiovascular performance. The amount of sleep and its quality also deteriorate with increasing age. As a result, elderly people are the main consumers of hypnotics, which have various side effects. A greater understanding of how circadian rhythms and sleep are disturbed by disease is necessary to enable therapeutic intervention. For example, data from this project are expected to provide a greater understanding of how sleep is affected by dysfunctional neurotransmission, typical for a range of neuropsychiatric disorders. In addition, there is a well-known trend for increased incidence of obesity, diabetes and metabolic dysregulation, which is often associated with reduced sleep quantity and quality, or disrupted wake/sleep patterns. Finally, this project will determine neurophysiological links between brain mechanisms underlying sleep and torpor. Inducing a reversible hypometabolism that mimics natural torpor in humans could have important influences on critical medical situations, including myocardial or cerebral ischemia, haemorrhagic shock, septicaemia, and organ transplantation.

What outputs do you think you will see at the end of this project?

The overarching aim of this project is to attain better understanding of the effects of sleep deprivation on the brain and the body, and of the benefits of sleep for metabolic regulation and cognitive functions.

This project will have high impact for society, the economy and well-being because it will lead to a greater understanding of the mechanisms which regulate circadian entrainment, sleep/wake timing and sleep quality.

Data from this project are expected to provide a greater understanding of how sleep is affected by dysfunctional neurotransmission, typical for a range of neuropsychiatric disorders.

Finally, this project will determine neurophysiological links between brain mechanisms underlying sleep and metabolism.

Who or what will benefit from these outputs, and how?

This project has academic and non-academic beneficiaries, including industry and patients. As our work will examine the fundamental mechanisms that underpin biological sleep need, this project will benefit a broad academic community. This includes basic and clinical researchers from the fields of neuroscience, sleep physiology, cognitive and circadian neurobiology, and neural engineering. The findings from our project will inform future studies addressing the effects of insufficient or disrupted sleep on brain function and bodily physiology, and will contribute to the development of novel approaches for sleep enhancement. The last years have seen a major increase in efforts to manipulate, or "enhance" sleep non-invasively and non-pharmacologically using direct or indirect (sensory) brain stimulation. Numerous companies spun out world-wide to develop these technologies, which attracted multimillion investments from venture capital firms and research funding. Our project will provide important experimental models and data that will inform future studies on sleep "enhancement". This project will also provide novel knowledge that will improve reproducibility of rodent studies, and will help to establish

novel refined rodent models for biomedical research. Our project will combine conventional transgenic approaches widely used in the field with a careful evaluation of the role of stress and environmental conditions, such as light. This will set the highest standards for sleep studies and will benefit numerous laboratories across the globe working on translational research.

How will you look to maximise the outputs of this work?

Outputs from this project will be maximised by collaborations and data sharing.

The protocols and electrophysiological data will be made openly available for access across the scientific community.

Al publications will be deposited on preprint servers and made open access upon acceptance.

Our work is regularly presented at national and international conferences, seminars and workshops.

Species and numbers of animals expected to be used

- Mice: 15000
- Other rodents: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Laboratory mice (Mus musculus) and Siberian hamsters (Phodopus sungorus) will be used in this project.

A part of the project will rely on mouse models, as this is the most commonly used species in sleep and circadian neurobiology, and techniques for chronic electrophysiological recordings, circadian phenotyping and transgenic manipulations have been well established in this species. These are also the phylogenetically lowest mammalian species commonly used in the laboratory with a brain sufficiently large to accommodate the recording electrodes required by this project.

Some experiments will be performed in Siberian hamsters. These animals show a pronounced seasonal physiology, including photoperiodism and photorefractoriness. We have established a successful breeding program for Siberian hamsters, which is designed to maintain winter phenotype in our hamster colony. When under short photoperiods, animals will be kept singly housed will be weighed and pelage colour will be scored every week. Animals that show high adaptation to short photoperiod after 8-10 weeks will be returned to the breeding protocol or included in torpor experiments. The brain size and anatomy of hamsters is similar to mice. The surgical procedures for implanting electrodes in Siberian hamsters are well established and will be similar to this procedure performed in mice. We will perform continuous sleep recordings in a subset of adult hamsters, where lighting schedules and ambient temperature will be varied to enable comparison with mice.

There is no alternative to using live hamsters in this project. Sleep and torpor are behavioural state and can only be defined and fully investigated in live animals.

Typically, what will be done to an animal used in your project?

Genetically altered mice and Siberian hamsters will be bred. They will undergo surgery to implant electrodes or probes that will allow us to monitor behaviour, body temperature or brain activity continuously. Mice maybe monitored in free moving or tethered conditions. They will also be singly housed during some of this monitoring.

The electrodes will also allow us to stimulate specific brain areas.

Mice may undergo chemical genetic alteration aimed at ablating or inducing genes of interest.

Animals may undergo sleep deprivation by being exposed to gentle stimulus or novel objects. We may also expose animals to altered light cycles to replicate those experiences that are like jet lag in the human. Behavioural tests will play an important part in our studies and animals will undergo habituation prior to testing. Some animals will under be exposed to periods of fasting or given restricted amounts of food or food at designated times rather than adlib.

The maximum duration of our experiment is 12 weeks but typically 3-6 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Weight loss (up to 15% decrease) for the duration of fasting/scheduled feeding single-housing typically for up to 12 weeks during sleep/circadian monitoring transient changes in the animals motor functions due to altered gene function.
transient discomfort and/or weight loss associated with gavage administration of substances local inflammation or post-surgical pain discomfort, minor surgical complications (transient).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: sub-threshold (50%), Mild (25%), Moderate (25%)

Hamsters: sub-threshold (50%), Mild (25%), Moderate (25%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sleep, torpor and waking are complex behavioural states, which require use of live animals. Numerous brain areas are implicated in various aspects of memory, cognition and sleep-wake control and cannot be fully emulated in laboratory conditions or using computer modelling. The processes associated with cognition involve multiple distributed brain systems and therefore can also only be studied in alive freely-behaving conscious animals. Laboratory mice and Siberian hamsters are the best species for this project, as the techniques for chronic neuronal recordings and sleep studies have been well established in these species. These are also the phylogenetically lowest species of mammals commonly used in the laboratory with a brain sufficiently large enough to accommodate the recording electrodes as required by this project.

Which non-animal alternatives did you consider for use in this project?

Organotypic cultures, computer models.

Why were they not suitable?

Simple in vitro models do not allow the contribution of inputs originating from other brain areas to be investigated, which play a crucial role in the local and global neural dynamics during waking and sleep. The mechanisms of whole body metabolism can only be studied in vivo

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The determination of experimental and control groups in mouse and hamster experiments, numbers of animals and experimental design are based on extensive experience with the models

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A variety of measures will be used to reduce the number of animals for this project. Proper surgical procedures and postoperative care will result in better data quality thereby reducing the number of animals necessary to achieve the goals of this project. In order to reduce the total number of animals used to address the questions of this project, both mice and hamsters will be used, because depending on specific experimental series one or another species is more appropriate and suitable for obtaining reliable results using a minimal number of subjects. Specifically, some behavioural tasks, as well as pharmaco- and opto-genetic tools are better established and validated in mice, while hamsters are established species for investigating spontaneous seasonal torpor.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Careful colony management will reduce the number of animals necessary to achieve the research objectives.

We expect that not all animals will be able to complete some of the experimental series (e.g. some animals, not more than 20%, may be “slow learners” in the behavioural tasks). Those animals that will not reach the desirable performance level in the behavioural tasks will not undergo any invasive procedure and will be excluded from the experiment.

In some experiments, a conditional deletion of the gene of interest will be used by gavage administration of tamoxifen, which is known to produce more reliable results, and will therefore allow reducing the number of animals, which would undergo cranial surgery, behavioural tasks or other procedures.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the procedures used in this project are well established and routinely used in the field. We routinely evaluate technical improvements to improve experimental conditions, specific procedures and animal welfare.

A part of the project will rely on mouse models, as this is the most commonly used species in sleep and circadian neurobiology, and techniques for chronic electrophysiological recordings and circadian phenotyping have been well established in this species.

Manipulation of the genetic status of mice by the administration of substances enables us to restrict the severity of those animals under the breeding programme. Most of our models are established or emerging models of neurological and neurodegenerative conditions such as Parkinson’s or Alzheimer disease and the use of genetic manipulation means they do not need to experience the phenotype unless it is required for an experiment.

Modern methods of mouse genetics enable us to selectively monitor and modulate the function of selected neuronal population in a highly refined spatio-temporal manner.

Surgical implantation of electrodes is necessary to record brain activity chronically in freely behaving rodents, and may require single-housing. However, the animals will be kept in pairs or groups for most of their lives providing social enrichment, and all singly-housed animals will have appropriate environmental enrichment provided, such as varied types of nesting materials.

Sleep deprivation is performed by the most ethologically relevant way, i.e. by providing naturalistic stimulation, instead of using long-term instrumental procedures, which appear to stress the animals.

Systemic injections, such as via subcutaneous, intraperitoneal, oral (gavage), intravenous routes, intraocular or with mini-pumps will be performed using the recommended route or that with minimum potential for adverse effects.

Appropriate choice of anaesthetic and analgesic regimes for pain relief will be used.

Why can't you use animals that are less sentient?

Using mammals is required for this objective because the anatomy of the brain and metabolic regulation in fish, amphibians and reptiles are significantly different from mammals

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For behavioural experiments, we have chosen appetitive tasks or investigation of spontaneous behaviours, which rely on a reward rather than aversive reinforcement.

Miniaturisation of implanted devices.

Monitoring of locomotor activity and body temperature, which is a gold-standard in circadian phenotyping and sleep research, is a non-invasive approach.

Carefully controlled housing conditions, proper surgical procedures and postoperative care, including pain management

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA guidelines, NC3Rs, ARRIVE guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By attendance at both internal and external NC3R's meetings. Attendance at internal animal welfare meetings where updates are provided by both the NC3R' regional manager and the Named Information Officer.

54. Elements that control the initiation and progression of fibrosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

transgenic, fibroblasts, LRP-1, cre-lox system, pathology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify the role of specific genes, proteins and regulatory elements within genes that initiate, maintain the progression of connective tissue fibrosis. We specifically wish to test gain and loss of function of these specific genes in lung and skin.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fibrosis is defined as excessive tissue scarring, a common feature of most chronic diseases. There is very little in treatment for these diseases; most likely because each of these organs has a different purpose, is exposed to diverse environmental factors, and is composed of different cell types, there are unique features and consequences of tissue

fibrosis among these organs. We will focus our efforts on two organs: the skin and lung. We have previously shown that CCN2/CTGF and LRP-1 have a role to play in the pathogenesis of fibrosis. In addition, macrophages and epithelial basement membrane ECM-fibroblast cross talk have been shown to mediate part of this pathology. have been shown to mediate part of this pathology. It would be essential to characterise the mechanism by which they enforce their role. The benefit of this work is to understand better the pathophysiology of fibrosis and highlight molecules that can be used as a target to ameliorate the condition.

What outputs do you think you will see at the end of this project?

We hope to unravel the sequence of DNA that express during fibrosis and /or events that allow us to understand how the fibrotic process is initiated and maintained in skin and lung; especially, the role played by matricellular proteins, immune modulators and signalling molecules. The outcome will be communicated to the scientific community through publications and providing animal models of this pathology.

Who or what will benefit from these outputs, and how?

The ultimate beneficiaries are the animals and humans who succumb to this disease as we may provide targets for drugs that will either halt the initiation or progression of the disease state. Until then, the scientific community who are developing therapies will benefit, as well as pharmaceutical companies as they will be aware of the result of our investigation through publications and dissemination of our results.

How will you look to maximise the outputs of this work?

We will be using expertise in different areas: collaborating with clinical colleagues to interrogate the animal model as to the role of certain genes or molecules that are highlighted in human data.

Consolidate our research with similar models carried out elsewhere. To maximise the output, our work will be disseminated though our publications, press releases, national and international meetings to ensure we reach a wider audience.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are mainly using transgenic animals with cre-lox system in order to delete or overexpress the genes at the time we need. Mice are the smallest mammalian organism in which these technologies are available. The development of lung and skin are comparable to human tissues, and they breed in sufficient numbers to address funding cycles (mainly three years). We will use both embryos and adult mice to visualise the cells that are secreting excessive component of the extracellular matrix in the presence and absence of

the genes that this project is focusing on. The mechanics of the breathing cycles that inflate the lung and forces the expansion of the alveoli surrounded by the extracellular matrix that provide resistance cannot be replicated in less sentient animals.

Typically, what will be done to an animal used in your project?

In lung experiments: Single transgenic mouse carrying a floxed gene would be mated to a Cre mouse and double transgenics would be given a drug which will delete a gene during adulthood. The mouse will be administered bleomycin to induce lung fibrosis. mice will be monitored by in vivo µCT to analyse the level of fibrosis over three weeks and will be sacrificed at different intervals to harvest the lung for cellular and histological analysis.

In skin experiments: A mouse deleted of a specific gene may undergo punch biopsy of which will be monitored over two weeks. When a luciferase or fluorescent transgene is included, the mice will be imaged over time and then sacrificed and wound is compared with unaffected skin by various cellular, biochemical, histological and molecular means.

Similar treatment will be used with knock out or overexpressing mice to study the role of immune signalling in this process.

What are the expected impacts and/or adverse effects for the animals during your project?

In lung fibrosis, breathing distress can be seen with mice as they cannot cough but exhibit head twitching. The mice may refrain from activity about two days after bleomycin treatment. They will be weighed daily to monitor them. Normally they recover, if not they will be killed. Bleeding from the injury to skin, or extra scratching that prevent wound healing from occurring naturally. Skin irritation can occur in response to shaving or hair removal and animal may scratch the shaved skin.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity may be expected in 50% of mice that undergo lung fibrosis and 50% in skin injury.

Bleomycin induced lung fibrosis causes localised inflammation within the lungs and skin. At high dosage, bleomycin can cause breathing distress, the inflammation may exacerbate the condition, but the repair process normally subsides after initial treatment to be replaced by Extracellular Matrix deposition.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Fibrotic process is multifactorial and involves a number of cells responding to each other as well as other insults. Neither cells nor ex-vivo can be used currently as a replacement. We need to use animals in order to understand the whole picture and mice in particular, since we can manipulate their genetics in a defined and control manner. The mechanics of the breathing cycles that inflate the lung and forces the expansion of the alveoli surrounded by the extracellular matrix that provide resistance cannot be replicated in cell cultures or less sentient animals.

Which non-animal alternatives did you consider for use in this project?

Whenever possible, experiments are conducted in cells first to check the system is working before we test them in animals. This includes defining DNA sequences as enhancers, working out the function of ADAM17 in macrophages, Cre-lox system, imaging of transgene in cells before we move to animal model.

Why were they not suitable?

The complex interaction between cells in an organ and those circulation from the blood such as macrophages in lung and skin cannot be replicated by one or two cell types. Therefore, we need a whole living organ to test the role of the genes involved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Depending on the model, different number of mice may be needed. Our Null hypothesis= no change in ECM after injury. Alternative hypothesis: any change decrease or increase (Two tailed t-test). For comparison of skin treatment in terms of collagen change using two tailed- t-test on collagen changes; power calculation using our previous results suggests that with level of significance 0.05 and power 0.9 a std. dev. 0.43 we would need N=6 (G* power)

In repeated measurement, the level of significance >0.05 should be divided by the number of comparisons=3 (days after injury) This would increase the N=7.

A typical gain and loss of function experiment for pulmonary and dermal injury would include N=6 in each group;

Group1 sham PBS No Cre + TX Group 2 sham PBS +Cre +TX Group 3 injury No Cre- +TX Group 4 injury Cre- +TX

For one gene at three time points (1, 2 and 4 weeks)=72 x2 (gain and loss). Therefore, for 5 genes/ conditions =720 mice. Experiments may be repeated for intervention x2 =1440 animals

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental design allocated the right controls to make sure that the results are meaningful. In addition, introducing transgene that can be visualized such as luciferase or fluorescence will enable longitudinal study in the same animal rather than using more animals for the different end point.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of animals needed was based on power calculations as shown above based on published results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have refined two injury models over the last 5 years which are resulting in reproducible results. The bleomycin model in lung fibrosis which we identified the right concentration that does not reduce weight of the animals and not cause excessive fibrosis that causes severe adverse effects on tested animals.
Nonetheless allows us to monitor mice over four weeks. The other refinement is the wound repair or localised dermal fibrosis where we reduced the punches to two from 4 on each animal.

Why can’t you use animals that are less sentient?

Skin and lung are different structures and functions in mammalian system compared to fish for example or other less sentient. We need adult mice because we need to replicate lung and skin repair and diseases and therefore embryos are not suitable.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Over the last 5 years, we have already refined these two injury models.

We will always try to provide alternatives in route of administration of substances: for example, through food or drinking water rather than injection. Provide analgesic following surgery and increased monitoring and weight measurement to ensure animals are recovering. Terminate experiments when new unexpected phenotype occurs or consult local vet in case of scientific importance

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In the scientific community that work on animals , we all follow as the Animals (Scientific Procedures) Act 1986 (ASPA) and guidance. New development that focuses on " lessons learnt" disseminated by the NC3R website, LASA recommended maximum volume of administered substances and guidelines for blood removal as well as intervals between imaging sessions (LASA appendices A-C).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As an animal user, I currently receive updates from the NC3R through emails and the website and through the meetings held locally by the NC3R regional programme manager.

55. Mechanisms and treatments of craniofacial birth defects

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

craniofacial, cleft palate, craniosynostosis, treatment

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our research aims to improve the diagnosis, understanding and treatment of craniofacial disorders such as cleft palate and craniosynostosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Collectively, craniofacial abnormalities rank amongst the most common birth defects that may affect a new-born baby. These include cleft palate and premature fusion of the skull bones, which is known as craniosynostosis. Treatment of these disorders is a long term process and typically involves each child being cared for by a dedicated team of consultant

specialists including clinical genetics, radiology, dentistry, maxillo-facial surgery, anaesthesia, speech, language, hearing and psychological therapy.

The primary treatment for these defects involves complex surgical remodelling of the skull and facial deformities, which is aimed at protecting brain development and facilitating breathing, feeding, visual function, as well as the restoration of a normal craniofacial appearance. Although surgical correction is reliable, there is often a need for repeated surgical interventions from birth to maturity.

What outputs do you think you will see at the end of this project?

During the life of this project we expect to increase the diagnosis and understanding of the genetic, biological and molecular events that cause craniofacial disorders. This information will be published in peer-reviewed scientific journals so healthcare professionals can access this and inform patients and their families.

While the clinical application of a novel treatment may be some years into the future, by the end of this project we expect to have laid the groundwork for a new treatment of craniosynostosis that does not involve surgery.

Who or what will benefit from these outputs, and how?

New knowledge that improves our understanding of the diagnosis and molecular mechanisms of craniofacial disorders will be published in peer-reviewed scientific journals so healthcare professionals can access this and inform patients and their families. This will be possible within the lifetime of the project.

A potential non-surgical new treatment will have an enormous impact on the patient's quality of life and the development of the child as a whole, and on the patient's and families' quality of life. Full application of a new treatment into the clinical environment probably exceeds the life of the project.

How will you look to maximise the outputs of this work?

Our research is a collaborative project involving a multidisciplinary team of scientist and clinicians in the fields of mechanical engineering, developmental biology and craniofacial surgery.

Data produced as part of this project will be published in peer-reviewed journals, and where possible presented at (inter)national scientific meetings.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our research uses transgenic mouse models that mimic human craniofacial disorders. Mice are the animal of choice when studying genetic disease. Our work aims to understand the origins of the disease and develop ways to prevent or treat the disorder. For that purpose we mainly use embryos and pre-weaning animals when the disease is in it's early stages.

Typically, what will be done to an animal used in your project?

In this project, transgenic mice are used for breeding to create embryos or young animals (up to 21 days) for our biological studies. These studies mainly use post mortem tissues.

Adult animals (up to 3 months) are used for the development of a new treatment for craniosynostosis that replaces surgery. For this purpose animals undergo mechanical loading under anaesthesia. This involves applying a small load into a animal's skull bones for 10 minutes every day for two weeks.
Further analysis to assess the efficacy of the treatment is done post mortem.

What are the expected impacts and/or adverse effects for the animals during your project?

Inherently, animals mimicking human craniofacial disorders will be adversely affected by the features of the disease (e.g. craniosynostosis). However, these animals are usually viable and breed normally, indicating a low level of severity. When in use, these animals will be carefully monitored by appropriately trained staff and specific husbandry methods will be applied to keep animals healthy.

Where we apply mechanical bone loading, animals will be under general anaesthesia. This is not because the procedure is painful, but because the animals have to stay still during the procedure. Previous studies have shown that animals recover quickly and do not show any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Transgenic animals with a craniofacial disease are categorised as mild, with a small number (approximately 1%) showing moderate or severe features. Animals without a phenotype -including wild- type controls- are characterised as sub-threshold.

For the mechanical loading procedures, work under a previous licence has shown that no additional adverse effects are observed as a result of the loading and/or anaesthesia. Therefore the expected severity relates to the extend of the craniofacial phenotype in almost all cases.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Research into craniofacial birth defects concerns the mechanisms by which the head of an embryo/fetus develops its specific shape and associated function, and the disturbed mechanisms that underlie abnormal shape and function. Hence, an understanding of normal and abnormal development that leads to birth defects requires analysis of whole animals. While in silico modelling and in vitro tissue culture experiments can provide useful information, they cannot mimic the complexity of functioning organs in vivo, let alone the entire body.

Which non-animal alternatives did you consider for use in this project?

A possible alternative that was considered is the use of ex vivo tissue culture to replace in vivo experiments. Using this method allows the culturing of dissected bone tissue for a limited amount of time.

Why were they not suitable?

While this is suitable for a limited number of specific experiments, it does not allow analysis of the 3D structure of the skeletal system, in particular the skull. Also, it does not replicate the relationship between bone and the surrounding tissues e.g. muscle.

Importantly, the need for tissue does not negate the need for animals and there is a real risk of using more animals using a suboptimal experimental method.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on historic use of animals for similar projects and forward planning of future research projects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Part of the research that is done outside of the scope of this license involves computer modelling of mechanical loading. This has allowed us to estimate the parameters for our in vivo experiments reducing the need to test a large range of experimental conditions using a (much) larger number of animals. Whenever possible, we use the NC3r's EDA to estimate numbers needed for experimental cohorts.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We aim to reduce the numbers of animals by using the most efficient and state-of-the-art breeding and husbandry methods available. We also include statistical power analyses to identify the minimum number of animals that we need in order to answer the research questions being posed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To achieve the research aims of this project we use genetically altered (GA) mice. Breeding of GA mice is performed to produce experimental animals needed for the study of the cellular and molecular mechanisms that underpin the relevant human diseases. Mechanical loading of bone tissue is employed to assess its potential as a novel treatment for human craniofacial disorders. Apart from breeding and mechanical bone loading, the large majority of experimental analysis is performed post mortem.

Why can’t you use animals that are less sentient?

Genetically altered mice enable the construction of animal models of human biology and/or disease that can be used in numerous ways to improve our understanding of disease processes and to develop new methods for diagnosis and approaches to therapy. Many studies of embryonic development employ sub-mammalian vertebrate or even invertebrate species. While each of these model systems has its advantages, the over-riding benefit of mouse studies is the relatively straight forward extrapolation of results to humans, and therefore to clinical disease. It is for this reason that genetic modification in mice forms the basis of this research programme.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We aim to minimise animal welfare costs by using the most efficient and state-of-the-art husbandry methods available during the breeding of GA mice. Colonies of GA mice are managed using good practise guidelines supplied by the NC3R and the The Jackson Laboratory. For mice with a craniofacial phenotype, increased monitoring is used to ensure animals are able to drink and feed as normal.
Sunflower seeds are used to enrich their diet and wooden blocks are used to manage any malocclusion.

We use bespoke equipment to minimise the welfare costs associated with procedures requiring the in vivo testing of novel treatment protocols. A 3D printed nose cone is used to

allow mechanical loading of the skull while using inhalation anaesthesia, avoiding the need for injectable agents and/or head restraint.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will employ the good practise guidelines provided by LASA and the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will employ the good practise guidelines provided by LASA and the NC3Rs and ensure these are up-to-date at all time by regularly checking their websites and signing up to relevant newsletters. We also stay abreast of the scientific literature concerning the 3Rs.

56. Visual function and gene therapy in ocular disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Retina, Gene therapy, Vision, Eye

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to better understand how the eye processes visual information and how different genetic and degenerative conditions affect this. A major focus of the project will be to evaluating the safety and success of new gene therapies and will also aim to solve some of the technical limitations currently facing this therapeutic approach

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are many aspects of visual function that we still do not understand, including how particular genes define the function of the different cell types within the retina. The

outcomes of the project will enhance our understanding of how the visual system works and in particular will deepen our understanding of pathological conditions that cause partial or total loss of sight. For the majority of conditions that result in blindness no treatments are available to halt the progression of the disease or to improve vision. The work outlined in this project will support the development of new treatments that will aimto prevent or reverse blindness.

What outputs do you think you will see at the end of this project?

The work of this project is expected to advance the scientific understanding of how the retina process light information, particularly which cells and what mechanisms are important for specific aspects of visual function. It is also likely to advance our understanding of how particular genetic conditions affect vision and why, with an emphasis on identifying which molecules are linked to particular genes and which cells need these molecules to function properly. By the end of the project we should have identified new candidate molecules to improve vision or prevent blindness in several eye disorders, including diseases caused by genetic conditions as well as visual problems associated with aging or physical damage. The research will also pioneer new technologies that aim to overcome the current technological limitations of gene therapy that may have broader applications in other fields of medicine.

Who or what will benefit from these outputs, and how?

The work of the project will benefit the wider research community particularly those working in the fields of visual neuroscience, genetics and gene therapy, by providing new insights into the physiology of visual function and development of new technology to treat genetic conditions.

Patients with genetic and degenerative conditions affecting visual function will benefit from this research through gaining a better understanding of the pathology of their disease, potentially including improved diagnosis and more accurate prognosis. They also stand to benefit from the development of new therapies that will be able to improve their visual function and/or slow or prevent disease progression.

How will you look to maximise the outputs of this work?

Findings from the project will be regularly disseminated in internal seminars, inviting insight from a broad range of scientific disciplines. The work will be presented more formally at national and international conferences and published in peer reviewed, open access scientific journals when appropriate. New intellectual property arising from the findings will be identified and appropriately protected by the filing of patents promoting the advanced development of these findings for translation to the clinic.

Species and numbers of animals expected to be used

- Mice: 3300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All experiments for this project will be performed in mice. Both in-bred strains of “wild-type” mice and genetically altered strains will be used. Many genetic strains are matched genetic models for the genetic conditions that cause retinal dystrophy in human patients. This makes them very valuable models to study the physiological and pathological consequences of the disease and to accurately evaluate the potential for a new therapeutic intervention

Typically, mice will be used in these protocols post weaning age for 2-6 months. This is to allow the visual circuitry to fully develop and model "adult" presentation of ocular diseases.

For some aspects of the project mice will be used at pre-weaning age (P0-P21). This is to allow measurement of aspects of the disease that are apparent in early development. Treatment with novel therapeutics may also be trialed in pre-weaning age mice to evaluate the importance of therapeutic intervention at early stages of disease progression.

Typically, what will be done to an animal used in your project?

Typically mice used in this project license will undergo the following procedures:

Mice will undergo behavioural monitoring in specialised experimental set ups that allow their responses to visual cues to be measured.

Whole eye responses to light stimuli will be recorded using electrodes placed on the surface of the eye. These experiments are performed under general anesthesia for the purpose of restraint. These measurements will typically be performed before and after therapeutic intervention, or at different time points during the lifespan of an individual mouse, to measure changes in visual function during development of the disease.

Experimental animals will receive injection of experimental or sham substances into the eye under general anesthesia for the purpose of evaluating the safety and/or efficacy of novel therapeutic agents.

At the end of all in-vivo studies, mice will be humanely killed. Tissue (particularly from the eye) will be taken for further study. Study duration may be from several weeks up to 2 years.

What are the expected impacts and/or adverse effects for the animals during your project?

- Mice will be purposefully bred with genetic conditions that cause poor quality vision or blindness. This will cause some degree of sensory deprivation for part or all of the lifespan of the animal.

- Behavioural monitoring and measurements are not expected to cause adverse effects or distress.

- Repeated general anesthesia required for measuring electrical responses of the eye has the potential to cause adverse effects. Experiments will be designed to minimise the duration and number of procedures carried out under general anaesthesia. Mice will be carefully monitored during their recovery.

- Ocular injection procedures can cause localised trauma to the eye (for example small

retinal tears, retinal detachment, localised bleeding) and/or transient increased pressure within the eye. These issues typically resolve quickly and spontaneously within a day or so. Occasionally the injection can cause localised inflammation, which would lead to some discomfort. This is usually avoided by the application of antibiotic ointment at the end of the injection procedure. Injected mice will be checked daily until all adverse signs of the injection have resolved.

- The introduction of novel experimental or therapeutic genes is designed to alter the function of specific cells within the retina. They are either not expected to cause changes to visual perception, or only slight to modest changes to visual perception, and are not expected to cause any discomfort. However mice will be regularly monitored by observation in the home cage to look for signs of visual disturbance that might be causing distress (for example, excessive eye closure when awake).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall for this project 60% of mice the expected level of severity Moderate and for 40% of mice it is Mild.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project is aiming to look at the very fine detail of how biological systems are able to process visual information. This requires that the cells and circuits develop normally as part of an entire biological system. Similarly, the response to therapeutic intervention needs to be assessed in an intact biological system if it is to be developed for use in human patients. This allows more accurate prediction of the therapeutic effect as well as allowing for observation of important adverse effects.

Which non-animal alternatives did you consider for use in this project?
Considered alternatives included 2D and 3D (organoid) cell cultures, computer modelling and studies performed in humans.

Why were they not suitable?

Cell culture

Cell cultures are unable to replicate entire biological system, including all the cells types, their neurological connectivity, blood supply and immune response. These are important aspects to model if the aim is to understand how biology creates visual perception, the changes that occur in disease and critical assessment of new therapeutic targets. However, cell cultures and organoids will be used to fulfil the overall scientific goals of the program of work. They will be used to directly replace animal experiments wherever possible (for example in screening vector serotypes specificity) and they will be used in parallel to animal studies to enchance the general scientific conclusions and/or statistical power of study outcomes through meta-analysis whenever possible.

Computer modelling

Not enough is known about the biology, the connections between cells and visual function to be able to model diseases accurately enough to use computer models to answer scientific questions. However, computor models will be routinely used in the program of work to refine research questions, aid design of experiments and increase the statistical power of study outputs (for example by using bootstrapping methods to predict or model variability).

Studies in humans

The methods that will be used to study the how the biology functions, for example through introduction of experimental substances that alter the function of retinal cells, are too invasive to undertake in human subjects. However non-invasive studies in volunteer human subjects and patients (for example psychophysical measurements and electroretinograms) will be undertaken in parallel throughout the program of work to continually refine research questions, maintain translational relevance and to enhance the scientific conclusions through a multidisciplinary approach.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimation is based on previous knowledge and experience working in the field of visual neuroscience and gene therapy. Historical and published data for all of the techniques and some of the specific genetic strains named in this project provide an estimation of variance for many planned experiments. This allows the number of animals providing results with a clear interpretation to be predicted using statistical power calculations.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

General considerations

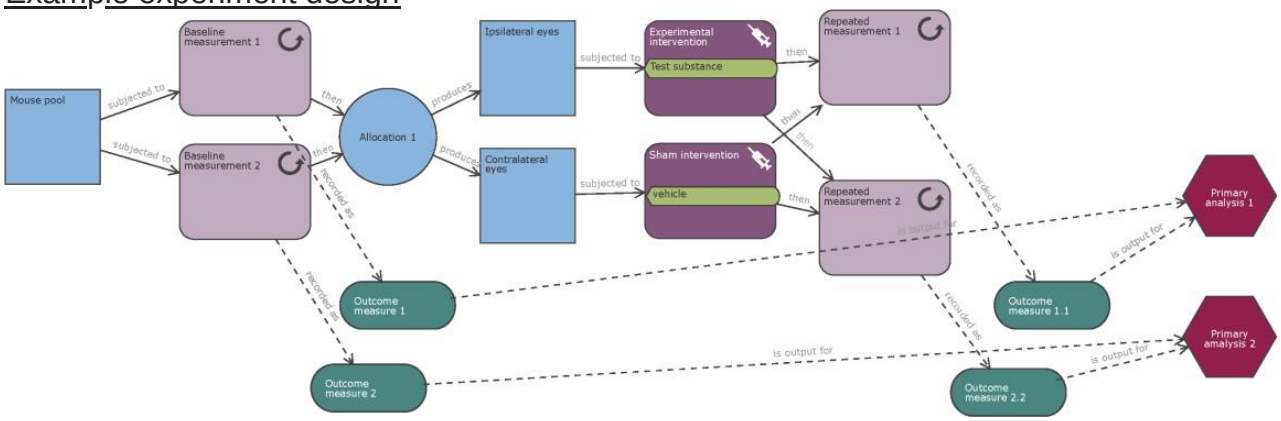
- The use of power calculations was used to predict sufficient sample size.

- Incorporation of block randomisation of treatments (to left or right eye, and/or across animals housed in the same cage) will be used to maximise the statistical power of each animal used in each study.

- Randomisation of left to right eye will be used wherever possible to provide internal controls and maximise the statistical power of each animal used in each study.

- Meta-analysis will be incorporated into the analysis where multiple measurements (for example behavioural measurement and electro-retinograms) are performed within single animals to maximise the statistical power of each animal used in each study. This can be done whenever each outcome can be used independently to support or reject a hypothesis.

Example experiment design



What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Historical and published data will be used to guide the design of new experiments. Where historical data for particular models or techniques is unavailable pilot studies will be undertaken to explore unforeseen technical challenges or variability before expanding to use on larger groups of experimental animals.

Throughout the duration of the project the experiments carried out in animals will be complimented by work done with computer models, human subjects and 3D tissue cultures made from human stem cells. These alternative methodologies will be used to undertake any related experimental work for which invasive techniques and/or intact biological systems are not required. For example, tissue cultures will be used screen the potential suitability of new therapies before using them in animals (for example screening vector serotypes). They will also be used to define and refine research questions. For example, studies measuring patient vision or predictions made with a computer model can be used to decide which specific aspects of retinal function need to be investigated further in an equivalent genetic mouse model of the disease. Computer modelling can be used to more accurately predict variability from pilot data using bootstrapping methods, enhancing the use of power calculations. Wherever possible statistical meta-analysis will be used to analyse outcomes from related studies within the multidisciplinary approach.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Both in-bred strains of “wild-type” mice and genetically altered strains will be used. Many genetic strains are matched genetic models for the genetic conditions that cause retinal dystrophy in human patients. Specific strains may include Cnga3-/-, Pde6c-/-, Abca4-/-, Cep290rd16, Gnat1-/-, Pde6b-/- mice. This The match with human genetic condition makes them very valuable models to study the physiological and pathological consequences of the disease and to accurately evaluate the potential for a new therapeutic intervention. A laser induced model of focal photoreceptor loss in C57 wild-type mice will also be used to model the pathophysiology of macular degeneration in humans. The general approach of these studies center on performing comparative physiological and behavioural studies in genetically modified mice that closely model the pathological condition in patients. Techniques include electrophysiological measurements of the retina (ERGs) and measurement of visually guided behaviours. Interventional approaches, such as AAV-based gene therapy, will be used to try to alter the pathophysiology of disease progression. Important techniques for these approaches include ocular injection techniques.

Why can’t you use animals that are less sentient?

Mice are the lowest order vertebrate that has an adult retinal structure similar to humans, comprising many of the same cells types, structural features and cell functions. The genetic mouse models to be used in the project are an exact match for the genetic problems causing blindness in humans. This ensures that the findings from this research will fulfil the objectives of the project; advancing our knowledge of how the retina processes information and progressing the development of new therapies to cure blindness.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures will be continually reviewed for possible refinement. A recent refinement include changing from vision based operant conditioning tasks to a low-severity behavioural assessment paradigm based on instinctive responses to naturalistic visual cues.

Advice from the NACWO and NVS will be regularly sought in particular when implementing new techniques.

Highly experienced investigators will carry out and/or supervise surgical procedures and physiological measurements.

Mice will be housed with several cage-mates unless mice need to separated for specific reasons, (e.g. in-cage fighting). When used, periods of single housing will be kept brief (up to 48h) before attempting reintroduction to cage mates.

Mice will be provided with quality bedding material, with particular consideration of

minimizing eye irritation (i.e. moderate chip size, dust free). Mice will also be provided with home cage enrichment.

Peri-operative monitoring and analgesia will be used for as long as necessary following procedures to ensure minimal suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgical procedures will be performed in keeping with best practice guidelines (LASA Guiding Principles for Preparing and Undertaking Aseptic Surgery)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute has a NC3Rs advocate who regularly disseminates new information about experiment design, methods and replacement technologies to all investigators involved in animal research. The scientific literature is continuously scrutinised and discussed by academics at the institute through informal lab meetings, journal clubs and seminars. We will strive to identify and implement new techniques that could promote the 3Rs.

57. Poultry welfare: effects of housing and management

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

poultry, housing, management, beak trim, disease detection

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to improve the welfare of poultry by studying their housing and management conditions (or some aspect affected by these conditions, such as disease). There are 3 main sub-aims to address this:

Aim 1: Establishing how poultry can be housed and managed without beak trimming. Birds will be kept in one or more housing systems and at stocking densities that may reflect commercial practice so that the results are likely to translate to industry. Because bird strain has been shown to affect the results, we will use strains that are used commonly in the UK and the EU, and/or which show differences in injurious pecking behaviour, and/or which have been shown to differ in beak shapes due to their beak or bone morphology. Birds may be left with intact beaks, or may be compared to birds that are beak trimmed using one or more commercial methods, in order to establish if birds can be housed without beak trimming (e.g. without injurious pecking or pecking-related mortality being much higher than birds that are beak trimmed). Trimming methods and age at application will follow common agricultural practice to make the results relevant to the industry. Birds may be exposed to mildly aversive conditions (e.g. lack of environmental enrichment), since pecking behaviour is known to be exacerbated by stress in commercial environments, which we would aim to mimic. Birds may be given access to novel

enrichment (e.g. hay bales, string) to help reduce injurious pecking, which might alleviate the need to beak trim. Birds may undergo pecking tests, whereby the pecking damage they inflict on an inanimate model is measured. The scientific outputs of these studies will be the observations of differences in e.g. behaviour, injurious pecking rates and/or feather pecking damage, body weights, feed intake, or physiological signs of stress measured via blood sampling. This information will help elucidate ways to house these types of poultry without the need to beak trim while still safeguarding their welfare.

Aim 2: Determining production and welfare levels for different strains of broilers from hatch through to rearing, catching, transport, and slaughter (including meat quality). Broilers will be housed in styles that mimic commercial practice including for such schemes as the RSPCA Assured Scheme guidelines (https://business.rspcaassured.org.uk/media/qbuhlsvd/meat-chickens-standards-rspca.pdf), so that the results are more likely to reflect industry practice. Birds will be reared in litter-floor pens from hatch and video recorded for behaviour throughout the trial. Birds will be fed nutritionally- appropriate diets and the feed consumed will be recorded. Bulk and/or individual weights of the birds will be taken at regular intervals, as will welfare quality measures such as hock scores, foot pad scores, and/or gait scores. At the end of the growing period, birds will either be culled directly at the PEL for tissue/meat quality data, or after a period of transport to a processing plant. To mimic commercial transport conditions, birds may be loaded into transport crates and may either be a) driven along a prescribed loop that begins and ends at the PEL, with bird inspections carried out every time the PEL is reached, with the final journey ending at a processing plant or back at the PEL; or b) driven directly to a processing plant. At the processing plant, birds will be killed using commercial methods and meat quality measures recorded. This information will help us determine production (e.g. weight gain, feed consumed, meat quality) and welfare (e.g. foot pad score, gait score) measures for each strain of bird which will identify which birds can be used in higher welfare schemes. It will also allow for determination of which strains of birds can be used in production while potentially having better welfare than other strains. The novel strains will be compared to known established slow-growing broiler strains. The scientific outputs of these studies will be welfare quality measures such as footpad and hock scores, lameness scores, cleanliness scores and time spent in various behaviours, as well as production measures such as bird weight and feed conversion ratios. This information will help us determine the levels of welfare for different strains of broilers and assess which strains could be used in higher welfare schemes which could encourage more producers to become involved in these schemes.

Aim 3: Using technologies to detect early signs of disease. Laying hens will be housed in styles that mimic commercial practice (e.g. litter floor pens or enriched cages), and will be fitted with automatic recording equipment (i.e. sensor technology) suitable to their size and species (such as accelerometers and/or tags that track their location). Hen activity from the sensors plus recordings of hen behaviour from live observations or video recordings will be measured concurrently. Hens will be assessed before and after a vaccine challenge to stimulate changes in behaviour that mimic sickness behaviour. In order to reliably induce sickness behaviour using vaccines, the hens may be previously unvaccinated. The aim is to see if the sensor technologies can identify these 'sickness behaviours' in birds, which could be used in commercial systems as early warning indicators. This is a particularly important technological advancement that could be used in large (commercial) flocks, where stock worker observations alone may not be adequate to identify early changes in flock behaviour due to illness. This will contribute to good management of flocks.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Hens and broilers are the workhorses of agriculture: in 2019, there were approximately 25.9 billion chickens in the world (statista.com), mostly reared to feed people via eggs and meat. As a consequence of being domesticated farm animals that are housed for much, if not all, of their lives, chickens rely on the ways that they are housed and managed by us for a good-quality life. The work described here focuses on housing and management methods to improve the welfare of chickens. This work aims to look at solutions to common problems experienced by hens and broilers due to the way they are kept or managed, such as beak trimming, disease, and rapid growth rates, that are practical (i.e. able to be implemented at farm level) while being sensitive to the needs of chickens.

What outputs do you think you will see at the end of this project?

For laying hens (beak trimming): the work will generate information on which commercial housing methods, used with or without additional enrichment, and/or which hen strains or types of beak morphologies can be used without the need to beak trim.

For broilers: the work will provide evidence of what strains of birds can meet production targets while having improved welfare over conventional fast-growing strains.

For laying hens (disease detection): this work will identify useable technologies that help producers detect the early signs of disease in large poultry flocks, which can improve the success of treatment and/or limit the spread of disease to other flocks. In all cases, outputs would include scientific publications, trade articles, and conference presentations.

Who or what will benefit from these outputs, and how?

For all areas investigated, beneficiaries will include commercial poultry, poultry breeders, poultry farmers, consumers, and fellow scientists. These are unlikely to be fully realised until each project is completed (up to 2 years after the completion of this licence).

How will you look to maximise the outputs of this work?

Broilers: work is typically done in collaboration with breeding companies and animal welfare and/or accreditation schemes, thus outputs are disseminated directly to the place of maximum impact; outputs will also be disseminated in peer-reviewed journals and technical (trade) articles.

Laying hens (beak trim): work will be done in collaboration with a major laying hen breeding company, and will make use of their existing genetic database and parent flocks; outputs will be disseminated in peer-reviewed journals and technical (trade) articles.

Laying hens (disease detection): work will be done as part of a PhD project, whereby the student is required to publish his work in peer-reviewed journals. The work will also be presented at scientific conferences and disseminated to the technology producers.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 1800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Studying the pros and cons of housing and management techniques for hens and broilers relies on the response of the whole animal in order to judge what is beneficial (or not) to their behaviour, health and welfare. All animal types and life stages are chosen on the basis of relevance to commercial practice. Broilers are typically housed as juveniles (from day old up to 12 weeks), because this is the period of growth to slaughter, whereas hens are typically studied as adults (16 weeks onwards) as this is when they are producing eggs, but may also be studied as juveniles, since this influences well-being as adults. Particularly where we want to study sickness behaviour in hens, we may use non-vaccinated pullets (i.e. from hatch to sexual maturity) for later use in those experiments.

Typically, what will be done to an animal used in your project?

Birds will often be housed in commercially-relevant housing (in terms of floor surface, available furniture, and stocking density). Some birds may undergo blood sampling to measure their physiological responses. Some birds will not be beak trimmed and therefore may be at greater risk of damage from feather pecking and cannibalism, if they develop. Some birds will be given a vaccine to stimulate a short-term sickness response so that we can measure if novel technologies can identify sickness behaviour. Experiments typically last for several weeks or months, in order to study long-term effects on behaviour.

What are the expected impacts and/or adverse effects for the animals during your project?

Long-term impacts may come from living in commercial-style poultry housing, such as weakened bones (hens in enriched cages cf. floor systems) or greater keel bone damage (floor systems cf. enriched caged), or foot pad disorders (broilers on litter at commercial stocking density). With beak trimming, long-term pain and lasting harm are potentially more likely to occur due to *not* applying this commercial treatment, if damaging pecking behaviour develops. For birds undergoing beak treatment, the effects have been shown to have short-term effects on beak related behaviours (i.e. days). Birds challenged with a vaccine are expected to show short-term sickness behaviour; however, this is expected to be transient and the work proposed only uses poultry-approved products; therefore this is not outside the experience of poultry normally. Sickness-behaviour studies may use previously non-vaccinated poultry, to more reliably generate a response.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: 80%

Moderate: 20%

(Calculation: Protocol 1 (15% of 100 birds moderate) + Protocol 2 (15% of 1600 birds moderate) +
Protocol 3 (100% of 100 birds moderate) = 355/1800 moderate = 20%)

What will happen to animals at the end of this project?

- Rehomed
- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Behaviour and welfare studies need to study the whole animal and their responses to their environment.

Which non-animal alternatives did you consider for use in this project?

For studying pecking behaviour in different strains of hens with different beak shapes, we are using models for hens to peck at (rather than pecking at other birds). While we understand that models (e.g. letting hens peck at agar gels, or dummies covered in chicken skin) will not reflect the exact damage that a live bird would receive, they will allow us to get a relative measure of different damages inflicted by different beak shapes.

Why were they not suitable?

In other studies in this licence, there are no models that can encompass the complex multi-system mental and physical activities of the whole animal to give accurate responses to the measure we want to undertake.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on the types of projects we will undertake and the related numbers of treatments and replicates per experiment, per project:

Currently, we do trials looking at broiler breeds without the need to run the study under license, and in those trials, we use 1600 broilers

Plans for studying beak treatment and beak shape amount to no more than 100 hens

Plans for studying the use of sensors to detect disease amount to no more than 100 hens

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We base our animal numbers on prior experience and after discussion with a statistician, to ensure that the number of animals used is neither too high nor too low. We use optimal experimental designs and analyses that take account of all sources of variation, to get the maximum information from our studies. The use of simulated commercial conditions in some studies impacts the number of animals used (e.g. they are typically higher than laboratory-based studies), however this means that the relevance of our work to the agricultural industry is likely to be greater.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever possible, we share data from our studies with students (BSc and MSc level) for dissertation projects.

Where animals must be killed for tissue collection, we will offer extra tissues to colleagues in the local area for use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Chickens are used because their housing and management systems, and consequences of farming (and how the chickens respond) are the areas of interest.

Why can’t you use animals that are less sentient?

In order to reflect on commercial farming of animals, it is important to use the species used by the farming community to get accurate data.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

With every experiment performed, we carry out a harms/benefits analysis, and review these retrospectively to see how measures can be refined for future similar trials. These are the requirements of our AWERB. This assists us in planning future trials to minimise welfare costs to animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Various guidance provided at the NC3Rs website.

Home Office Code of Practice on non-human primates, farm animals and birds (Dec 2014).

We also use ARRIVE guidelines for publishing research appropriately, so that other researchers can refine their techniques accordingly.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We share knowledge on best practices with other research groups doing similar studies. I am in receipt of monthly email updates from NC3Rs about their events and publications.

58. Improving the understanding and treatment of Parkinson's disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Parkinson's, Therapy, Motor symptoms, Non-motor symptoms, Neurodegeneration

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to improve our understanding of the processes that underpin Parkinson's disease and to find better treatments for this debilitating, chronic condition.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are currently over 6 million people living with Parkinson's disease and in 2016 alone PD caused over 211000 deaths. Prevalence rates have increased by 22% in the past thirty years alone, making Parkinson's one of the fastest growing neurodegenerative disorders. Parkinson's affects motor coordination in individuals but triggers many other non-motor symptoms too, including anxiety, pain, sleep disorders, cognitive dysfunction and bladder dysfunction, to name just a few. Drugs are available to bring some relief of the motor

symptoms. However, the gold standard drug, levodopa, causes side- effects in many people that invoke uncontrolled, excessive movements so is less than ideal. Moreover, the underlying causes of some of the symptoms in Parkinson's, such as pain, are also poorly understood and so their management with existing drugs is also currently inadequate. Finally, there are no drugs currently available that slow down or better still stop the progressive death of the vulnerable brain cells which drive the ever-worsening symptoms. The work undertaken in this project will explore new avenues for discovering drugs that can bring much-need protection or repair to the affected brain cells. In addition, by exploring some of the non-motor symptoms such as pain and cognitive dysfunction, as well as those underlying levodopa-induced excessive movements we will increase our understanding of the causes behind these symptoms and side-effects, respectively, and therefore help to unveil new treatment strategies.

What outputs do you think you will see at the end of this project?

This project will provide new information on therapeutic approaches that could lead to drug treatments to slow down the progression of Parkinson's or repair existing damage in the brain post diagnosis.

There is potential for some of these approaches to progress into clinical trials, if successful in our animal studies. In addition, we will provide new information on the mechanisms that contribute to the development of some non-motor symptoms in Parkinson's disease, especially pain. This will allow us, and others, to explore new avenues for providing pain relief to people living with Parkinson's. Our findings will be published in scientific journals and also shared with the Parkinson's community through our contacts with the Parkinson's UK charity, for example and with the wider community through Twitter.

Who or what will benefit from these outputs, and how?

In the immediate term, our project outputs will benefit other scientists and clinicians working in the Parkinson's field by generating new knowledge to fill some of the gaps in our current understanding of the disease. By filling these gaps we hope to help in the discovery of new therapeutic avenues for treating symptoms and underlying brain pathology in Parkinson's, and thereby trigger new projects during the course of this one. Some of our strategies will involve 'repurposing' existing medicines already proven to be safe for use in humans. In these cases, these drugs could enter clinical trials within less than 5 years, potentially before this project ends. In other cases, we may uncover strategies for which no currently approved drug exists. In this way, chemists will benefit as their expertise in developing new chemical entities for this novel pipeline will be required. These new compounds will take much longer to reach clinical trials, but will certainly offer hope for the future for people living with Parkinson's disease.

How will you look to maximise the outputs of this work?

We will continue to network with fellow scientists and clinicians to exploit any findings we make to the fullest. Presentation at scientific meetings and expanding on existing collaborations, both in the UK and abroad, will ensure the impact of our outputs is maximised.

Species and numbers of animals expected to be used

- Mice: 650

- Rats: 1750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using adult rats and mice in this project. The adult stage is most appropriate as Parkinson's rarely affects individuals under 30 years of age. The brain architecture of mice and rats is well characterised and in many cases bears a close resemblance to the cellular structure and connectivity of the human brain. Their genetic makeup is also similar and they express most of the same proteins that we do. When treated with chemicals or pathological proteins, these animals also develop a condition which resembles Parkinson's. Their brain cells in relevant regions degenerate and the animals develop motor and non-motor symptoms similar to those seen in people with Parkinson's but on a much more condensed time-scale in keeping with their limited lifespan. The use of two species provides a more robust readout for drug discovery pipelines as we can be sure the drugs are not just effective in one species. In addition, they can generate different kinds of models with chemically-induced models often used in rats and pathological protein models induced more in mice.

Typically, what will be done to an animal used in your project?

Rats or mice are typically investigated initially for their baseline, control behaviour. This might involve testing the animals motor ability in simple arenas, or testing their memory for objects they see. These are non-painful, non-invasive tests that require minimal handling from the operator. After baseline scores have been gathered, animals are typically rendered mildly parkinsonian by injection of a chemical or pathological protein into a region of the brain affected in Parkinson's disease - the striatum. This happens under general anaesthesia and animals quickly recover from this surgery. The chemical injections take around 3 weeks to kill the relevant brain cells and do so by mechanisms that replicate those happening in the brain in Parkinson's disease. The pathological proteins take much longer, usually 6-9 months, to kill the relevant brain cells. However, the main protein - alpha synuclein - is the one thought to be a key trigger in Parkinson's in people so this model allows us to interrogate the pathology more fully. In both models, a partial loss of brain cells is the desired level, so the animals are only mildly parkinsonian. The animals are looked after throughout by the research team who will perform more non-painful, non-invasive behavioural tests at pre-determined intervals (usually weekly or monthly). In many cases, animals are treated with investigational drugs either while the brain cells are dying (looking here for so-called neuroprotective drugs) or after at least half of the cells have died (looking here for so-called neurorepair drugs). Drugs will be administered by injection or by mouth. At the end of the treatment period which may be a few weeks in some studies, but several months in others, the animals will be humanely killed and the brains removed for analysis to establish whether the drug treatments have worked as predicted. Other organs may also be taken if relevant to the study, such as spinal cord or bladder.
What are the expected impacts and/or adverse effects for the animals during your project?

Animals that are rendered parkinsonian do tend to lose some weight after surgery so are given additional nutrition during the post-operative week or two. This can persist for a few

weeks before returning. Immediately after surgery, animals might feel pain at the incision site. However the local and systemic administration of pain killers is routine and should keep this to a minimum. Some test drugs or the solution the test drug is dissolved in may also cause diarrhoea. If this happens, animals are given extra hydrating gels to prevent dehydration. Based upon our prior experiences, we do not expect to see any abnormal behavioural impacts in our project.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Because of the surgical procedure used to generate our models of Parkinson's disease the majority of our animals (~80%) will fall into the moderate severity category. However, ~20% will fall into the mild severity category. These will include animals used for working out the way a new drug is handled by the body and animals that are used to generate control tissues, for example.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Parkinson's disease results from loss of cells in specific regions of the brain. This loss of cells affects the brain's ability to function properly, leading to symptoms of impaired movement and other non-motor symptoms like anxiety or cognitive deficits. The cells and multiple connections that make up the brain systems that control movement and these other relevant behaviours are complex. As such it is impossible to study this disease without the use of animals.

Cell-based models can be useful for examining the vulnerability of cells in isolation and the effectiveness of potential drugs on improving the health of these isolated cells. However, in their usual habitat of the brain, these cells are surrounded by multiple other supportive or indeed destructive cells that together control the environment and functionality of the brain. Cell-based models can offer no insight into this complex environment. They also offer no means of examining the effectiveness of new drugs to reverse symptoms relating to Parkinson's. For these reasons, we require the use animals to model Parkinson's and permit us to achieve the aims of our project.

Which non-animal alternatives did you consider for use in this project?

We have recently introduced computer-based 'bioinformatics' techniques into our research programmes, alongside the existing cell culture work and isolated brain slice work we had already incorporated. When used together these non-animals alternatives allow us to screen for anticipated changes at a single cell level and pre-select only those agents that have clear potential to progress through to the animal studies. Around a third of our activity

falls within this area. However, as noted above animals are required, ultimately to address our objectives.

Why were they not suitable?

We need fully integrated, complex brain systems that are controlling movement and other body systems affected in Parkinson's disease. Non-animal alternatives unfortunately do not offer these things, although they can be helpful early indicators of potential, as noted above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based the overall estimation on the numbers used in the past five years when funding and ongoing projects were of a similar size to those planned in this project. We have reduced these numbers by a third, compared to our previous licence, in light of the increased use of computer- and cell-based studies to inform the animal work.

For all experiments we will use a group size which is the smallest compatible with achieving statistically meaningful and robust results. These group sizes have been estimated using a combination of results from our own previous studies and those available from existing scientific literature (where available) and checked using online tools like the NC3R's Experimental Design Assistant (https://eda.nc3rs.org.uk/eda/landing), which also helps in establishing the most appropriate statistical tests to select.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have considerable experience in this type of work and have published extensively in peer-reviewed journals so are confident in the robustness of our experimental design and analysis. We have used the NC3R's Experimental Design Assistant (https://eda.nc3rs.org.uk/eda/landing) when planning the studies that were of a new design and to check that previously used designs are optimised in terms of experimental steps and analysis.

Variability will be kept to a minimum by perfecting the accuracy of our technique, using animals of the same strain and age and ensuring control animals are treated as closely as possible to those in the test group. Reduced variability facilitates use of smaller group sizes. Where fitting with our objectives, for example when examining symptomatic relief with a single treatment, we will use randomised crossover designs. These allow each treatment or dose to be tested in the same group of animals, sequentially.
Not only does this reduce variability again, it also markedly reduces the overall number of animals used.

The use of computer and cell-based screens has allowed a reduction in numbers of animals used to address our research objectives.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When undertaking studies with a completely novel design we will conduct small-scale pilot studies from which we can gain valuable insight into the minimum number of animals required to achieve our objectives. In addition, we will ensure that the maximum information possible is gathered from each animal. We will obtain multiple data readouts from each animal often comprising: measures or motor and non-motor signs; cell counts in specific brain regions; cellular and molecular markers that change with pathology or treatment. We will also use spare tissues for undergraduate and masters student projects, ensuring nothing is wasted. When reporting our data we ensure we follow the latest ARRIVE guidelines so that our findings can be confidently used to inform other researchers and therefore help longer-term to optimise the numbers of animals used in the research community (Percie du Sert N et al. The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research. PLoS Biol 2020, 18(7): e3000410).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Whilst the animal model that best recapitulates human Parkinson’s disease is the MPTP-treated primate, it is unacceptable to use this model at early preclinical stages of therapy and pathogenic investigations that form the focus of this programme of work. Hence, rodent preclinical models will be used here.

The models used most often in this project are generated by the introduction of chemicals that induce cell death in brain pathways known to be affected in Parkinson's disease. In most studies, these agents are introduced directly into relevant brain regions whilst the animals are under general anaesthesia. We induce so-called hemiparkinsonism. This involves causing pathology in one side of the brain only and produces a milder phenotype than a bilateral model would. In most of our studies we will use the chemical **6-hydroxydopamine** to cause the pathology. Moreover, we will generate a partial lesion model - aiming for around 50% cell loss in the key brain region. This degree of cell loss is sufficient for our objectives and offers a refinement from the full lesion model we often used in the past. These animals recover well from surgery. They have no impairment in their general day-to-day abilities so are able to function like healthy animals, despite having brain chemistry and cell degeneration on one side of the brain that is appropriate for these studies. They also express a wide range of mild symptoms (both motor and non-motor) that will aid in achieving our objectives. Studies in the 6-hydroxydopamine model usually last between 1 and 12 weeks, depending on the nature of the investigation; studies investigating repair of the nervous system are the longest and extend out to the 12 week

point. When treated for at least 11 days with the gold standard symptom-relieving drug levodopa, these animals develop a side-effect reflective of that seen in patients - so called levodopa-induced dyskinesia (excessive unwanted movement). This validated **model of levodopa-induced dyskinesia** will also be used in this project. Once it is induced, animals require only weekly injections of levodopa to maintain this side-effect which is expressed only for up to 2h after each levodopa injection, and not when animals are between dosing, thereby ensuring distress is minimised.

One weakness of the 6-hydroxydopamine model is its lack of clear alpha synuclein pathology. Alpha synuclein is a protein that aggregates in the brain of people with Parkinson's and is thought to play a key role in the progression of the disease. We will therefore use two additional models that are reported to exhibit this pathology. One of these introduces pathological forms of **alpha synuclein** directly into one side of the brain. The pathological protein spreads slowly throughout the brain causing mild disease state that develops very slowly. The alpha synuclein pathology appears after a month, but motor impairment and cell loss in the brain do not appear until around 6-months. While these studies are therefore much longer term, the mild phenotype is not anticipated to cause suffering or distress. Like the 6-hydroxydopamine model, this is again a partial lesion model where degeneration of 50% maximum will be achieved.

The second model displaying alpha synuclein pathology is the **rotenone** treated rat model. This model differs from the others in that rotenone can be given by injection into the body, rather than requiring surgical administration. No general anaesthesia is needed. However, as the rotenone reaches both sides of the brain eventually, this is a bilateral model and can cause a more profound motor impairment that can impact on the animal's daily activities. When this is the model of choice, animals are monitored daily to ensure they are able to move around and eat and drink without assistance.

The final class of model we may use has no pathology. These models are induced by dosing animals for a day or two with chemicals, such as **reserpine or haloperidol,** which alter the brain chemistry to prevent correct functioning of those pathways that control movement. These are mild interventions that are reversible within a few days. These models can be used for testing the ability of drugs to reverse motor symptoms but do not offer a platform for investigating the pathology of the disease or therefore drugs that can interrupt the pathology.

Why can’t you use animals that are less sentient?

We acknowledge the existence of invertebrate models of Parkinson's but while these are useful to gain information relating to the genetic influences in the disease, they have very few dopamine neurones, the ones affected in Parkinson's, and a limited behavioural repertoire so will not be useful to support our objectives. The need to monitor parkinsonian symptoms also means that the use of terminally anaesthetised animals is not appropriate. Parkinson's disease affects adults, usually those older than 30. In order to ensure appropriate translatability of our research findings, the use of immature life stages is therefore also not appropriate. Our objectives thus require adult mice and rats.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As noted above, we have refined our model by reducing the size of the lesion we induce from a full loss of cells in the relevant brain region to a partial (~50%) loss of cells. This helps to minimise the impact on the animals. We have also refined our surgical procedures

by routinely: using inhalational iso-fluorane as the preferred anaesthetic, ensuring good recovery rates and reduce mortality rates (<5%); using a micro-infusion pump to improve both accuracy and consistency of intracerebral injections; administering local and systemic pain killers prior to recovery from anaesthetic. We have also increased our monitoring frequency of animals post-operatively keeping extensive records of weight and appearance. We have incorporated more non-invasive behavioural testing of motor ability over drug-induced rotational testing to reduce stress. Animals are also exposed to their experimental environment (habituation) and apparatus plus pre-trained in any behavioural test to reduce stress during the studies. Whenever dosing, we will always use an injection needle only once, in line with best practice. Our staff are trained to the highest standards of competency and display a great deal of care towards their animals which further reduces any stress for the animals. We will continue to act upon advice from the named veterinary surgeon and other staff intimately involved with the Biological Services Unit to ensure that animal suffering is minimised. Finally, when models with potentially better clinical representation become available, we look to introduce these into our studies as refined models, as inthis case with the alpha synuclein models.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue to use the NC3Rs website as our go-to- resource. This houses a valuable range of resources relating to welfare assessment, selecting and refining appropriate humane endpoints, best practice in analgesia and anaesthesia, for example. Their refinement guidelines include a range of e- learning resources and links to external publications.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive the NC3Rs Newsletter which has regular updates on the latest advances in all aspects including refinement. We will implement those applicable to our project after consultation with the relevant on-site animal staff.

59. Developing Treatments for myotonic dystrophy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

myotonic dystrophy, treatment

Animal types	Life stages
Mice	adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop treatments for myotonic dystrophy by 1) investigating the pathological mechanisms underlying this condition in different organs and tissues, and 2) testing novel compounds targeted to these mechanisms.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Myotonic dystrophy type 1 (DM1) is the most common form of muscular dystrophy in adults and is a highly debilitating condition, which affects 1 in 8000. There are more than 100,000 patients in developed countries, with an average life expectancy of 58 years. In addition to the health-related issues, there is a very high social cost to DM1, 50-70% of DM1 patients of working age are likely to be unemployed. Figures produced by the

Muscular Dystrophy Association USA indicate that the cost of DM to the US economy in terms of medical and non-medical expenses and lost income is roughly $450 million dollars per annum. There is currently no treatment for DM1, although some interventions are available for some complications of the disease such as diabetes and alterations in the sleep-wake cycle. However, they are limited, not effective, and do not treat the core symptom of the disease – muscle weakness and wasting. The central nervous system (brain and spine) effects of this disease have also been overlooked until recent years, despite the cognitive and psychological effects having a detrimental impact on quality of life. Being able to understand the pathological process across different organs, and how our compounds may be developed to ensure all aspects of the disease are treated is vital.

What outputs do you think you will see at the end of this project?

The ultimate aim of this research project is to develop a drug treatment for Myotonic Dystrophy. This project will provide information to support our drug development, and allow us to optimise our compounds, so after this project we can move into the final stages of drug development before testing in humans. This information will be used to support grant applications and potential collaborations with drug companies. Where not commercially sensitive, work will be published in scientific journals and presented at scientific meetings.

Who or what will benefit from these outputs, and how?

In the short/medium term the scientific community will benefit from new knowledge and improved understanding of this disease. In the mid to long-term publication of findings on the pathological mechanism of myotonic dystrophy in academic journals will disseminate this new knowledge further. In the long-term, we hope that patients will benefit from this work in the form of a treatment for a currently incurable disease.

How will you look to maximise the outputs of this work?

To advance the development of our therapeutic drugs we are working with our establishment to ensure that we have the appropriate support when we are ready to take this treatment to the next stage. In addition, we already have patents on our compounds, which may be expanded during this project. We collaborate with other groups and will publish findings in journals of good standing in the field. We will also present findings at national and international conferences.

Species and numbers of animals expected to be used

- Mice: 680

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Replicating the complex disease of myotonic dystrophy requires a mammal. Mice are the chosen species for this project as genetic models of the disease have been developed in the mouse. Adult mice are required as myotonic dystrophy is a progressive disease and time is needed for the genetic mutation to lead to the pathological processes.

Typically, what will be done to an animal used in your project?

We will use genetically altered mice that have mutations to mimic myotonic dystrophy, or in other proteins that are key for our understanding of how our therapies are working. For some of these mice, we will be able to control when the mutation is turned on – using a drug in their drinking water or food.

These genetic mice (or control mice that do not have the mutation) will typically be tested on tasks that assess movement, strength and drinking ability (requiring water restriction for a maximum of 16hrs prior to testing). And /or undergo tests of learning and memory (cognitive tests). These tests require food or water restriction to motivate behaviour (with weight loss no greater than 15% of free-feeding weight).
The motor tests are likely to be repeated daily for 5 days, cognitive tests may require additional training with sessions of approx. 30 mins in length for a number of weeks.

Following training the mouse may then be administered the compound (most likely by daily intraperitoneal injections for 5-10 days) and then testing will be repeated (as above) and tests for myotonia, which require an electrode to be inserted into a muscle will be carried out under anaesthesia, during which the animals will be humanely euthanised (terminal anaesthesia).

What are the expected impacts and/or adverse effects for the animals during your project?

The transgenic models we propose to use should not show significant overt symptoms as seen in some patients. We expect them to be able to feed, drink and groom normally. So are not expected to induce adverse effects.

There may be mild stress induced due to food, water restriction and handling for behavioural testing (movement/strength and cognitive). As well as during induction of anaesthesia for the terminal phase of the study.

There is the unlikely potential for irritation, damage, infection due to injections of compounds.

The novel compounds we are developing may induce side effects including: Disruption of gastrointestinal function (constipation / diarrhoea), Skin rash / hair loss, Mucosa inflammation, Loss of appetite / weight loss, Liver damage, Increased risk of infection. However, only small numbers of mice will be tested when a new compound is introduced to look for side effects. The mice will be monitored and if seen appropriate steps will be taken to prevent suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the majority of animals to fall into the mild severity band (70%), however, some may reach a moderate (30%) due to potential side effects ofcompounds.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no suitable alternative to animals to model a progressive multi-system disorder like myotonic dystrophy. We need to see if our treatment strategies can improve complex behaviours, both cognitive and movement.

Which non-animal alternatives did you consider for use in this project?

We have considered and are using other non-animal alternatives where possible. This study forms part of a broader body of work in which potential drug treatments for myotonic dystrophy are tested in biochemical and cell based systems to identify those most likely to have beneficial effects. We also use computational modelling to design molecules and understand their pharmacokinetics prior to in vivo work.

Why were they not suitable?

Cell based assays and modelling cannot tell us if the compound has a beneficial effect on motor or cognitive ability in a whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Group size depends on the outcome being assessed (Approx. n=4 to 12). Wildtype littermates or wildtype background strains may be required as a control group to ascertain the normal behavioural response and non-specific effects of the compounds on these behaviours. Over the course of the project, it is likely that up to 10 large studies will be conducted assessing compounds/interventions/effects of mutation. Therefore approx. 480 mice will be used for this project. There may be additional studies required to further information about compounds dose, piloting assays or transgenic crosses = 200 mice. Totalling 680 mice for this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will carry out power calculations to ensure the optimum number of animals used to meet the scientific objectives. We have made use of the NC3Rs Experimental Design Assistant and this tool will be used to help design study protocols. Where we can we have

made sure we are using both sexes in our studies, to improve the scientific outcome and reduce the number of animals that must be bred. We have considered whether multiple objectives can be addressed with a single group of animals, and carefully considered the use of control groups. The most sensitive assessments will be used, to reduce the number of animals required. This includes the fine assessment of facial function using equipment to assess drinking, rule learning and attention using operant chambers, and the gold standard of EMG for the assessment of myotonia.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use the most efficient breeding strategy, with close monitoring of colonies to ensure we only breed animals that are required. For new compounds, transgenic lines or assays we will perform pilot studies. We will collect tissues from animals to allow a wide range of ex vivo assays to be undertaken from a single study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Transgenic models of myotonic dystrophy will be used to assess the effect of either the mutation on the mice or the effects of novel treatments. Transgenic models will also be used to understand more about the biology of the disease, and the pathways we are targeting with compounds, these may be bred with the transgenic models of myotonic dystrophy. We do not expect these models to have a significant overt effect on the health of the mice, and deficits will only be detected using sensitive tests.

Drug administration

The most refined method of administration, which suits the profile of the drug will be selected, with appropriate volumes being based on current guidelines. In most cases this will be via Intraperitoneal injection or intramuscular for compounds. It could also be orally either via gavage or in food and water. Doxycycline will need to be administered long term in inducible transgenic models, to "switch-on" the mutation.
Behavioural assessment

These are required to assess the outcomes of any genetic models or drug interventions. The most refined methods for handling will be used throughout experiments. A combination of cognitive tests will be used to assess different aspects of thinking (Maze tasks for memory, operant conditioning for things like attention and rule learning, and novel object recognition for other aspects of memory). These tests cause a minimal amount of distress for the mice. The animals can explore the equipment and voluntarily respond. Motor tests include grip strength, rotarod (which assesses endurance of the mouse to walk on a cylinder like treadmill for max. of 5 mins), assessing general levels activity and

measures of drinking function. There may be some mild distress related to handling, but this will be minimised through slowly training the animals on the tasks and giving adequate time between tests.

Food OR water restriction is necessary for some of the tasks above (operant conditioning, maze tasks, drinking function) as just giving rewards are not sufficient to encourage mice to do the tasks. However, these will be for a limited time, ensuring animals do not lose more than 15% of their body weight, and both water and food restriction will not be carried out together.

Electromyography (EMG)

In order to assess the electrical function of the muscle it is necessary to carry out EMG measures. Myotonic discharges (spontaneous runs of electrical discharges from muscles following the insertion of a needle electrode) are seen in patients and used as part of the diagnosis for myotonic dystrophy.
These abnormal discharges are also seen in the mouse models and are a key feature of the disease.

For this, a fine needle will be inserted into a muscle group (limb and/or trunk) and electrical activity recorded. This will be performed under anaesthesia, and the animals with be humanly euthanised whilst under anaesthesia, which is more refined than performing it as a recovery procedure.

Why can’t you use animals that are less sentient?

Replicating the complex physiology of myotonic dystrophy requires a mammal. Mice are the chosen species for this project as genetic models of the disease have been developed in the mouse.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Transgenic Models: We aim to use mice that do not have overt health problems, however they will be monitored and if signs of ill health / weakness are observed, weight will be monitored, wet mash will be provided to aid feeding and advice sought from the named veterinary surgeon.

Drug administration:

Experimental compounds will only be tested if they have previously been assessed for their effectiveness in cell cultures. The maximum dose will be informed by the pharmacokinetics of the compounds, and will be tested on limited numbers of animals (1-2) initially to ensure they do not cause adverse effects. Administration routes will be dependent on the bioavailability and half-life of the compounds. As these are initial studies on these novel compounds bioavailability needs to be ensured, so it is likely that intraperitoneal or intramuscular injections will be used. Maximum volumes will follow current guidelines and the duration and frequency of treatment will be limited considering the overall impact on the animal (see protocols for exact limits). The compound will be of appropriate pH (4.5 – 8) and free from pathogenic material. During the period of compound administration body weight will be assessed, as well as daily monitoring of general condition. Swift and appropriate action will be taken if adverse events are seen, for example discontinuing drug administration and humane killing of the animal

Doxycycline was selected as it has fewer side effects than tetracycline, and it will be administered via the drinking water, as this is more refined than repeated injections. Water consumption will be monitored to ensure that it is not reducing water intake.

Behavioural assessment.

Habituation and handling: The most refined methods for handling will be used throughout experiments, and animals will be habituated to handling prior to experiments to reduce stress.

Each **motor assessment** can be assessed a limited number of times, with a defined rest period, to prevent exhaustion (see protocol section for limits), and animals will be pre-screened to ensure they are capable to perform the taskss.

Drinking assessment (lickometery): If animals are housed in these cages for extended periods (>2h) a shelter or tube will be provided and the temperature of the room will be increased or warming mats will be placed under part of the cage to prevent hypothermia. As bedding can not be put in these cages as it prevents the apparatus from recording accurately.

Food and water restriction:

Mice will not undergo both food and water restriction simultaneously. We will ensure mice will have bedding to help thermoregulation during periods of food and water restriction.

Food restriction represents the most refined method of motivation as hunger causes the least amount of distress. The animals will be without food for a minimum of 4 hours and up to a maximum of 23 hours per day for a maximum of 12 consecutive weeks. We aim to refine this by employing the minimal amount of restriction time required to motivate the animals to perform in the behavioural test. Weight loss will not exceed 15% of free-feeding body weight and animals will be returned to free-feeding status if weight can’t be maintained at appropriate levels.

Water restriction represents the next most refined method to motivate performance, and can be required to assess drinking function. For other tasks it is preferred in situations where food restriction is not motivating performance effectively, as it can achieve stable changes in body weight more effectively.
The animals will be without water for a maximum of 16 hours prior to testing for a maximum of 5 consecutive days. We aim to refine this by employing the minimal amount of restriction time required to motivate the animals to perform in the behavioural test. Weight loss will not exceed 15% of free-feeding body weight and animals will be returned to free water status if weight can’t be maintained at appropriate levels. Both restriction regimes have been published extensively, and there is evidence that water restriction results in better performance in operant conditioning tasks.

Electromyography (EMG)

This will be carried out under terminal anaesthesia, with careful monitoring of anaesthetic depth. This is more refined than performing a recovery procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Good Laboratory Practice and relevant LASA and NC3Rs guidelines to ensure experiments are conducted in the most refined way. Work will be reported in line with the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am on the 3Rs working group within my institute, so am aware of advancements across the sector. We regularly monitor the 3Rs webpage, and receive email updates. We will implement any changes we learn of that could be of benefit to our animals.

60. Sensory and emotional processing of pain in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pain, Nociception, Anxiety, Depression, Pharmacology

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to achieve a deeper understanding of the sensory and emotional component of pain states. This project aims to investigate the neurobiology of pain, identify new molecular targets and introduce novel approaches to treat chronic pain to offer better pain relief and improve overall quality of life of people living with pain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pain is a protective mechanism necessary for survival that informs us of tissue damage that will require time to heal. While normally of biological benefit, pain can sometimes persist, either after healing or due to on-going disease, and become chronic; such conditions are particularly difficult to manage with current therapeutic approaches. Pain

also triggers aversive and threatening psychological feelings and patients in pain are more likely to become depressed and anxious, have disrupted sleep patterns and generally have a poor quality of life. It has been estimated that about 365 million days are lost per annum in the UK alone through pain related illness.

Pain commonly presents as a result of an injury or a disease; however, it is also a separate condition in its own right, not just an accompanying symptom, affecting millions of people worldwide (Vos et al, 2017). In Europe, chronic pain affects at least 19% of the population, reduces the quality of life and the ability to work, therefore presenting a huge social and economic burden (Breivik et al, 2016). The major types of clinical pains arise from surgery, trauma and disease and can be classified as pain from inflammation (rheumatism and arthritis), nerve injury (chemotherapy-induced pain, post-herpetic neuralgia, diabetic neuropathy, AIDS), and cancer. It has been reported that pain is poorly controlled in up to 4.2 million patients dying with cancer. One of the reason for this is the clinical fear of producing an addicted state if opiates have been prescribed. Among patients who suffer pain, 33% had pain all or most of the time and 87% of those with pain rated it as moderate to severe. Pain control is still in its infancy. Only 33% of patients with nerve injury achieve pain relief with current pharmacological approaches and this relief is often only partial and accompanied by side effects. 20% of people with cancer have movement-related or neuropathic pain, and perhaps one-third of visits to Pain Clinics are from patients with similar pain not due to cancer.

Our goal is to achieve a deeper understanding of the neurobiology of pain states in order to offer better pain relief and improve the quality of life of people living with chronic pain.

What outputs do you think you will see at the end of this project?

It is usual to associate pain with injury and to assume that once the injury has healed the pain will dissipate. In fact, 19% of Europeans suffer from moderate to severe pain that does not resolve even though the injury has healed. Injury, whether though surgery or accident is known to alter pain sensitivity but how this occurs is not known. In the short-term our work aims to uncover the mechanisms responsible for this altered pain sensitivity and therefore is likely to identify potential biomarkers for the susceptibility to chronic pain in vulnerable individuals. By combining different behavioural paradigms and molecular biology in mouse models of pain, we will demonstrate that manipulation of physiological pathway, e.g. autophagy, can alleviate the pain and comorbid changes observed in patients. Moreover, research into the control of pain states has identified neuronal pathway connecting the spinal cord and brain that are key to the regulation of on-going pain. It was shown previously that destroying these pathways alleviated on-going persistent pain in rats and companion dogs. This approach has however not translated to human patients. At the end of this work we will demonstrate that our approach, using constructs made from botulinum toxin can silence but not kill pain-signalling neurons.

Pain has two main components, a sensory and an affective or ‘emotional’ component and both have to be considered when searching for new analgesics. Using the behavioural paradigms described in this application, we will fully characterise the two component of pain and identify novel and effecting analgesics for the treatment of pain.

New treatments for chronic pain in humans will emerge from our studies that will use various approaches to obtain a better understanding of the neurobiology of pain state and uncover new targets and new approaches for pain therapies. We will identify new pathways to analgesia and identify new drugs for the control of persistent pain states that are more effective that the currently available analgesics.

While clinical trials are currently testing whether the modulation of autophagy, a major intracytoplasmic protein degradation pathway, could improve the treatment of cancer and neurodegenerative diseases, targeting autophagy to reduce chronic pain has been poorly investigated. At the end of this work, we will demonstrate that manipulation of autophagy improves not only the ongoing pain but also the emotional state of injured mice. This will be fully investigated before moving towards clinical to meet clinical needs.

We have recently demonstrated that botulinum conjugated to dermorphin is as effective as morphine but without the side effects of tolerance and addiction in mice. We will now explore the reversibility and toxicity of this treatment before moving towards translation. For this reason, when the effect of botulinum-based construct will wear off, analgesia will be re-instated with a second injection of the constructs.

We believe that, in the long-term, new treatments for chronic pain will emerge from the different approaches outlined in this application and we will identify clinically relevant approaches opening the way to future translational research.

The outcomes of our research will be published in open access journals and presented at national and international congresses attended by basic scientists and clinicians. Our work will undoubtedly provide benefits to a number of people.

Who or what will benefit from these outputs, and how?

Our group first of all will use the data produced with this project to obtain further funding for our research.

Other researchers in the field will also directly benefit from the advancement of the understanding of the neurobiology of pain states that our work will provide.

Pharmaceutical companies and NIH have already shown their interest of our work and are constantly on the lookout for new potential targets for the treatment of persistent pain states. Our work is of substantial translational value and of particular importance in the current battle against addiction and drug overdose that has been triggered by over-prescription of opioids for chronic pain in USA.

The longer term aim is for clinicians and patients to benefit from our work, in particular in clinical settings where patients are constantly looking to understand their condition and questioning how proposed treatments work. Chronic pain patients will also directly benefit from the identification of novel targets when new drugs are available for clinical use.

How will you look to maximise the outputs of this work?

The outcomes of our research will be published in open access journals and presented at national and international congresses attended by basic scientists and clinicians.

We will use the data produced with this project to obtain further funding for our research. Moreover, pharmaceutical companies and NIH have already shown their interest of our work and are constantly on the lookout for new potential targets for the treatment of persistent pain states. Our work is of substantial translational values and of particular importance in the current battle against addiction and drug overdose triggered by over-prescription of opioids for chronic pain.

Species and numbers of animals expected to be used

- Mice: 2550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All experiments will be carried out in rodents in order to compare the data with previous and ongoing studies from our and other laboratories. The anatomy, neurochemistry and physiology of pain control systems are well documented and there are well-established models of chronic pain in this specie. As such, the use of rodents will facilitate the interpretation of the data in a meaningful way. Moreover, with the wide range of existing transgenic, mutant and knockout models make mice an irreplaceable model for our studies.

Pups will be used only when injection of an inflammatory agent is required to prime the nociceptive system at this age.

Typically, what will be done to an animal used in your project?

To address our 3 Objectives, we have designed our project around classical and translational models of pain (e.g. models of disease in which pain is a symptom). We also use a range of behavioural approaches to monitor animals' well-being and the development of the hypersensitive states. Anumber of interventions are required before or following the induction of the pain state to reduce animal pain behaviour and/or to allow us to identify the signalling pathways involved in the pain behaviour.

We use the least severe pain model possible. Acute Pain measurements generally requires injections of substances such as capsaicin (the pungent 'hot' component of chili peppers) or formalin without anaesthetic so that behavioural assessment can be made of acute pain sensitivity within minutes after injection. Inflammatory pain can be modelled with paw injection of substances either for short acting inflammatory lesion or for a longer lasting inflammatory state where maintenance of the condition is being studies. Neuropathic models are more severe models, although the increased sensitivity is relatively modest albeit long lasting. We also use a model with strong translational value such as chemotherapy. In some cases, the use of sham operated animals will be required as a negative control. The sham surgery will be used to control for pain from superficial structures. Mice undergoing sham surgery, compared to naïve animals, will experience nociceptive signalling from superficial structures but not from deep tissue.
For a particular experiment, we chose the model most likely to help us answer our scientific question. When exploring early molecular pathways activated in the early stages of a pain state, which is a potential key step in the identification of novel targets for the treatment of pain states, we often use acute models. Nociceptive stimulation results in molecular changes in the cell body of the primary afferents, in the dorsal horn of the spinal cord and in brain areas relevant to pain signalling and it is then possible to map changes in signalling pathways. However, when we are interested in the mechanisms that maintain chronic pain states in humans and the role of higher brain structures in the maintenance of these pain states, we use classical models of persistent pain, both of inflammatory and

neuropathic nature, well-described in the literature. In this instance, it is important to monitor animal behaviour for up to 6 months after the induction of the pain state, a time at which others have demonstrated the development of comorbidities such as depression and anxiety in rodents with persistent pain, a particular focus of this licence.

Behavioural assessment will occur before and after the induction of pain state. The development of the hypersensitivity will be investigated with behavioural methods that are non-invasive and cause very little distress. Behavioural test can start up to 2 weeks prior the induction of the pain state or prior to any intervention that might precede the induction of the pain state.

A number of intervention will be used before and/or following the induction of the pain states to reduce animal pain behaviour and/or to allow us to identify the signalling pathways involved in the behaviour.

At the end of our experiments, we always take tissue for molecular analysis and for confocal microscopy analysis. We will use great care in ensuring that mice are well maintained and suffer minimal distress as well as using best practice surgical procedures. Environmental enrichment, such as carton tubes and wooden artefacts, will be provided though this may be tailored so as not to affect experimental measurements. Such environmental enrichment stimulates the animals and contributes to their physical and psychological well-being. At each stage anaesthesia will be considered as described more fully in protocols below.

What are the expected impacts and/or adverse effects for the animals during your project?

We have chosen models that have been widely used in the pain field for many years. This will allow us to build on previous data and to compare our work with that of others and will ensure that we do not need to characterise novel models that might not be suited for the study of both pain mechanisms and translational approaches for the treatment of chronic pain in humans.

We will use pain models that generally cause some mechanical hypersensitivity and threshold testing procedures will be used to monitor for obvious signs of distress. Injection of substances such us formalin or capsaicin induces a pain state that will resolve within one week. Chronic stimulation with eg CFA, carrageenan or cytokines produces a maintained mechanical and thermal hyperalgesia. The inflamed area swells and becomes sensitive and shows signs of erythema. The area of inflammation will be regularly inspected but in our experience has never developed into an open wound. Injury to peripheral nerves leaves some motor impairment and local soreness at the site of incision.

Animals will be monitored closely for 2-4h following injury and the observed daily following the induction of the pain state.

Our models are moderate in that they generally produce a moderate increase in mechanical sensitivity and we will not use the more invasive models unless absolutely necessary to replicate an experiment in the literature. We will use local anaesthetic and analgesic whenever possible but only when this will not compromise the experiment. At the termination of the experiment animals will be killed (to take fresh tissues for molecular analysis) or perfused, when microscopy is going to be used to assess changes in the nervous system.

Animals will be humanely killed if they exhibit any of the following signs for more than 24h following appropriate interventions and the NVS and/or NACWO will be consulted: hunched appearance, reduced activity, altered gait, piloerection; or continued weight loss of (greater than 10%) despite supplemental feeding.

Once animals lose 5% weight, loss monitoring will be increased and steps taken to prevent further weight loss and/or enable weight to be regained. Wet mash will be added directly into the cage.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect 100% of animals on this project to develop moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In most of our studies it is essential to use animals rather than cultured cells in dishes. The use of animals (male and female rodents) is essential for this application because we are working on a complex experience, pain, which is processed at various levels in the central nervous system and it cannot be modelled in vitro. Rodents are known to display long-term emotional-changes in long-term pain states similar to that seen in humans. Therefore, rodents are an excellent model to study the overall long-term behavioural and molecular changes associated with the developments and maintenance of persistent pain states. Moreover, they are also an important and crucial step to investigate the actions of novel treatments for pain states.

Which non-animal alternatives did you consider for use in this project?
Although non-protected invertebrate species such as *Caenorhabditis elegans* or *drosophila melanogaster* do contain neurons, they do not display appropriate behaviours, nor do their nervous systems contain the appropriate structures or complexity, to be a useful model of pain in humans.

Why were they not suitable?

In most of our studies it is essential to use animals rather than cultured cells in dishes. The complex diseases we study require that we look at the behaviour of the whole animal.

All our experiments will be carried out using rodents as these animals also enable the use of the advanced genetic tools needed to dissect the cellular circuitry of the nervous system in a precise, neuron subtype-specific manner.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We are experts in experimental design and always use both our experience and statistical approaches to estimate the number of animals we need in our experiments not to waste or overuse animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We routinely use randomisation and blinding in our experimental designs to prevent subjective bias. The number of animals used during the course of this project will be minimised by attention to experimental design and statistical power calculation using previously determined measures of variance and effect size estimates based on previous and pilot experiments. *n* numbers will be calculated using online resources including the NC3Rs experimental design assistant.

Often we use both sexes of animal in our experiments, so our results can be applicable to the whole population. This is also taken into account when estimating our sample size. We also seek specialist statistical advice where required for new study designs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our experience in the field and the appropriate use of pilot studies always ensure that we keep numbers of animals to a minimum but that we use appropriate sample size. Moreover, when possible and if a number of experiments are run at the same time, controls are shared across study groups to reduce further the number of animals used. Novel test compounds provided by our collaborators are never used in animals without being first tested in vitro and in a small group of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents are an appropriate species for studying the functional of neural circuits. Rodents are mammals and sufficiently similar to humans to be of relevance for human biology; secondly, they have been used extensively as model organisms so this study can build upon earlier experimental results.

We use models of pain or altered sensation that are well validated and clinically relevant. In our models, the severity limit is never greater than ‘moderate’ and attention will be given to minimising the irritation and pain felt by the animal where possible. We will use pain models that generally cause some mechanical hypersensitivity and threshold testing procedures will be used to monitor for obvious signs of distress. Experiments will not be continued for longer than is absolutely necessary. Models will be selected on the basis of their relevance to the problem being studies and attention will be paid to reducing suffering to the lowest possible level. We will not use more invasive models unless is absolutely necessary to demonstrate the analgesic properties of a specific compound in specific model of pain.

Our pre-emptive approach (Protocol 6) to silence key neurons in the nociceptive pathway will avoid unnecessary suffering in the animals. Moreover, local anaesthetic may be used at sites of incision as an analgesic and systemic analgesics will be given routinely unless there is evidence that they would interfere with the development of the model or our experimental outcomes.

We have chosen models that have been widely used in the pain field for many years. This will allow us to build on previous data and to compare our work with that of others and will ensure that we do not need to characterise novel models that might not be suited for the study of both pain mechanisms and translational approaches for the treatment of chronic pain in humans. Importantly, we have started engaging with clinicians and with the patient community through patient and public involvement activities to ensure that our chosen models have translational value (i.e. that the animals display patient relevant symptoms),as we want our work to be of maximal benefit for the patients.Our behavioural approaches will also provide us with valuable information with high translational value.

All experiments will be performed on mice, as the ‘simplest’ mammalian model available, however if a larger size and/or increased intelligence of rats will be required to make it more likely that an experiment is successful, then we will submit a project licence amendment to add rat as necessary.

Why can’t you use animals that are less sentient?

Whereas nociception is a well-known process in all vertebrates, animal models with lower sentience (e.g. fish) cannot be used here. It has been demonstrated that fish lack the neocortex known for processing sensory information in mammals and therefore they cannot be used to achieve the aims of this project. Moreover, it is still not clear how pain is perceived and how it affects fish behaviour.

Mice are mammals and sufficiently similar to humans to be of relevance for human biology; secondly, they have been used extensively as model organisms so this study can build upon earlier experimental results. The anatomy, neurochemistry and physiology of pain control systems are well documented and there are well-established models of chronic pain in these species. As such, the use of rodents will facilitate the interpretation of the data in a meaningful way.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use great care in ensuring that mice are well maintained and suffer minimal distress as well as using best practice surgical procedures. Environmental enrichment, such as carton tubes and wooden artefacts, will be provided though this may be tailored so as not to affect experimental measurements. Such environmental enrichment stimulates the animals and contributes to their physical and psychological well-being.

We will use local anaesthetic and analgesic whenever possible but only when this will not compromise the experiment. The use of anaesthesia for ip injections of chemotherapeutic substances will reduce stress in the animals and improve animal welfare.

At the termination of the experiment animals will be killed by a schedule 1 procedure (to take fresh tissues for molecular analysis) or perfusion, when microscopy is going to be used to assess changes in the nervous system.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will regularly monitor the Home Office web page for technical advice and guidance related animal research.

All the interventions listed in this application will follow the N3CRs guidelines. LASA guidelines on administration of substances will be used.
LASA 2017 Guiding Principles on Record Keeping for Personal Licence Holders will be used to achieve a good project management

The ARRIVE Guidelines will be used to improve the quality and reliability of our published research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Home Office website (https://www.gov.uk/guidance/research-and-testing-using-animals) will be visited regularly to stay informed about Home Office circulars, Statistics (annual statistics and trends), Publications, Guidance documents and Codes of Practice.

Moreover, regular meetings with Named Veterinary Surgeon (NVS) and Named Animal Care and Welfare Officer (NACWO) will be hold.

61. Immunity to viruses and virus-based vaccines

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

virus, immune system, inflammation, vaccination, cancer

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged
Hen eggs	embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate how manipulation of the immune response to viruses can be beneficial in two different but related scenarios, namely: 1) if the immune response to a virus causes disease to the host and 2) if a virus is a major component of a vaccine that is designed to protect against cancer or a different (heterologous) viral infection and associated disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The COVID-19 pandemic has demonstrated how harmful immune responses induced by viral infections can have deadly consequences. Understanding how to dampen these responses can lead to the development of new therapeutics to treat virus-infected individuals. The COVID-19 pandemic has also shown how important vaccines that are based on viruses are - both the Oxford/AstraZeneca and Johnson & Johnson COVID19 vaccines are (safe) viruses. Viruses have great potential as vaccines not only for infectious diseases but also cancer. Understanding how to induce the best possible immune

response against these 'viral vaccines' will maximise the chances of future success of these preventative medicines.

What outputs do you think you will see at the end of this project?

The proposed studies will advance our understanding of how viruses induce immune responses, how these responses can cause damage if they are not regulated properly, and how virus-induced immune responses can be harnessed in vaccination strategies. These studies of both virus-induced inflammatory responses and virus-based vaccines will undoubtedly lead to numerous publications, as evidenced by our track-record as a laboratory. We have a track-record of publishing data from animal studies even if the findings show no effect, ensuring that other scientists do not perform unnecessary experiments on animals.

During this licence we will work with the University innovation team to develop patents based on our findings, and will work with pharmaceutical partners, sharing our data where our results suggest that drugs already exist that could be used to treat harmful immune responses triggered by viruses. Our studies will also inform the development of vaccines that may be generated for future translation into human studies at the end of this project.

Who or what will benefit from these outputs, and how?

Studies of Virus-Induced Inflammation: These studies will inform the development of anti-inflammatory strategies in the treatment of virus-infected individuals. Depending on what we find, it is conceivable that certain drugs may already be used to treat individuals in inflammatory diseases such as arthritis. Therefore, it is possible that research in this 5-year project may provide evidence to support clinical trials at the end of this project that examine the use of existing drugs in virus-infected individuals. It may also discover new pathways to target where existing drugs are not available. These approaches could lead to patient benefit in ~10 years.

Virus-Based Vaccines: Vaccines that are based on viruses such as adenovirus and cytomegalovirus represent exciting approaches to induce potent immune responses that could be directed to other viruses such as influenza, but also cancer. With colleagues at the home establishment, we are developing different virus-based cancer vaccines and testing them in parallel in human systems.
Clinical colleagues are already performing clinical trials using virus-based cancer vaccines. Therefore a clear pipeline exists that means that performing clinical trials using virus-based vaccines at the end of the 5-year project is a possibility. Studies looking at the combination of vaccines and other methods of immune manipulation, or using more novel vaccines (e.g. those based on cytomegalovirus) may take longer (6-10 years)

How will you look to maximise the outputs of this work?

In all cases we will disseminate our findings through publication in high-profile manuscripts and also using open access preprint vehicles such as Biorxiv, thus enabling access for all to our research free- of-charge. As stated above, we will also continue to publish negative/unsuccessful results. For studies of virus-induced inflammatory responses, as stated above, we will collaborate with pharmaceutical companies to identify druggable pathways that could be used to treat harmful immune responses triggered by viruses. We have clinical collaborations established to enable effective translation of our findings regarding virus-based cancer vaccines into patients. We will also disseminate our findings to the general population through press releases and interviews. We will also patent all

relevant findings to aid the development of products as a consequence of research outlined in this project.

Species and numbers of animals expected to be used

- Mice: 9200
- Hen Eggs: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the lowest vertebrate group in which the viruses and virus-based vaccines that we will use have been well characterised. Numerous reagents exist to therapeutically target molecules of the immune system in mice and modified mice lacking genes that may influence virus-induced immune responses exist. Furthermore a large number of conditional knockout mice also exist which will enable investigation of specific regulatory pathways in cell types that are essential in the regulation of antiviral immune responses. In most of our studies of both virus-induced inflammation and virus-based vaccines, we will use adult mice as their immune systems have matured and are best characterised. However, we also wish to study neurological inflammation that is induced by cytomegalovirus. In humans, cytomegalovirus is the most common congenital infection, causing devastating life-long neurological defects. In mice, a well-characterised model exists for congenital cytomegalovirus infection that involves infecting newborn mice with mouse cytomegalovirus (MCMV). Thus in some experiments, we will infect newborn mice with MCMV and study virus-induced inflammation.

Typically, what will be done to an animal used in your project?

In the case of studies of virus-induced inflammation, a mouse will be infected with virus either by either injection or administration in the nose. Signs of illness will be monitored and mice may also be treated with a substance to manipulate the immune response to reduce inflammation. These substances will be administered by injection, or by intranasal administration or through drinking water. In some experiments, the long-term behaviour of the mice will be measured after ~9-12 months, studying, for example, how an infection can affect mouse cognition.

For vaccination studies, a typical experiment would involve vaccinating a mouse with a virus-based cancer vaccine, usually by injection, and then bleeding mice monthly to measure the induction of the immune response. After several (up to 9) months, the mice would then be challenged either with an infection such as influenza, or a cancer (either a cell line or using mice that you can induce cancer development in). Development of the cancer or infection will be assessed over time (typically days for infections, weeks for cancers) before mice will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

For virus-induced inflammation, mice will experience mild to moderate weight loss in the first 7-10 days of infection. If virus infections are performed in mouse strains that are susceptible to Alzheimer's disease, some of these mice may show accelerated cognitive decline, as observed through readouts such as altered novel object recognition. In the case of neonatal cytomegalovirus infection, mice may lose weight but will likely demonstrate abnormal brain development. Here, most experiments will only last for 2-3 weeks before the mice are humanely killed. Therefore mice will not experience long-term neurological abnormalities.

For vaccination studies, mild weight loss may be observed after vaccination for the first 3-5 days before resolution although many vaccinated mice will experience no signs of vaccination/infection. During challenge with viruses, weight loss may be observed as with virus-induced inflammation studies. For cancer vaccine studies, tumour growth will likely be observed in mice. These will be measured for up to 4 weeks post-cancer challenge. Some mice in cancer vaccine studies may experience no tumour development however.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For studies of virus-induced inflammation, based on previous experience with these models, we expect ~40-50% of mice to experience moderate weight loss as a consequence of virus infection. In vaccination studies where we are challenging with infectious agents, we expect 20-30% to experience moderate symptoms during infectious challenge. In the case of cancer vaccines, we expect 60% to experience moderate severity as a consequence of tumour induction.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immune responses induced by infections are very complex and there are no *in vitro* techniques that recreate an intact immune system. Because these studies cannot be replaced by using either computer modelling or *in vitro* experiments involving cell lines or animal or human tissue, live animals must be used. This proposal will investigate complex inflammatory networks that are triggered in response to virus infections. It will also study how viruses can be used as vaccines to protect from other viruses and from cancer. These networks will likely involve numerous cytokines and pathways that act on a multitude of immune cell types in different organs of the body.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we will perform *in vitro* infections using systems recently developed in our laboratory. Specifically, during the last PPL we developed human genetic systems to study virus- induced inflammation that is based on human stem cell technology. We validated this model by showing that modelling an influenza-induced inflammatory response in this human system showed major parallels to inflammatory pathways triggered during influenza infection in mice. Therefore, we will use these in vitro models wherever possible, particularly for studying inflammatory immune responses to inform decisions of what experiments will be worthwhile performing in mice.

We have also, as a laboratory, moved away where possible from the use of *in vivo* generated mouse CMV (MCMV) stocks. Nearly all of our studies (both inflammation and vaccine work) now utilise *in vitro* generated MCMV rather than virus generated in mice.

During the lifetime of this project I hope to further reduce in vivo work, particularly the neonatal CMV infection work where we examine the impact of virus infection and associated neurological inflammation on neonatal brain development. In particular, we have been awarded a seedcorn funding to establish a human brain organoid-based HCMV infection system to study CMV-induced inflammation in the brain. If validated, this will form the foundation of an additional in vitro assay in our pipeline of studying CMV-induced inflammatory pathways where, if a given anti-inflammatory intervention strategy fails to affect inflammation within these brain organoids, they will not be tested in vivo. We hope that this model system will also support more in vitro mechanistic studies of how CMV induces inflammation in the brain.

Why were they not suitable?

To assess the true complexity of inflammatory immune responses and, critically, to be able to assess the therapeutic efficacy of approaches to target virus-induced inflammation, small animal models are required. Furthermore, for testing virus-based vaccines and for understanding whether these can protect from cancer, we need to test these approaches in mouse models of cancer. Cell-based systems such as those from human stem cell approaches cannot recreate the complexity of an immune response induced by a vaccine and then be used to assess whether the vaccine-induced immune response can control cancer development. This is far too complex to model *in vitro*. Moreover, 3D-based systems or computer modelling also could not be used to recreate the full complexity of an immune response induced by viruses.

For some of our studies, we still need to use MCMV stocks that are isolated from the salivary glands of mice. This is because salivary gland virus best infects the salivary glands itself. This is important because shedding of HCMV in human saliva is a main source of virus that infects unborn babies and causes life-long neurological defects in these individuals. We want to identify how we can stop this process and therefore need to study CMV infection in the salivary glands using the optimal mouse models available, hence some of our work will still require virus that we have grown in the salivary glands of live mice.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experimental designs to be utilised are simple and have been used, with slight variations, in our laboratory for a number of years. Indeed, I personally have been working with the influenza and CMV mouse models for 20 and 15 years, respectively. Therefore, for most experiments little optimisation of regimes is required, keeping the number of animals required as low as possible. However, when we develop new approaches (such as testing a new type of virus-based vaccines) we routinely consult the departmental statistician to ensure that our experiments for the particular approach are powered correctly.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All PhD students and post-docs in the lab will have performed a course on use of statistics in biology and will be well versed in use of "power calculations". This means that they will be able to use "power calculations" to work out what the minimum number of animals is needed in order for a given experiments to produce a meaningful (statistically significant) result. This is important, not just for making sure that no more animals than necessary are used, but also because using too few mice means that it might not be possible to draw a conclusion from the experiment. As stated above, when we perform new approaches in our lab, our lab members also consult with our institute statistician to obtain external expert statistical advice.

Members of the lab also use a set of guidelines called "ARRIVE" guidelines found on https://arriveguidelines.org/. These are an extremely useful set of recommendations which are designed to help researchers ensure that they perform their animal work in the most robust way possible. The purpose is to enhance the quality and reliability of the findings of individual labs in order that their work can be more easily reproduced by others. These principles form the cornerstone of animal work performed in our lab. We will also use the NC3Rs Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

There are several measures we will take to reduce animal usage:

We will share control groups wherever possible. For example, we aim to test multiple anti-inflammatory strategies concurrently with the same single control group

We will perform longitudinal analysis on the same mice. This is particularly relevant for vaccine studies where we study vaccine-induced immune responses over time by taking regular blood samples and measuring vaccine induced immune responses

As described in detail elsewhere, for studies of viral and cancer vaccines, we will study both vaccines at the same time and use the other group as control for much of our analysis. For example, when measuring induction of cancer-specific immune responses we will use our flu vaccine group as the cancer-irrelevant control. When measuring influenza-specific immune responses induced by our flu vaccine, we will use our cancer vaccine as our influenza-irrelevant control. Thus, we will concurrently develop two different vaccine approaches at the same time using the same mice.

Randomisation is also used to ensure validity of results. Due to the nature of the tumour models that are used, whereby tumours arise at different times in individual animals, experiments are often performed in sub-groups (enabling randomisation within blocks). This approach builds additional robustness to the experimental findings as any conclusions drawn come from findings which have withstood the natural variation occurring within experimental units.

Variation amongst mice / experiments is kept to a minimum by conducting procedures at a similar time of day, using uniform and well validated techniques and equipment. In all cases individual mouse variation e.g. body weight, tumour size etc, are taken into account.

Where possible, experiments are performed in a blinded fashion. Animal samples taken to the lab will be coded and key measurements conducted by a researcher who is blinded to the experimental code e.g. measurements of immune cells in tumours or virus-induced weight loss. Tumour volumes are measured by technicians who are not aware of what (or whether) mice received interventions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will predominantly use the mouse cytomegalovirus (MCMV) and influenza models as these are the best-characterized small animal models for these infections. Both infection models induce comparable inflammatory responses to those observed in humans. Importantly, the virus strains used in animal models for both MCMV and influenza are well characterised, so we know exactly how much virus to give to mice to induce a certain amount of disease that is well within UK Home Office restrictions. Also, using mice enables us to administer treatment strategies for virus-induced inflammation with minimal distress such as simple subcutaneous and intraperitoneal injections that we typically use that do not require anaesthesia. Similarly, for virus-based vaccine work, the mouse enables relatively painless sub-cutaneous injections during vaccination. Here, mouse models of cancer are also well characterised which will enable the examination of virus-based cancer vaccines with minimum suffering to animals.

In all procedures animal suffering will be minimised through good animal handling techniques and strict adherence to monitoring procedures. These monitoring procedures ensure that adverse effects associated with viral infection and vaccinations will be minimized, this keeping pain and distress caused by infections to an individual animal at a minimum.

Why can’t you use animals that are less sentient?

For many experiments we will require an adult immune system as this will model best the patients that often suffer from severe viral diseases such as during influenza infection. The same is true for our vaccination studies where our aim is to generate vaccines to target cancer and respiratory diseases where older individuals are more likely to suffer from these diseases and thus will be the primary target population for these therapeutics. Importantly, however, for CMV infection studies, we will be increasingly using the neonatal mouse model for some of these studies, thus using more immature, fewer sentient mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All new techniques (or combination of techniques and/or immune intervention strategies) are subjected to scrutiny with respect to harms to the individual animal. Score sheets are updated to reflect any relevant observations relating to animal welfare. We also work closely with the animal technicians and NACWO to ensure that all parties are aware of potential adverse effects and how to respond accordingly.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines for the welfare and use of animals in cancer research, Workman et al, British Journal of Cancer, 2010, 102(11):1555-77

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay informed about advances in the 3Rs (reduction, refinement and replacement) through published literature, such as the recent development of brain organoids as a model for CMV-induced brain inflammation. If we validate this as a model for studying brain inflammation induced by CMV, we will likely replace significant amounts of neonatal MCMV work.

Students and post-docs in the lab also attend and participate in workshops which are run by the "National Centre for Replacement, Reduction and Refinement of Animals in Research" - this provides the lab with the opportunity to learn about the latest innovations which help reduce the need for animal models or which improve experimental designs such that fewer animals are needed.

62. Unravelling the role of tumour microenvironment in mediating resistance to anti-cancer therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Tumor Microenvironment, Therapy, Extracellular vesicles, Metastasis

Animal types	Life stages
Mice	embryo, neonate, adult, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To better understand how tumours respond to therapies and why current therapies have limited efficacy in some cases, often associated with cancer spread (metastasis). Importantly, this knowledge will provide the rationale for the design of new, improved combinatorial therapies that we can take to the clinic and improve the management of this deadly disease (i.e. better response rates, improved survival of cancer patients).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

While we have made significant progress in treating some types of cancer successfully, cancer remains one of the most life threatening diseases humans encounter. Over the last two decades we have discovered that cancers that develop in a particular organ eg breast, represent multiple different types of cancer, each of which develops slightly differently and needs different therapeutic strategies. Notably, it is now widely accepted that tumours are not just "bags" full of cancer cells, but contain several other non-malignant cells such as immune cells and endothelial cells that form blood vessels which supply the tumours with nutrients, thus supporting their growth. Many anti-cancer treatments show limited therapeutic efficacy due to alterations (either pre-existing or acquired during therapy) on these normal cells of the tumour, which consist the tumour microenvironment. Tumours that are refractory or resistant to therapy have higher chances of spreading to secondary sites, leading to metastasis. Thus, cancer remains an incredibly complex disease and understanding why some tumours do not respond to current therapies will help us identify better therapeutic strategies that will eventually stop cancer from being a life-threatening disease.

What outputs do you think you will see at the end of this project?

We expect multiple beneficial outputs from our programme of work:

We will generate significant amounts of new biology that we will share with the scientific community;

We will generate multiple publications that we will ensure are available on open access so that as many people as possible can read our research, learn from our experiences and data, and use the data to generate new hypotheses; It is likely that our programme will generate/characterise one or more new compounds/drugs/tracers that will be translated into humans in clinical studies and trials;

Our research will allow us to attract more grant income that will enable us to train more new young scientists in the field of in vivo research.

Who or what will benefit from these outputs, and how?

Our programme of work will benefit many stakeholders:

The scientific community will benefit from our publication of and public speaking of our data;

The public will benefit from the revelation of our new biology and also our development of new therapeutics. By enhancing knowledge and providing new therapeutics clinical management of patients will change for the better;

A new cadre of scientists trained in the development of, management of and conducting animal experiments will be generated as a consequence of this programme;

As our data will inform scientists in our fields of the new biology, certain animal experiments that would otherwise have been conducted will no longer be necessary reducing the numbers of animals used.

How will you look to maximise the outputs of this work?

The knowledge and experience, good and bad, that we develop within the programme will be made available as widely as possible. This will include research manuscripts, scientific reviews, oral presentations and regular updates on our websites. This will deter other researchers, pharma and biotech companies from wasting time, money and mice. By becoming Key Opinion Leaders in our respective fields we (Principal Investigators) are already approached by commercial sources for guidance on research programmes and our continued research programme is likely to extend those relationships. In addition my team regularly speak with members of the public through numerous public engagement opportunities that we run and often discuss our need for and justification of animal research. In almost every case the public support our work avidly.

Species and numbers of animals expected to be used

- Mice: 13100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice as a model system to faithfully recapitulate the human disease. These studies will focus on understanding why certain anti-cancer therapies often fail to produce tangible clinical benefits.

Cancer is a disease of organs and tissues, and in essence involves the formation of new aberrant organs called tumours, which are composed of multiple interacting cell types. It is not possible to accurately recapitulate these abnormal organs in culture (i.e. petri dish), and it is only by studying their progression and responses to targeted therapies in animal models that we can learn more of the basic mechanisms of cancer and ultimately design more effective anticancer therapies. Using cells grown in a laboratory does not accurately reproduce all the components that affect tumour development and stages and will not be representative of what could happen in a whole living organism and how it may respond to treatment. For example, we will mainly use adult mice as they will have a fully developed immune system, one of the key features that a tumour 'hijacks' in order to grow and spread, which we would like to study and with the ultimate goal of targeting the 'hijacked' cells. We will also use mice that have been genetically engineered to develop cancer. The types of mutations introduced into the mice are usually designed to resemble human disease stages as our programme seeks ultimately to develop translational therapies i.e. novel treatments that can be given to patients, or improved treatment regimes. It is essential that the genetically altered (GA) animal models faithfully recapitulate the human disease (i.e. stages and response to therapy) to allow us to examine tumour responses to therapies and to identify the molecules (proteins) involved, which ultimately will serve as novel therapeutic targets. In addition, by using mice with inducible genetic changes, that is, genes we can essentially switch on or off, genes that may cause developmental defects (often harmful or lethal in early development), can be regulated by activating the gene(s) in later stages of mouse development, typically during adulthood.

This allows us also to determine whether the gene would be targetable in an adult (eventually adult human) even though it would have been harmful to target in the embryo. Lastly, the use of GA animals engineered to express a molecule of interest specifically in a cell type of interest (i.e. immune cells) are very powerful as they allow us to selectively

target a molecule in a cell type of interest and study its function during tumour development, progression and response to treatment. This knowledge will improve our understanding on how tumour adapt/respond to therapy and will lead to identification of new therapeutic targets.

Typically, what will be done to an animal used in your project?

Typically, cancer cells will be injected into a mouse to allow a tumour to form. Alternatively, some mice have been genetically engineered to develop tumours spontaneously, which faithfully recapitulates the human disease. After a period of time (dependent on the model used, ranging from weeks to months for some slower growing genetic models) the primary tumour may then be removed surgically (under anaesthetic and with pain relief given, according to the advice given from our Named Veterinary Surgeon). Over time (again model dependent) in some of the models metastases (sites of secondary tumours) will form, typically in the lung, liver and bones. We will then be able to image these tumours (under anaesthetic) using modalities such as magnetic resonance imaging (MRI) or bioluminescent imaging (BLI), both standard minimally invasive imaging techniques used widely in animal-based research. Mice will be given different treatments, either as single agents or a combination of agents to try and find the best regimen that could be applied in the clinic. These could be administered via injection or orally. Tumour-free mice (no cancer cell injection) will be used in some experiments to analyse the effects of drugs or biological compounds released by tumours (i.e. extracellular vesicles) in mediating host responses (i.e. inflammation) which are known to pre-condition organs to allow cancer cell colonization and metastasis formation. Blood samples may be taken during the course of the experiment from the tail vein (one drop only removed with limited samples taken) and also at the end of a study where the mouse could have more blood removed under terminal anaesthesia from which they would not be woken. The blood sampling allows us to analyse the effects of a treatment and could help us develop a liquid biopsy applicable to humans, reducing or replacing the number of invasive procedures a patient may have to undergo. At the end of each study all mice are killed humanely and tissues taken for analysis for research. Most studies typically last from days up to 3 months from start to finish, with mouse health being monitored closely taking into account various factors such as appearance, body weight and behaviour.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the mice used will be genetically engineered to develop a specific type of cancer or disease. As the disease progresses tumour(s) will develop and eventually the primary tumour will spread to other parts of the body. Primary tumours may grow in size to impair mobility but will either be removed surgically (under anaesthetic with pain relief) or the mouse killed humanely before this happens. If a tumour spreads, for example, to the lungs, it may impair breathing but again mice would only experience the minimum discomfort possible before receiving treatment or being euthanised. Some tumours may become ulcerated. In cases where mice present superficial ulcerations, or deep ulcerations that do not exceed the 2mm in diameter, animals will be monitored daily. In cases where deep ulcerations exceed the 2mm in diameter, animals will be euthanized within 24 hours. Some cancers cause weight loss, for which we would provide a softer easier to digest diet. Some therapies or treatments may have some toxicity, for example, chemotherapy, which is also toxic in humans.

Treatments will be administered within ranges that are relevant to patient (mouse) size for the minimum time required possible (usually twice a week, for 4-6 weeks in most cases).

Any weight changes, behavioural changes (hunched posture etc) will be monitored closely. Adverse effects relating to therapies are not expected to reach beyond mild or transient moderate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice are anticipated to experience mild (30% of mice) to moderate (70% of mice) severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our goal is to understand the complex biology of cancer and to use this knowledge to develop therapeutic strategies to stop cancer being a fatal disease. To do this we must use systems that match the complexity of human cancer. Cancers are complex organs consisting of multiple cell types which support tumour growth, such as immune cells and fibroblasts,as well as endothelial cells which form blood vessels. Blood supply ensures nutrient delivery to the tumour and removal of metabolic waste, thus supporting tumour growth. Moreover cancer cells use blood and lymphatic vessels to migrate and colonize distant sites where they form metastases.

We use the mouse as an experimental organism for the following reasons: it is an accurate representative of most human organ systems; its diseases show similarities to human diseases; genetic manipulation of the germ line is practical; there is an extensive genetic foundation present in the form of inbred strains of mice and in technologies to map disease loci. We have chosen these preclinical tumour models to truthfully recapitulate the mechanisms that tumors employ to grow. These mouse models will help us to provide useful and reliable insights into the biological mechanisms employed by the tumor to grow, contributing to develop therapeutic drugs with a high potential impact in clinics.

Which non-animal alternatives did you consider for use in this project?

We use the mouse as an experimental organism for the following reasons: it is an accurate representative of human organ systems; its diseases show similarities to human diseases; it enables the growth of experimental tumours that recapitulate the hallmarks of human cancer, including the ability to form metastasis and establish the complex interactions among cancer cells and other host cells, such as vascular and immune cells, which also regulate tumour progression. There are no alternative experimental models (e.g. in vitro assays) that could answer the complex biological questions we wish to address with this project.

However, depending on the scientific question and the nature of cell interactions we wish to study, we will employ co-culture experiments (2D and/or 3D) where possible to reduce the number of animals used in our studies. For instance, we will employ in vitro T-cell mediated cancer cell killing assays, co- culture of primary or immortalized macrophages with cancer cells etc. To study cancer cell invasion and metastasis, we may also use alternative models (if appropriate, i.e. in cases were the molecular mechanism does not rely on complex interactions with complex cellular components such as cells of the immune system) such as the chick embryo assay or zebrafish embyos. Yet, this depends on the complexity and nature (i.e. plasticity, half life) of cells of interest as well as the readout of our experiment.

Moreover, we will perform meta-analysis of publically available datasets from cancer patient cohorts to identify the most clinically relevant mechanisms. For instance, we will seek to identify which signalling molecules or cellular components out of our candidates are associated with disease progression and/or response to treatment in humans, and this will allow us to focus on specific mechanisms and interactions that are most promising to have a translational relevance. This will further reduce the number of in vivo experiments and as such the number of mice used for our studies.

Why were they not suitable?

In vitro systems developed to date can model many disease processes, however they will never fully recapitulate the complexity of a live tissue served by blood vessels and lymphatics and having innate and adaptive immune cells, all of which are key elements of whether a tumour can grow and spread.

Testing anti-cancer drugs in mice in vivo is the only way to assess the importance and relevance of specific interactions between the cancer cells and their stromal microenvironment (including blood vessels, infiltrating macrophages, etc…).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use statistical programs, applying the unpaired T-test to compare data means or ANOVA with post- hoc paired comparisons, to calculate the differences between expected populations. The statistical significance (or not) of the actual data provides guidance about the minimum number of animals that assure, to the best of our knowledge, a statistically significant outcome. For assessing quantitative effects (e.g., tumor volume; various histological parameters, etc…), our previous experience with the models described here provides guidelines. Briefly, primary tumor growth are relatively variable, so the retrospective statistics give a group size of at least 7-10 mice per cohort/arm in each experiment, depending on the tumor parameters analyzed. Thus, we will evaluate cohorts of 7-10 mice per experiment that should be at the same stage of disease progression or treatment to assure that the results are consistent. We always aim to perform each experiment once. Yet, due to variable factors that may vary between experiments (i.e.

eliminate animals due to tumour ulceration, failure to form tumours etc), or f the results of one experiment are trending toward statistical significance, then the experiment will be repeated with additional mice, aiming to achieve statistical significance, or exclude. However, since tumour response to targeted therapies can be relatively variable (i.e. some tumours may naturally develop resistance while others respond), and we intent to use new combinatorial treatments with unknown phenotype/ response outcome (i.e. some mice may respond, others may be refractory, while others may develop secondary resistance), this may result in classification of experimental animals of a given treatment into subgroups. Inevidably, this will result in reduced animal numbers per subgroup. To study the mechanism of action of the new combinatorial treatments, and only if we observe a trend toward a statistical significance, then new mice will be enrolled until we obtain confidence on the reproducibility of our data and/or a statistical result. Moreover, this number of mice used provides us with sufficient tumor tissue to perform isolation of relatively rare cell types by fluorescence-activated cell sorting and subsequent gene expression studies. We also referred to other relevant published research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments will be carried out following good laboratory practice. All experiments will be designed after careful examination of the literature, with regards to treatment i.e. drug dosage, treatment regime and with the aid of the NC3R's Experimental Design Assistant. Whenever possible use of in vitro assays will reduce the numbers of animal required.The minimum number of animals will be utilised for each experiment performed under this Programme of work while maintaining a reliable and measurable output. Sample size calculations will be performed before each experiment so that experiments are adequately powered statistically. Many of these are already done for the experiments planned in this proposal. Using the appropriate numbers of animals is essential to answer reliably the questions we are addressing. This ultimately avoids wasting animals and repeating experiments unnecessarily.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will maximise the amount of information we obtain from each animal e.g. harvesting as many tissues as possible at the end of study for use for the current and future studies and to share with other researchers when we have fully utilised the samples we need.Imaging technologies will be a vital tool in reducing the number of animals required for each experiment as this removes the need to kill animals at time points to observe tumour progression. To minimise confounding factors we will undertake the following:

experimental design will be well planned with constant checks

within each experiment, animal groups will be maintained under the same husbandry conditions, unless otherwise recommended by the NACWO or NVS

within each experiment, mice will be randomly assigned to different groups

experiments will always be statistically controlled

in some experiments but not all, blinding may be applied (i.e. animal experimentator may use coded drug preparation for the study.

In rare cases, pilot studies will be performed for therapeutic studies where no data are available regarding dosage to reduce the number of mice potentially receiving an ineffective or a dosage beyond maximum tolerated dose (MTD). We will set up the most efficacious breeding programs, with harems to reduce the number of males required and where possible we will breed to produce the maximum number of the genotype(s). For example, if we only require homozygous knockout (KO) mice for our studies we will try to breed homozygous KO male and females to produce only the KO genotype we require, thus reducing the number of unwanted heterozygous or wild type pups that would otherwise be culled.

When reporting on in vivo experiments for publication we will conform to the ARRIVE guidelines and latest NC3R guidelines to minimise unnecessary studies.We will archive genetically modified mouse lines as frozen sperm or embryos to reduce the number of living mice we have to maintain and to allow sharing of these lines between researchers, providing further opportunity for reduction.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Immunocompetent, immunodeficient and Genetically Modified Mice (GEMM) will be used. Some of the GEMM will naturally develop cancers of interest (including breast) so that we can investigate the biology of the developing disease and test our treatments in a model that most closely matches human diseases. Immunocompetent or immunodeficient mice will also be injected with cancer cells (of mouse or human origin) subcutaneously (sc), orthotopically or intravenously (iv), as required by the scientific question, to allow tumour formation. In some cases, tumour-free mice will also be used (untreated, treated with drugs or extracellular vesicles (EVs)). Experienced researchers will inject the animals minimising pain and discomfort to mice.

In most cases, mice do not develop any pain or discomfort as a consequence of their developing cancers and we terminate the animals before such discomfort occurs due to tumour size, or when the general condition of the mouse becomes evidently compromised and signs of distress become obvious. MRI or microCT in vivo imaging of deep tissue tumours provides confidence we can deliver this intention.

In some cases, mice will require anaesthesia and surgery for orthotopic injections and will receive analgesia post-op to minimise discomfort. In some cases, genetically manipulated cells that contain bioluminescence or fluorescence will be used so we can accurately monitor tumour development, metastasis and response to therapy using non-invasive methods so as to minimise pain and harm to animals. All experimental mice are routinely examined for their activity, overall condition and food/water intake. Mice that show signs of pain, distress and/or compromised general conditions will be monitored closely with the local BSU staff and the NVS, and will be humanely killed, as required.

The mice will be immediately removed from the experiment and euthanized if/when they present one of the following humane endpoints:

Compromised ability to walk, eat, drink, urinate or defecate. These functional impairments may occur in a minority mice as a consequence of one of the following: (i) abnormal growth of an individual tumor, which may compromise functions such as locomotion, appetite and/or excretion; (ii) tumor invasion into the chest or peritoneal cavity, which may compromise organ function. Regardless of the ability of the operator in performing tumor cell inoculation, orthotopic or subcutaneous tumors may occasionally invade the chest or peritoneal cavity (orthotopic) or the muscle (subcutaneous).

Difficulty of breathing (dyspnea) possibly caused by metastatic pulmonary tumors.

Persistent hunched or non-responsive to stimuli mouse

Each tumour reaches a volume of 1.25cm3 or becomes ulcerated (>2mm in diameter). Animals will be killed earlier if the tumour ulcerates (>2mm in diameter) or impedes any vital function (e.g. locomotion, mastication, excretion).

Why can’t you use animals that are less sentient?

Most of our experiments require tumours to develop over a time period, which is a result of complex interactions between live cells. These animals will be treated with therapeutic drugs and tumour responses will be monitored/assessed. Thus it is not possible to use animals that are terminally anaesthetised. We use mice as they closely reflect the biological processes in humans that we are trying to investigate. Thus if we were to use non-mammalian models (drosophila, xenopus) we would not recapitulate the biology that occurs in humans. Our choice of mice is the simplest mammal that through years of research by ourselves and others provides us with confidence that our experimental designs are likely to be as close to our therapeutic goals as possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We already are successfully implementing imaging methods at our Institute to improve the analysis and monitoring of deep tissue cancers that occur either through orthotopic implant or grow in transgenic mice. This has improved how we apply experimental therapeutics as we can now 'recruit' mice that have similar volume tumours at Day 1 of a protocol, instead of starting therapy on a cohort at a predetermined time interval after injection. This also allows longitudinal studies that formally required cohorts of mice to be killed at intervals, thus saving many mice. By internal talks and eventually publication we are sharing these improvements with our local and distant scientific community. The imaging protocols (MRI or microCT) have the immediate benefit that there is limited chance that an animal develops an internal tumour that exceeds home office limits. All our mice are kept in individually ventilated cages (IVCs) under barrier conditions, to avoid any infections in immunocompromised mice. Mice are monitored daily for any adverse effects to avoid suffering at all times. We have extensive experience of working with GAA mice so we are aware of health problems and can take timely action to minimise suffering, to ensure pain relief is quickly administered whenever necessary and we have clear guidelines on humane endpoints.

To limit severity in our cancer models we will:

measure tumours regularly to prevent tumours exceeding the legal size limit

determine humane endpoints to produce valid scientific outcomes

image mice to detect unexpected sites of tumour development

use labelled cells to image mice for tumour spread and metastasis

perform pilot studies on orthotopic cancer models to characterise kinetics of tumour growth and metastasis.

perform mammary fat pad orthotopic injections without surgery, under anaesthesia (i.e. isofluorane).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have been following the ARRIVE guidelines and will follow the most up to date version of these that are published by the NC3Rs. We will also make use of the Experimental Design Tool (https://eda.nc3rs.org.uk) and the PREPARE guidelines (https://norecopa.no/media/7832/prepare- guidelines.pdf), as well as the Workman et al guidelines for Cancer research (Workman et al, British Journal of Cancer, 2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute regularly hosts updates in experimental animal usage, including developments in 3Rs that I try to attend or send representatives from my team. I and members of my team also regularly attend NC3R events to hear new development on how other researchers conduct their research.

63. Circadian regulation of chronic inflammation

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Circadian, Inflammation, Arthritis, Colitis

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to explore how the function of the immune system varies over the course of the 24 hour day, and how these daily changes impact on the development, progression and treatment of chronic inflammatory conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic inflammatory diseases such as rheumatoid arthritis (RA), colitis and psoriasis are debilitating conditions. The estimated prevalence of these conditions within Western society is 5-7%. The symptoms of chronic inflammatory diseases often show daily variation. For example, RA patients report increased pain and joint stiffness in the early morning. Similarly, biological markers used in the clinics to assess disease severity fluctuate over the course of the 24 hour day.

The circadian (24 hour) clock is a timing mechanism which synchronises animal physiology to the 24 hour environment created by the earth rotating on its axis. This biological timer regulates numerous aspects of physiology, including sleep-wake cycles,

feeding and metabolism, the gut microbiome, hormone secretion and the immune system. Disruption of the circadian clock, through environmental disruption (e.g. shift work) or through genetic disruption is associated with increased incidence of inflammatory diseases.

The circadian clock plays a critical role in regulating the normal working of the immune system and ensuring appropriate inflammatory responses are mounted when the system is challenged. This work investigates mechanistic links between the biological timing and immune systems to understand the involvement of the clock in regulating chronic inflammatory disease. An ultimate goal of these studies is to reveal novel therapeutic targets or improve existing therapeutic regimes to treat disease through the use of biological timing (chronotherapy).

What outputs do you think you will see at the end of this project?

A major output from this project will be an advance in our knowledge regarding clock control of immune responses. More specifically, information generated from these studies will contribute to our understanding of how the circadian (24 hour) clock affects the development and progression of human chronic inflammatory diseases. This information will further our understanding of how circadian disruption (a consequence of rotating shift-work) may impact on the function of the immune system in health and disease.

It is predicted that data generated by these studies will have a positive impact on the diagnosis and treatment of human chronic inflammatory disease. An example here is the implementation of chronotherapy - timing therapeutic interventions with the peak of disease symptoms. To maximise these positive benefits, it is essential that information obtained from studies outlined here is disseminated effectively. This will be achieved through: publication in academic journals; presentation of data at conferences; and through public engagement events.

A secondary benefit of this programme of work is the advancement of research methods. This may be in the form of refining or enhancing current methods or through the development of new transgenic mouse lines. The data generated from this project will be made available to other researchers in the scientific community at the earliest appropriate time therefore informing further scientific discovery within our research community.

Who or what will benefit from these outputs, and how?

Healthcare sector: There is a growing understanding of the importance of considering circadian time in the diagnosis and treatment of inflammatory disease. This work will further our knowledge of how the circadian timing system interacts with processes underlying human chronic inflammatory conditions. It is hoped that these studies will promote further incorporation of "clock logic" into clinical practice in the long-term. That may be through standardising the time of day at which a patient's blood is sampled for a disease biomarker, or through recommending the best time of day at which to take medication.

Scientific community: This programme of work will generate new research tools and advance research methods which will be shared with the scientific community. Data generated in this project will advance our basic understanding of clock control of immunity and will be of benefit to the wider research community.

General public: The importance of the circadian clock and good sleep hygiene for maintenance of health is becoming widely recognised by the general public. Information obtained through this project will be of interest to people engaging in shift-work and patients suffering with chronic inflammatory disorders. It is becoming more and more evident that disruption of the circadian clock has negative consequences on health. Whilst sometimes circadian disruption cannot be avoided (e.g. shift-workers), for some individuals small lifestyle changes may have a positive impact on health. In order to engage the general public, we will continue to reach out via public engagement events run by the University and charities.

How will you look to maximise the outputs of this work?

Outputs from this work will be published in highly visible journals targeting a multi-disciplinary audience. Through the use of social media (Twitter) and the establishment press office, we will publicise these publications as widely as possible to engage with the general public. In the past, this has led to opportunities to present our research on the radio, television and news websites. We appreciate that it is important to disseminate negative findings to minimise replication of experiments across research institutes. On going work will be presented at international and national meetings aimed at circadian biologists, immunologists and specialised clinicians. To maximise the benefit of our research we will continue to engage with the general public and relevant patient groups through organised events. These activities are important for maintaining public interest in our research and also further developing trust in UK research.

Species and numbers of animals expected to be used

- Mice: 24 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These studies will utilise juvenile and adult mice, which may be genetically modified. Mice are the most appropriate species for these studies as the systems which we are studying here (the body clock and immune system) are well reproduced between mice and humans.

Typically, what will be done to an animal used in your project?

Animals may be monitored non-invasively for behaviour under normal or altered environmental conditions (typically for periods lasting 2-6 weeks). These environmental manipulations include changes in the light/dark cycle, changes to the composition of the diet or changes in timing of food availability. More rarely, animals may undergo physiological monitoring using implanted telemetry devices (requiring a brief surgical procedure) or imaging facilities (under recovery anaesthesia). Rarely repeated imaging may be utilised (up to 8 times in one day). Changes to rhythmic biological signals (such as hormones or microbial metabolites) may be instigated through implantation of hormone pellets under the skin (brief surgical procedure); through application of antibiotics; or through administration of a chemical reagent. On occasion when utilising specific strains of

transgenic animals a gene inducing agent may be administered to the animal in order to "switch off" the gene of interest.

To instigate chronic inflammation different approaches will be utilised, each modelling a different human chronic inflammatory disorder. In each instance, mice will usually only be maintained in a chronic inflammatory state for 5-10 days. Each of these models will be used alone (never in combination).

Joint inflammation: This may be induced via an injection of collagen which drives an autoimmune response and chronic inflammation of multiple joints (collagen induced arthritis, CIA) or via use of methylated bovine serum albumin which drives a resolving inflammatory arthritis affecting just one joint (antigen induced arthritis, AIA).

Gastrointestinal inflammation: This may be induced via temporary administration of a chemical agent in the drinking water which causes damage to the gut barrier. This drives inflammation of the colon which resolves over time when the chemical agent is withdrawn.

Skin inflammation: This may be induced via application of an agent to the skin of the ear or the back, which causes a resolving local inflammatory response.

Prior to, or during these procedures to induce an inflammatory response, the immune system may be manipulated. This may be via application of reagents to target specific pathways. On rare occasions the immune system may be manipulated further through irradiation to deplete host immune cells before replacement with donor cells. Additionally, reagents may be administered which target the clock or the immune system to establish their effects on inflammatory processes.

Animals utilised in these models of inflammation may be assessed using *in vivo* imaging, collection of small volume blood samples and/or assessment of metabolic function or gastrointestinal function. To assess metabolic function, animals may be administered an injection of insulin or glucose and blood samples taken, or may have harmless metabolic tracers added to the drinking water. To assess gut barrier permeability animals may be orally administered a fluorescent labelled sugar prior to collection of small volume blood samples.

In some instances, a line of mice will be utilised which express a green fluorescent protein which can be converted to a red fluorescent protein through application of violet light. Here, animals may be briefly anaesthetised and exposed to this light source in order to be able to track the movement of cells from one site in the body to another.

In addition to these procedures, mice will be used in this project for breeding, and for provision of cells and tissues for *ex vivo* studies.

What are the expected impacts and/or adverse effects for the animals during your project?
Animals may experience mild adverse effect such as temporary stress or brief pain and discomfort. Temporary stress may be induced by a brief period of restraint (e.g. in order to administer an injection) or alterations in their housing environment (e.g. single housing). Mice may experience a brief period of pain and discomfort in response to dosing (e.g. injection or oral gavage) or blood sampling (e.g. tail bleed) or following surgical intervention to implant a telemetry device or hormone pellet or to apply a photoconverting light source. In these instances the stress and discomfort will be transient.

Weight loss may occur after manipulation of the diet, but will be transient and will either reverse or stabilise. Transient dehydration and weight loss may occur as a consequence of addition of an agent to the drinking water which may make it less palatable or as a consequence of irradiation protocols.

Models of chronic inflammation will induce localised inflammatory responses resulting in pain. Models of arthritis (collagen induced arthritis (CIA) and antigen induced arthritis (AIA)) will lead to swollen, inflamed joints and may results in reduced mobility. CIA is a polyarthritic model whereby multiple joints may be affected. Animals are usually maintained in an arthritis condition for 7-10 days. Affected animals exhibit reduced activity and may exhibit some weight loss. AIA is a monoarthritic model of resolving inflammatory arthritis whereby only one knee joint is affected. Here, animals are usually maintained in an arthritic condition for up to 10 days. These animals may exhibit a brief period of reduced activity (1-2 days) and rarely exhibit weight loss. On occasion (<20% AIA animals) mice may be manipulated to induce one or two subsequent "flares" after the initial insult in order to model periods of increased disease activity experienced in human disease.

Gastrointestinal (GI) inflammation is associated with pain, development of diarrhoea, occasionally the presence of blood in the stools and weight loss. The inflammation inducing agent is withdrawn after a period of time (usually 5 - 7 days) after which the inflammation resolves. On occasion (<20% colitic animals) mice may be manipulated to induce one or two subsequent "flares" after the initial insult in order to model periods of increased disease activity experienced in human disease.

Skin inflammation is associated with reddening, scaling and thickening of the skin. This is associated with pain and discomfort and weight loss. Here animals are usually maintained in this condition for 5-10 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The studies outlined in this project will result in a cumulative impact to the animals (mice) that are sub- threshold to mild (approximately 60 percent) or moderate (approximately 40 percent) severity rating.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In the context of organ-level inflammation, it is currently not yet possible to replicate the complex multi- cell environment underpinning disease. Thus, *in vitro* cellular models and *in silico* models have limited application as a replacement for studies of chronic inflammatory

disease. In order to study complex interactions between the circadian timing system and immune responses, mouse models are the most appropriate approach.

Which non-animal alternatives did you consider for use in this project?

In vitro approaches include the use of single-type cell lines or co-culture systems (where two or more relevant cell types are studied together). We utilise these methods to inform the direction of animal studies. *In vitro* assays can be used to test how genetic or pharmacological interventions alter the function of the cell intrinsic clock and/or regulation of inflammatory processes. For example, *in vitro* assays using cell lines or primary cells allow us to first test a diverse range of potential therapeutic interventions and identify a small number of candidate molecules with the most potential for subsequent use *in vivo*. However, these approaches cannot replicate the complex environment of the joint, gut or skin and cannot replace the use of animals.

This programme of work is supported by parallel studies using tissue samples from humans. Synovial fluid and serum collected from healthy volunteers and rheumatoid arthritis patients will be analysed to assess time of day variation in inflammatory mediators and metabolites. Additionally the group routinely utilises online databases such as UKBiobank and NIHR IBD Bioresource to examine circadian features of patients with chronic inflammatory disease.

Why were they not suitable?

It is critical that any cell lines utilised possess a functional clock. Our experience is that a cell type may be rhythmic in a healthy animal, but once removed and cultured it becomes less rhythmic. This may be due to the absence of other signals (for example hormones) that these cells would normally be exposed to. Furthermore, *in vitro* assays cannot adequately model the complete array of inflammatory responses or address how systemic timing signals may modify these responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
Our grouping has extensive experience with the methods and approaches outlined here and of running projects of a similar scope. Consequently, estimates of animal numbers are based on previous experience and with careful consideration of the experimental design. Where protocols are new to the group, we will run small control experiments (taking advice from local colleagues with expertise in these models) to generate data on which to perform power calculations in order to plan future studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When considering the design of experiments underpinning this project we have consulted with statisticians to gain specialist advice on the types of experiments that will be

undertaken and the nature of the datasets that will be collected. We will continue to do this as the work develops. We will be utilising purpose written software (such as the NC3Rs Experimental Design Assistant) to further support experimental planning, randomisation and blinding.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout this project we will continue to optimise animal use wherever possible. This starts with efficient breeding of transgenic mouse lines, which we achieve through close monitoring (facilitated by specialist colony management software) and effective communication with technical staff managing the colonies. We aim to minimise numbers of animals bred whilst still achieving adequately powered, age and sex-matched groups of experimental animals. When individual projects have been completed breeding of relevant mouse strains will be minimised until a suitable time to preserve the colony by freezing down gametes.

Pilot studies are utilised to optimise experimental conditions when we are developing new approaches. Where it is appropriate we utilise technologies that permit longitudinal assessments in the same animal. Furthermore, we always look to maximise the amount of data that we can gather from a single sample using the latest technologies to their full capacity.

At the end of each experiment we carefully consider which tissues to collect with future studies in mind. By building a well archived tissue bank we are able to utilise existing samples in the laboratory to test new protocols or reagents without the need to utilise further animals. We make our banked tissue available to our collaborators. Through providing the wider scientific community with access to data generated through our studies (through online data repositories) we maximise the scientific knowledge than can be obtained from our animal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A substantial proportion of the methods that we will use in the project are non-invasive and involve simple environmental manipulations to study effects on circadian physiology and/or immunity. This includes modification of the lighting, meal composition or meal timing. These manipulations are unlikely to cause suffering or distress, however occasionally may require an animal to be singly housed. To minimise potential distress in this situation, where possible we will supply mice with environmental enrichment (e.g. plastic tubes, wooden logs or nestlets). Some animals may be subject to a brief surgical procedure, for example to implant a device which permits remote monitoring of mouse activity.

Where we seek to administer reagents to experimental animals we utilise the most refined route of administration possible. For example, we routinely administer antibiotics in the drinking water, rather than through oral gavage. In order to make the solution of antibiotics more palatable to the animals we add a sweetener. We always seek to minimise the numbers of doses of a treatment in order to achieve our objective.

Pre-clinical models of human chronic inflammatory disease will be used in this project, including inflammatory arthritis and models of gastrointestinal inflammation and skin inflammation. We have chosen the most refined models available to address our experimental objectives. For example, we no longer use the K/bXN model of arthritis (in which mice spontaneously develop severe erosive arthritis from an early age). With each of these models, we restrict the period of inflammation as much as possible to minimise animal pain and suffering without compromising experimental aims.

Why can’t you use animals that are less sentient?

We cannot replace these studies in mice with studies in another species (such as insects or fish) to achieve our objectives, as they lack the complex immune and circadian systems seen in higher order species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely seek to minimise stress and discomfort to animals during our work and achieve this by ensuring all researchers utilise appropriate animal handling techniques (e.g. tube handling where possible to remove animals from their cage) and by using environmental enrichment where possible, especially in instances where it is necessary to singly house animals.

Occasionally animals may undergo a brief surgical procedure. After surgery, animals are closely monitored and post-operative care provided (pain management with analgesics and provision of extra fluids). Analgesics may be provided in the form of a palatable gel to encourage voluntary ingestion.

Animals which develop chronic inflammation are monitored regularly, including monitoring weight loss and general condition. Analgesics may be utilised in animals exhibiting chronic inflammation, however the use of pain relief is not always compatible with our experimental aims. Where transient weight loss is expected as a consequence of the experimental condition, soft food (wet mash) will be provided on the cage floor as well as environmental enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure that our experiments are conducted in the most refined ways we continually assess our experimental design and re-assess approaches if the opportunity arises. We stay informed about best practice guidelines by referring to information provided by Laboratory Animal Science Association (LASA) and NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group stays informed about recent advances in 3Rs approaches by staying up to date with NC3Rs recommendations and developments. This information from the NC3Rs is obtained through interaction with their website, local seminars, contact with their staff and through social media (Twitter). We endeavour to adopt new tools as they evolve, such as the NC3Rs self assessment tools, in order that we focus our efforts here and keep up to date with successful initiatives utilised elsewhere. We also discuss further refinement opportunities with our NVS and NACWO and through interaction with colleagues at conferences, workshops and seminars.

64. Investigating new radiotherapy and drug treatments for cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, radiotherapy, chemotherapy, radiation

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop mouse models of cancers that are difficult to treat, and use these models to identify new treatments that can increase the effectiveness of radio and chemotherapy. We will also use the models to understand why some tumours are less responsive to radiotherapy or chemotherapy. Finally, we will investigate the effects of radiation on normal (non-cancerous) tissues with a view to reducing the side effects of radiotherapy treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

These studies are essential because many cancers are resistant to current treatments, which often include radiotherapy and chemotherapy. The proposed work will enable us to develop and test new radiotherapy and radiotherapy-drug combinations to treat cancer

more effectively. We will also study ways to reduce the adverse effects of radiation on normal tissues, in order to reduce harmful side effects of radiotherapy.

What outputs do you think you will see at the end of this project?

We will develop mouse models of cancers that are currently difficult to treat, including brain tumours, lung cancer (including mesothelioma), and head and neck cancer, and use these models to identify new treatments that will increase the effectiveness of current treatments, particularly radiotherapy and chemotherapy. We will also use the models to understand why some tumours are less responsive to radiotherapy or chemotherapy than others. Finally, we will obtain new information on how radiotherapy damages healthy (non-cancerous) tissues, and find out if certain drugs can reduce the extent or severity of this damage. Our studies will be designed so that they can lead directly to clinical trials. We will publish our results in high-impact scientific journals so that other researchers will have access to our models and our data. Experiments aimed at refining and improving our mouse models of cancer will create new and better models that are likely to give more accurate results. In parallel, further development of 3-dimensional cell culture models will enable more efficient evaluation of new cancer treatments while minimising the use of mouse models.

Who or what will benefit from these outputs, and how?

The benefits of this project are:

A more in-depth understanding of the biology of cancers that are difficult to treat, including brain tumours, lung cancers (including mesothelioma) and head and neck cancers.

Better understanding of why these cancers are resistant to current treatments, including radiotherapy and chemotherapy.

Accurate testing of new therapies for cancers that are difficult to treat; this will identify which treatments that are most likely to be successful in the clinic.

Improved understanding of the processes responsible for the side-effects experienced by patients undergoing treatment with radiotherapy or radiotherapy-drug combinations.

Improved understanding of the side-effects of radiotherapy and radiotherapy-drug combinations experienced by animals undergoing treatment; this information may help us find was to reduce side-effects experienced by both animals and humans.

Ultimately we aim to improve outcomes for patients with cancers that are difficult to treat by developing more effective treatments and reducing side-effects.

How will you look to maximise the outputs of this work?

To maximise the outputs of our work we will continue to work closely with academic and industrial partners across the UK and internationally, and continue to establish and lead working groups in the field of radiotherapy-drug combinations. New knowledge will be published in high impact scientific journals and presented at national and international conferences. In particular, we will continue to work with our networks of scientists and clinicians to ensure that the most promising treatments are tested in cancer patients as soon as possible. Unsuccessful approaches will also be published to add to the body of knowledge and minimise the chance of these approaches being tested by other

researchers.

Species and numbers of animals expected to be used

- Mice: 2650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using genetically altered mice or mice without an intact immune system that carry specific mutations in genes that are thought to play a role in cancer. This includes genes involved in the response to tumour development and response to treatment, including changes in the immune system or metabolic processes.

Genetically altered mice can model the genetic mutations of human cancers and allow us to look at the effects of these genes in normal non-cancerous tissues, as well as studying how cancers develop. We can observe the effects of gene alterations within the mouse host and their effects on tumour growth and response to treatment.

Mice do not have an intact immune system enables us to transplant human tumour cells and some specific types of mouse cells into the host mouse without rejection by the body. This is extremely important because it allows us to study cancers that grow in patients, and to test new treatments on these 'human' cancers. Transplant models also allow us to manipulate the genetics of distinct cell types (either the cells of the mouse host or external transplanted cells), to examine their impact on responses to anti-cancer therapy.

Most of our experiments will be conducted in young mice (typically aged 8 - 10 weeks at the start of the experiment). In some of our cancer models (either genetically engineered or transplanted) it can take many weeks or months for tumours to develop. For some experiments we will use adult animals (typically aged around 6 months at the start of the experiment) for two reasons: (1) cancer is more common in older people so adult mice can provide a more relevant environment, (2) some of the side- effects of treatment are more common in older people, so these can be studied more accurately in adult mice.

Typically, what will be done to an animal used in your project?

Cells from patient tumour samples or commercially available established cell lines will be injected into the animal to create cancerous tumours of the types being studied. Tumour cells may be injected into the brain (under general anaesthesia), under the skin (without anaesthetic if cells, with anaesthetic if tumour fragments) or both.

Radiotherapy may be administered (under general anaesthetic) and its effects on tumours and healthy non-cancerous tissues will be determined by imaging and/or by taking a tissue biopsy or sample. We will use established and emerging imaging and tissue analysis techniques to gain the most data from each animal. Some mice will have a perspex 'window' inserted into their skull (under general anaesthetic)- this will enable us to obtain detailed, real-time information about tumour growth and the effects oftreatments on cancers growing within the brain.

Mice may be treated with other anti-cancer therapies, either before or after radiotherapy, to investigate the effects of radiotherapy-drug combinations on tumours and on healthy non-cancerous tissues.

Therapies may be given before tumour injection, or at early or late stages of tumour development provided the animal is in good health.

Drug treatments may be given by mouth or by injection (without anaesthetic), depending on the type of drug.

Animals may be imaged non-invasively, using techniques such as ultrasound, CT, PET or MRI scans, pre- and post-treatment as a means of assessing the effects of treatment on tumours and healthy tissues. All imaging procedures are performed under general anaesthetic.

Experiments using the intracranial tumour model will generally last between 10 and 24 weeks. Tumours become detectable around 10 weeks after intracranial injections and studies of drug distribution and acute effects of radiotherapy and/or drugs will be completed within 12-14 weeks. Experiments studying the effects of treatments on long term tumour growth will be completed with 16 and 24 weeks, depending on how effective the treatments are.

Experiments using subcutaneous tumours will generally last between 2 and 12 weeks, depending on how rapidly the tumours grow and how effective the treatments are.

What are the expected impacts and/or adverse effects for the animals during your project?

Adult animals are susceptible to diseases of old age such as lumps and masses, eye problems, decreased muscle mass, and reduced strength and endurance resulting in loss of mobility, altered gait or reluctance to move.

Blood sampling can cause bruising (<5%), bleeding (<5%), or infection on very rare occasions (<1%).

Injections can result in momentary discomfort (100%) at the time of injection by the needle. In rare cases injections can cause tissue damage and infection (<1%), e.g. intravenous injection has a risk of vein damage.

Fasting may result in mild, transient stress.

The commonest side-effects of anti-cancer drugs are a decrease in white blood cells (<10%), anaemia (<10%) or gastrointestinal issues that cause weight loss or diarrhoea (<10%). These side effects typically last a few days.

Radiotherapy can cause different side-effects depending on the part of the animal being treated. The most common side-effects are hair loss (<50%, lasts several days), diarrhoea (<10%, lasts a few days), weight loss (<10%, lasts a few days) or increased respiration rate (<5%, lasts a few days).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All protocols have a moderate severity rating. All animals (100%) on protocols 1-5 will experience a moderate severity rating.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although many studies can be conducted using cells growing in the laboratory, they cannot fully model the complexities of cancer development in the body. It is well-known that the immune system and other bodily processes play an important role in cancer growth; these complex processes cannot be recreated in cell culture. It is also known that the effects of radiotherapy on tumours and healthy tissues are strongly influenced by the surrounding tissues and by the immune system. To our knowledge there are currently no non-animal alternatives that fulfil the criteria required for our experiments; this has been investigated using the website www.frame.org.uk.

Most new treatments developed in the laboratory have failed to provide benefits for patients; an important reason for this is that laboratory studies have failed to recreate accurately the immune system and other bodily processes which are important in the development of the cancers we are studying.

Which non-animal alternatives did you consider for use in this project?

We have considered laboratory based cell culture systems as alternative models, but these do not encompass the complex interactions between cancer cells, healthy tissues and treatments that occur in living organisms.

To address this, we have developed 3-dimensional cell culture systems that incorporate some of the features of the tumour microenvironment and can be used for some of the experiments in our research programme. This is reducing our use of animals. However, these 3-dimensional models are not available for all cancer types, and do not include all the necessary features of living organisms, so we still need to use mice for many of our experiments.

Why were they not suitable?

Cultured cancer cells show many structural and biological differences from cancer cells growing in intact tumours; these affect their growth and metabolism and also affect their response to treatment. There is increasing awareness that observations made in cancer cells growing in the laboratory differ from those made in cancers growing in live organisms. In particular, drugs and treatments such as radiotherapy that are found to be

effective in cancer cell culture systems are very often ineffective in the clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated that across the six protocols included in this project we will use approximately 2650 animals over the five year period of the licence. Approximately 1250 of these mice will be used in studies of tumours growing within the mouse brain, since this is the major focus of our laboratory.
Approximately 100 mice will be used in cranial window model studies - numbers are fewer than the other protocols because longitudinal data is obtained at multiple timepoints from each mice, so much smaller group sizes are needed. Approximately 500 mice will be used for studies involving subcutaneous tumour models; these will mainly (but not exclusively) involve studies of lung cancer (including mesothelioma) and head and neck cancers. Approximately 300 mice will be used in studied evaluating blood brain barrier penetration of therapies; smaller numbers of mice are needed for each of these drug delivery experiments than for efficacy studies, but we aim to evaluate multiple different drugs in this way over the period of the licence. Approximately 500 mice will be used for studies evaluating the effects of radiotherapy on key normal tissues.

The numbers of mice needed for each experiment have been estimated based on previous work in our laboratory and in the laboratories of our collaborators and partners. We have established the degree of variability of the models used and are therefore able to predict the numbers of mice required to obtain robust data. We have estimated the total number of different drugs and treatments that we aim to evaluate over the period of the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Pilot studies with 3-4 mice will always be performed when using new cell lines and therapies, and small studies to measure drug levels in brain tumour models will always be performed before larger studies. Data from the pilot studies will be used to determine how many mice are required to accurately assess the effectiveness of the new treatments.

For experiments involving tumours growing within the brain, we will start with small studies that measure whether drugs are penetrating the tumours at sufficient concentrations. before proceeding with larger experiments to see if the treatments are effective. If a drug does not penetrate the brain tumour sufficiently, we will not proceed with further experiments.

Where possible, we will use non-invasive imaging methods to monitor tumour growth and responses to therapy. This will permit studies of tumour growth over several weeks, in the same way that tumour growth is monitored in humans, and will avoid unnecessary sacrifice of animals at different time points. Obtaining imaging data at multiple timepoints increases the amount of information obtained from each mouse and often reduces the number of animals required for each experiment.

The NC3Rs online Experimental Design Assistant and G-Power tool will be also used to guide study design and calculate sample sizes required for quantitative experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Laboratory based testing in conventional 2D cell culture and more representative 3D cell culture models will be used to identify promising treatments prior to moving on to animal experiments. Pilot studies using 3-4 animals will always be carried out prior to proceeding with larger studies. These studies enable identification of adverse effects on animals, refinement of treatment protocols if necessary and determination of whether full-scale experiments to measure effectiveness are justified. Pilot studies also help us to answer scientific questions more efficiently.

Wherever possible, we will use non-invasive imaging methods to monitor tumour growth and responses to therapy. This will permit studies of tumour growth over several weeks, in the same way that tumour growth is monitored in humans, and will avoid unnecessary sacrifice of animals at different time points. Obtaining imaging data at multiple timepoints increases the amount of information obtained from each mouse and can reduce the number of animals required for each experiment. Tumours will be excised at the end of each study and assessed by molecular and/or histological techniques. We will preserve tissues for future research use and create sample databases that can be shared with other researchers. Other researchers in our Institute are developing non-vertebrate models of cancer (e.g. Drosophila (fruit flies) and mathematical models), which although limited at present are hoped to be expanded to many tumour types over the next five years.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The following animal models will be used during the project:

The intracranial tumour model will be used because it reproduces key characteristics of brain tumours including their interactions with the very specific environment of the brain. These interactions, and this environment, play crucial roles in determining the way in which brain tumours respond to treatments such as radiotherapy and drugs. It is therefore necessary to test new treatments for brain tumours in the intracranial tumour model. It is now well established that subcutaneous models of brain tumours generate very misleading results. By using the intracranial tumour model we will avoid unnecessary use of mice in misleading experiments.

The cranial window model allows live imaging at a microscopic level of tumour cells growing within the brain - without killing the mouse. The microscopy technique used to

visualise the brain provides the highest achievable resolution of live tumour cells in the animal, and imaging at multiple timepoints generates scientifically rich datasets that significantly reduce the number of mice needed for each experiment.

We will use subcutaneous tumour models when studying cancers that grow outside of the brain. For example, subcutaneous models recapitulate many of the key features of head and neck cancers, which arise in mucosal surfaces of the head and neck region. We will also use subcutaneous where orthotopic models are either unavailable, fail to reproduce the key feature of the cancer being studied, or are not amenable to radiotherapy. For example, many genetically engineered models of lung cancer generate diffuse or multifocal tumours that can not be localised for radiotherapy treatment. By ensuring that our models are as clinically relevant as possible we will minimise unnecessary use of mice in misleading experiments.

For all studies that require radiotherapy, we use a Small Animal Radiation Research Platform that incorporates a CT scanner and allows extremely accurate irradiation of tumours with 0.5mm precision. This greatly reduces the amount of tissue exposed to radiation and minimises the side-effects of treatment.

Why can’t you use animals that are less sentient?

It is essential that we use mice in order to model the genetic mutations of human cancers and allow us to look at the effects of these genes in a normal non-cancerous body and how the cancer develops over time. We can observe the effects of gene alterations within the mouse and its effects on tumour growth and response to treatment in a similar way to that in the human. It is not possible to implant human tumours in animals at a more immature life stage, and species that are less sentient do not possess the complex tissue architecture that is required to study tumour growth and development, and to enable measurement of the effects of treatments. Since tumour growth and response to treatment takes several weeks or months, it is not possible to perform these experiments in animals that have been terminally anaesthetised.

We will be using adult animals because cancer is a disease of ageing and some types of cancer take many weeks or months to develop into tumours.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pilot studies using 3-4 animals will always be carried out initially when assessing new agents to minimise the adverse effects on animals. Pilot studies will also be performed when using new tumour cell lines to determine the take rate and for characterisation of tumours. This will determine if a full-scale experiment is merited and will help answer scientific questions efficiently.

The use of non-invasive imaging will allow a number of data points to be acquired from the same animal, therefore reducing the number of animals used. During imaging, the body temperature of the mouse will be maintained and regulated to reduce potential harms caused by body temperature stress.

Our methods are refined and monitored to ensure the minimum pain and distress for the animal. All injections cause momentary needle-stick pain. Repeated injections on the same day are avoided. Only experienced handlers will carry out injections and they will use aseptic technique, fine gauge single use needles, good restraint, small volumes and

slow delivery. Intracranial tumour implantation is performed under general anaesthesia and pain and distress are further minimised by the use of analgesics and antibiotics.

Administration of therapeutic agents in the diet may cause unpalatability so mice are weighed for the first week after introduction of a new diet and those with 15% reduction in weight, compared to matched controls, will be returned to normal diet.

Animals will not be imaged more than 30 times (once per week for up to 30 weeks) using PET, fluorescent, bioluminescent or ultrasound modalities. For MRI scans, animals will be imaged no more than 10 times with a recovery period of 24hrs between scans.

All surgeries will be performed in a dedicated surgical suite and always using aseptic techniques and sterilised surgical instruments. Pre and post-operative pain relief, and anti-microbial therapy (for the cranial window model only) will be administered routinely to animals under-going surgery as advised by the NVS and in line with current guidelines. Mice undergoing surgery will be monitored closely during the surgery and frequently afterwards by fully trained staff. Animals will be maintained in a warm environment until recovery from anaesthetic.

For studies that require radiotherapy, equipment incorporating a CT scanner is used, which allows extremely accurate irradiation of tumours with 0.5 mm precision. This significantly reduces the amount of tissue exposed to radiation and hence reduces the likelihood and severity of normal tissue toxicity.

To minimise suffering, all mice are frequently monitored and humanely killed when exhibiting signs of altered health status and/or tumour burden. All users will be fully trained in monitoring tumour development for each model and will be signed as competent prior to initiating their studies. Any animals exhibiting 3 signs of moderate severity, or a single substantial severity will be humanely killed; however, other methods of monitoring e.g. the grimace scale and body condition scoring, will also be explored and adopted in to our routine monitoring if they prove useful.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all of our studies we will refer to the Guidelines for the Welfare and Use of Animals in Cancer Research (Workman et al, 2010) and ensure best working practice. We will consult the NC3Rs guidelines, including any updates or amendments, and monitor refinement where such practices are published (www.nc3rs.org.uk).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All our laboratory staff are fully trained and experienced in the experimental work undertaken. They are required to provide proof of training and take part in continuous professional development including updates in the 3Rs and any published advancements in the field. This is assessed on an ongoing basis by senior staff. Implementation of any advancements or amendments to best practice is overseen by senior staff to ensure the laboratory team are working to the most recent guidance. Having received funding from NC3Rs in the past, we are on their mailing list and have access to their online resources such as webinars.

One of the many benefits of working within consortia is access to new models, techniques

and resources that have been developed by other members of the group. We are members of a national Working Group that promotes and facilitates the development and sharing of advances in the 3Rs for radiotherapy researchers.

65. Mapping mechanisms for energy homeostasis in rodents: communication between brain and peripheral tissues via the action of fuel sensing protein kinases

Project duration

2 years 0 months

Project purpose

- Basic research

Key words

Diabetes, Obesity, Hypothalamus, Energy, Homeostasis

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To investigate how fuel sensing in a region of the brain, the hypothalamus, influences energy homeostasis via action in peripheral tissues.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The regulation of energy intake and expenditure is of high importance in health and in disease states such as type 2 diabetes (T2D) and obesity. Control of energy intake (e.g. by the ingestion of food) and energy expenditure (e.g. mobilisation of stored fuel for the fight or flight response) are coordinated and regulated by the brain, in brain centres like the hypothalamus. Metabolic diseases like T2D and obesity, manifest when energy intake and expenditure are out of balance, leading to the symptoms seen in patients, which in turn leads to a decrease in the quality of life of the patients. While we have a good understanding that the hypothalamus is involved in the control of energy balance, it is not

currently clear how the hypothalamus detects the changing levels of fuel (i.e. nutrients) in the body over time in order to achieve this balance. It is well documented that some proteins act as fuel sensors and their function is to detect changing levels of fuel, leading to changes in cellular function to deal with low or high fuel situations.

The core focus of this project is to investigate the role of the novel cellular fuel sensor (PAS-domain containing protein kinase; PASK) in the detection of nutrient status to control energy use in the hypothalamus. Our preliminary data indicate that PASK may be a target for more effective anti-diabetic and anti-obesity drugs, so the studies in this project will allow us to map how PASK works in the hypothalamus and, in the longer term, to inform future drug development.

What outputs do you think you will see at the end of this project?

At the end of this project we will have answered to the key question that we posited in our Aim: whether or not PASK in the hypothalamus is important for nutrient detection in the hypothalamus.

We will disseminate this information to the scientific community and to the public. We will publish our findings in peer-reviewed journals and disseminate this information to the scientific community at national and international conferences. We will disseminate our findings to patient groups and other interested stakeholders via our outreach programme.

Who or what will benefit from these outputs, and how?

In the short term, colleagues and other researchers in the field will benefit from the data we will obtain concerning the function of PASK in the hypothalamus.

In the medium term, the data will be published, meaning that the wider research and clinical communities will have a greater understanding of the mechanisms of nutrient detection and energy control.

In the long term, beyond the lifetime of this PPL, the project outputs will lead to further funding applications to perform research on drugs that regulate PASK function, which may impact upon patients through the development of novel therapeutics for adaptive energy control in diabetes and obesity.

How will you look to maximise the outputs of this work?

This work will generate new knowledge which we will disseminate through publication of the data and presentation of our findings at national and international conferences. We will publish the data even if the data should be negative in peer-reviewed scientific journals and/or in preprint so as to prevent repetition of the work.

Species and numbers of animals expected to be used

- Mice: 260

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice because the project aim focuses on mapping function within a complex system of nutrient detection and energy control. Because of the necessary relevance to human health and disease, we need to study these mechanisms in mammalian systems. Our rationale is the following:

While lower organisms can model individual elements of the mammalian system, the focus on energy intake and expenditure at the whole body level can only be conducted in live mice. Mammalian systems are required , as although lower organisms such as zebrafish are emerging as potential models in which to study metabolic diseases, they do lack some of the important modulators of energy regulation of mammals- e.g. brown adipose tissue.

Mice have previously been used to elucidate the involvement of PASK in the control of feeding behaviour and whole body energy balance. These studies have allowed us to elucidate the involvement of PASK in the regulation of energy homeostasis in peripheral tissues (like in fat and in the pancreas), but not PASK's involvement in the control of food intake and other energy balance mechanisms which are controlled principally by the brain e.g. in neurons in a brain region called the hypothalamus. We wish to use the same species for the continuation of this work as the data already gathered can be used to inform future project direction.

Because of the need for experimental approaches to isolate the mechanistic targets of interest, we cannot use human studies. The use of live animals is necessary because there are no appropriate alternatives and the timescale of effects spans over many days.

We will use adult mice because energy expenditure and resources change during development, and our aim is to study adult physiology.

Typically, what will be done to an animal used in your project?

Typically mice will be acutely injected with viruses in the brain to allow manipulation of PASK gene expression in specific neurons in the brain, which we predict (based on our preliminary darta) will lead to energy imbalance. To assess the effects of altered PASK gene expression, we will measure food intake and energy expenditure using non-invasive procedures which will take such measurements in an automated manner, i.e. reduce stress from handling. The ability of the mice to deal with glucose balance will be assessed by a glucose tolerance test which involves fasting mice, then giving them a sugary solution and measuring how quickly the glucose is cleared from the blood (as we do on patients with diabetes).

What are the expected impacts and/or adverse effects for the animals during your project?

Injection of the viruses in the brain will involve surgery. Following surgery, mice will feel pain and discomfort where the skin has been sutured (typically for up to 3 days). This can be accompanied by some weight loss or failure to gain weight (which returns to normal within 7 days). Mice can occasionally display signs of minor discomfort during administration of substances into the brain (which can last for up to 2 min). These signs do not last beyond the duration of the injection. Mice can experience stress as a result of the fasting for the glucose tolerance test.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals anticipated to experience a moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The successful balance between energy intake and use requires the interplay between many parts of the body such as the pancreas, the liver, the skeletal muscle and adipose (fat) tissues. Signals from the brain in response to changes in hormonal signalling and nutrient availability also modify important factors such as blood glucose concentration and feeding behaviour. Such complex interrelations cannot be reproduced in vitro and require a whole living organism. We make efforts to replace the use of rodents for our studies as much as possible. We conduct a lot of our work in vitro using cell lines and cell cultures. Thus, we are able to validate fundamental mechanisms in vitro, before evaluating their relevance to physiologically-relevant energy intake and use processes in awake behaving animals.

Which non-animal alternatives did you consider for use in this project?

I considered using neuronal cell lines or hypothalamic slice cultures.

Why were they not suitable?

Neuronal cell lines or hypothalamic slice cultures do not allow us to monitor feeding behaviour, effects on weight, and control of blood glucose.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based the number of animals to use on published data from other laboratories and from the experience of the PPL holder in these types of experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3R's Experimental Design Assistant to help us to design the experiments to ensure that the experiment uses the minimum number of animals but that it is sufficiently powered to achieve our scientific aims. The design is also guided by published data from similar types of experiments. We have tested the efficacy of the viruses in vitro so that we have confidence in them functioning as designed when used in mice.

To monitor energy expenditure, we will place mice in specialised cages that will allow us to monitor various parameters non-invasively and continuously. This will replace requiring regular handling by/presence of an investigator to make these measurements at regular intervals. This will mean needing to use fewer animals than if we had to collect samples/tissues time point by time point in order to get this information indirectly.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The efficacy of the viruses have been validated in vitro so that we have confidence in them functioning as designed. Experiments will be planned so that they can be published in accordance with the ARRIVE 2.0 guidelines. At the end of the experiment, we will harvest the maximal possible number of tissues. Tissues not immediately analysed will be archived and will be made available to other researchers working on similar questions.

We will use Cre-strains such that the genetic manipulation will be targeted only to cells that express Cre-recombinase in the animal. This will limit the effects of the genetic manipulation only to the sites that we are interested in probing, minimising off-target effects, and also lowering the animal numbers needed (due to a decrease in experimental noise from off-target effects).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To monitor energy expenditure, we will place mice in specialised cages that will allow us to monitor various parameters non-invasively and continuously. This will replace requiring regular handling by/presence of an investigator to make these measurements at regular intervals, which will reduce stress from handling.

Why can’t you use animals that are less sentient?

Mice are the lowest mammalian species for which we have evidence for similarities to humans in terms of systemic energy balance, which is why we chose to use mice for our studies. The energy sensing mechanisms are only fully developed in adulthood as many of

the cell types that are involved in this process would mature after birth. This is developmentally sensible as the nutrient requirements/provision pre- and post-weaning are different. As the effects of obesity and T2D are mainly concerned with effects in mature animals, our studies require the use of adult mice. We cannot conduct our studies on terminally anaesthesised animals as we will be measuring feeding behaviour as an output, and this needs to be conducted on mice that are freely moving.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will adhere to best practice in post-operative care and peri-operative administration of analgesia as advised by the NVS. Frequency of weighing will increase in the 7 days after surgery in order to monitor weight loss and supplement the use of welfare scoring sheets.

Monitoring will also be increased after any substance administration, particularly when substances/doses are administered for the first time. When substances are delivered directly into the brain, animals will be monitored closely for the first 30 minutes, so that we are able to detect any immediate unexpected effects of intra-cranial infusion.

We will acclimatise mice to the new cage environment which will allow us to monitor physiology in a non-invasive manner (e.g. use of the Phenomaster) to limit stress.

After every experiment we critically appraise what we do to seek out any ways to improve our models to refine procedures and endpoints, and reduce harm to animals. We will use welfare scoring sheets to empirically assess whether any modifications are effective.

We will use Cre-strains such that the genetic manipulation will be targeted only to cells that express Cre-recombinase in the animal. This will limit the effects of the genetic manipulation only to the sites that we are interested in probing, minimising off-target effects, and also lowering the animal numbers needed (due to a decrease in experimental noise from off-target effects).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to LASA guidelines (3Rs section) to minimise harms, use the PREPARE guidelines in the planning of our experiments, and publish protocols and data as recommended by the ARRIVE 2.0 guidelines to ensure reproducibility of data.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are kept up to date on 3Rs via periodical emails from our animal unit and from the NC3Rs newsletter, and have incorporated these in to our protocol. We will also monitor advances in the scientific literature that might be adopted to refine our procedures further.

66. In vivo imaging to develop cancer therapeutics

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

cancer (solid tumours), therapeutics, molecular imaging, cell tracking, immunology

Animal types	Life stages
Mice	adult, pregnant, aged, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We will employ new methods to visualize how cancer develops and spreads over the course of time, and use this new insight to study ways to efficiently treat cancers with better therapies

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Advanced cancer is a global problem that affects millions of people every year. The numbers of people that die of cancer are predicted to increase over the next 20 years unless there are improvements in the early detection and treatment of cancer. Thus there is

an urgent need to improve our understanding of multiple aspects of cancer if we are to increase patient survival rates; these aspects include, for example, how cancers evade detection by the body's own defenses, how cancers continue to grow rapidly despite being treated, and how some cancers spread so swiftly throughout the body.

This research will inform us better about human cancer and how it progresses as well as how to treat it efficiently. It will employ relevant animal models of and provide insights necessary to develop new and improve existing new cancer treatments.

What outputs do you think you will see at the end of this project?

New validated cancer models that can be traced throughout the body by imaging. These include models for breast, liver, lung, ovarian and skin cancers.

An expanded platform for in vivo traceable cell and gene therapies that is compatible with clinical use in humans. This includes relevant preclinical datasets that form the basis for their possible translation into the human setting.

Quantitative imaging data describing cancer progression and spread within the body in different cancer settings.

Quantitative imaging data validating therapies and therapy combinations intended to interfere with cancer progression and spread.

Who or what will benefit from these outputs, and how?

This project will enable us to better understand and quantify cancer development, progression and spread throughout the body by applying advanced imaging techniques. Through application of improved molecular imaging methodologies we will be able to better develop, monitor and validate next-generation cancer treatments.

We will use quantitative measures for cancer formation, growth and spread in non-invasive ways and thereby gain a better understanding of these processes. Our focus on repeat-imaging methodology will permit us to do this with less animals as compared to conventional approaches and also gives us access to statistically more sound data. The improved understanding of cancer that we obtain in this manner will be exploited to develop new and improve existing anti-cancer therapies and, importantly, validate them in a variety of relevant tumour models. Our research contributes to more reliable, more reproducible and also faster development of anti-cancer therapies.

Ultimately, the beneficiaries will be cancer patients who will be presented with better therapeutics and with better ways to monitor these therapies, and the health systems who can draw from better tailored therapeis and avoid debilitating and expensive treatments in patients who will not benefit.

How will you look to maximise the outputs of this work?

We will ensure the experimental design of every experiment is appropriate to answer the research questions we ask, using only relevant disease models, as well as the most refined available methods. We will further ensure that any materials intended for input into animal experiments are properly validated. Moreover, we will ensure that only appropriately trained personnel is involved in experimentation at every level (in vivo but

also ex vivo when using animal tissues). All this is aimed at minimizing failure of animal experimentation and waste of valuable animal-derived tissues.

As for newly developed models and imaging platforms, we will disseminate information as soon as reasonable to enable swift adoption among the local, regional and international research communities. Generally, we will aim to publish all research outcomes in line with the funders' and institution's policies relating to research exploitation and dissemination.

Species and numbers of animals expected to be used

- Mice: 5260

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The choice of the species is crucial to modelling human-derived tumours appropriately. The model species must support the growth of these tumours, must provide distinct levels of biological self-defense (‘immune system’), and be of a size that is compatible with the technical specifications of the imaging techniques (e.g. resolution) required to visualize the cancers in this species. At the same time it is best to use the species with the smallest self-awareness that meets these criteria, which in this case is the mouse.

We will use young adult and adult animals for experiments and will keep them only as long as experimentally necessary. Aged animals will be avoided whenever feasible as they could spontaneously form additional tumours, which may happen in some strains.

Typically, what will be done to an animal used in your project?

Animals will be induced to grow a tumour (either by giving tumour cells to animals or by manipulating animals to form tumours). These tumours will grow and progress to later disease stages either in the absence or the presence of therapeutic interventions while we will use imaging to visualize tumour and/or therapies in these animals. Animals will receive only one type of tumour. Some animals may serve as special control cohorts and may be subjected to the same procedures while not bearing a tumour.

Once experimental goals or predetermined humane endpoints are reached the animals will be humanely killed and tissues used for analysis and production of experimental data to answer scientific questions posed in this project.

An exception are animals maintained for breeding purposes who will not be induced with tumours throughout their lives. Some specially bred animals may be transferred to different licenses, hence not be culled under this authority.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will develop cancer as a consequence of administering cancer cells to them or inducing cells to become cancer cells. The majority of routes by which we give the

animals cancer will cause only mild discomfort. Some methods require surgery while animals are unconscious (due to general anaesthesia). Tumour cell induction may require the administration of specific agents and we will use previously reported and safe doses of these agents.

The development of tumours and their progression as required in this project will be the cause of moderate adverse affects including cancer spread. We will carefully and frequently monitor tumour growth in each individual animal including clinical markers such as, for example, appearance, indications of pain, weight and food intake.

Imaging requires the animals to be still and often also requires contrast agent administration. We have previously optimized anaesthesia and will use safe ranges of contrast agents. Consequently, no adverse events are expected to be caused by imaging.

For therapy we will use previously determined safe amounts whenever possible.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity any animal will reach in any of the protocols is MODERATE. Most procedures are MILD but animals may experience MODERATE severity as a consequence of tumour formation. We estimate 75% of the tumour-bearing animals to experience MODERATE severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We require the use of animals because

Regulatory agencies require animal data to demonstrate safety and efficacy before therapeutics or companion imaging approaches can enter human trials. Most of the agents to be studied have not been used in man before and require animal data before approval for human studies. In many cases, even if the mechanisms are well established, it is unethical to use the tools (inhibitors, cancer cells etc) required to validate the corresponding targeting mechanisms and to understand the biological mechanisms in humans. Consequently, multiorgan species as closely related as justifiable to humans are required.
Certain aspects of tumour biology and cancer progression/metastasis can only be studied in live animals (e.g. interaction of cancer cells with other body cells, spreading of cancer cells to other body locations, consequences of disturbed blood supply, tumour re-growth

after treatment etc.) because there are complex interactions between different body systems, which cannot be replicated in anything other than an intact animal.

Which non-animal alternatives did you consider for use in this project?

Prior to all in vivo work, human and animal cell-based methods as well as tissue-based methods (from already existing tissues) will be used as relative replacements to answer as many research questions as possible and build solid hypotheses to be subsequently tested in vivo. For example, this includes in vitro experiments in cells that are designed to determine target-binding efficiency, agent toxicity, agent stability; or experiments to form solid theories about the mechanisms of cancer spread, the ways the cancer uses to render treatments ineffective, and how the cancer overcomes the body's own defenses. Any new/improved candidate agents, which is found in this manner to be unlikely to succeed in animal or later human trials will be eliminated at this stage.

In very few exceptions it might possible to envisage replacement using humans, namely if an already approved therapeutic or imaging agent is repurposed for application in a different condition or application.

Why were they not suitable?

In vitro experimentation is suitable to reduce the candidate agent field to the most promising ones, and this is what we will employ as a general principle. It is not suitable, however, to model the complex interactions that take place in living multi-organ species. This includes aspects such as pharmacokinetics/dynamics and in vivo tumour progression/spread/heterogeneity as well as the various selection pressures that impact on these disease aspects. As these cannot be studied for the first time in humans for ethical reasons, animal research is necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A total of max 3100 tumour models and 250 naive animals will be needed to complete the work programme. These animals will be recruited from commercial breeders (or existing on-site breeding under license from commercial breeders; ~75%) as well as from our own colonies (~25%).

For the planned research, we estimate that we will need 2750 animals across different strains to supply us with the necessary not commercially available mice (see above), whereby the total number already takes into account different needed strains and the need to focus on one gender in some studies (i.e. breast cancer models require female animals only for tumour models). We expect ~30% of them to be used for cancer models.

This means ~2510 animals to be sourced commercially plus 2750 home-bred animals (to provide the 840 needed ones for tumour models), totalling 5260 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Imaging to determine tracer distribution rather than conventional ex vivo organ counting is a major contributor to reduction. It allows repeated time-dependant measurements on the same animal as animals are only killed at the last time-point; for example, if a study involves six time-points, the animal numbers are reduced to one sixth. Since each animal serves as its own control, the data are statistically also more robust, which in turn leads to further reduction as smaller cohort sizes are required (because inter-animal variability no longer needs to be taken into account at the experimental design stage).

Moreover, not only contrast agent distribution in vivo, but potential time-dependent and unexpected redistribution can be detected through serial imaging. The same accounts for therapeutics agents that can be tracers, either through chemical modification with an imaging agent, or, in the case of live cell therapies, through tracking these cells by imaging. The detection of cancer spread can through imaging be assessed in a more holistic way, and the reliance on studying pre-set organ sets or sacrificing animals prior to the development of metastases can be dramatically reduced.

All these attributes contribute to a greatly improved benefit:cost ratio (benefit=data quality/quantity, cost=animal numbers/procedures).

Pilot experiments will be performed where necessary on small cohorts, to provide statistical data allowing animal number estimations for definitive larger experiments. Where possible, multimodal imaging will be used to multiplex and study two or more agents/mechanisms simultaneously in the same animal. Multimodal cross-validation will yield superior data because each animal will be the control for itself – data will be intrinsically paired. Sometimes, it will be possible to study >1 tumour per animal, with the same advantages.

A typical study might be planned as follows: For testing of a new molecular therapeutic targeting metastatic spread in mice (Goal 1) including repeat imaging at 4 different time points, we estimate animal numbers using a power calculation (two-tailed t-test, $\alpha=0.05$, power=0.9, typical measurements of 7.8±3.5(signal) and of 2±1(noise) yielding $\delta=5.5$ with $\sigma=3.4$) yielding N=9 animals/group. To account for tumour growth variation and complications with anaesthesia, specific diets, interventions or treatments, we would oversubscribe each cohort by one animal, i.e. plan to investigate 10 animals/group and 20 in total. This approach ensures that accidental unexpected events do not result in the termination/failure of the experiment due to not reaching statistical significance because of sudden insufficient cohort members, and avoids a consequential repeat of the experiment. For the cost of 2 animals it is ensured that unexpected events to not cause the loss of otherwise 18 animals.

[For reference: the comparative study without repeat-imaging would need at least 80 as at every time point one cohort of each control and experimental animals would need culling to assess the effect. Larger cohorts sizes would also be likely as the standard deviations might be larger due to overcoming inter-animal variability when comparing different time points].

If target-to-background (signal-to-noise), or difference between experimental and control groups, is expected to be large (>1 order of magnitude change, e.g. in the case of comparing distant tumour burden in a spontaneously metastasizing tumour model that is

treated with an effective anti-metastatic agent), or found to be so by pilot experiments, statistical significance may be achieved with fewer animals/group. However, we will not use less than 3 animals per group to comply with generally accepted scientific reproducibility criteria in the field.

In summary, imaging in the context of this project, significantly reduces animal use while at the same time providing better and additional data compared to previous methodologies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The experimenters will be advised by the licence holder, deputies, and other members of the preclinical imaging community (which comprises biologists, chemists and technical staff) to ensure that the experiments are scientifically valid and eliminate those that are not.

The experimenters will be thoroughly trained in all necessary procedures to keep 'user-introduced' variability to a minimum. Certain measurements will be preferably taken by the same researcher to ensure consistency; one such example are calliper-measured growth curves of superficial tumours (which tend to be prone to user-to-user variability of using the callipers).

We will operate a regimen of open communication of our research within the our Department/School/Faculty to ensure any possible synergies between the studies of different researchers can be capitalized on (e.g. through "combined controls" and/or re-use of harvested tissues for different scientific purposes).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal models: We will use cancer models established in mice through either (i) injection of cancer cells, (ii) implantation of tumour pieces, or use of transgenic animals that can either be (iii) induced to form tumours ('user-controlled') or, (iv) in limited cases, spontaneously form superficial tumours. We will use non-metastatic and metastatic (inter- and intra-organ) models and models suitable to study tumour heterogeneity, tumour evolution, and treatment resistance. Only the models and progression stage that are key to a required outcome of each project goal will be used.

Methods: The use of tumour and metastasis models is necessary to preclinically validate new or improved cancer-specific therapeutic agents and investigate tumour progression/spread. New and improved agents will be validated in this project and hence, must be used in conjunction with the tumour models. Differing tumour models such as non-metastatic and metastatic ones are necessary to study tumour progression and

metastasis and tumour heterogeneity and evolution; in this context repeated imaging with specific molecular imaging contrast agents is a very powerful method to quantify cancer spread and molecular changes in cancerous tissues over time. Various animal preparation approaches to define and control the tumour microenvironment are essential for these studies; this includes modification of the immune system (either by using genetically altered strains or by sublethal whole-body irradiation or by immunomodulatory agents). Specific insight into molecular processes can be obtained either via genetic approaches (requiring switch on/off of certain genes in genetically altered animals) or via pharmacologic modulation approaches (e.g. inhibitor molecules). Surgical resection of primary superficial tumours is in some cases necessary (some metastatic models) to reach the experimental objective, because too fast primary tumour growth can lead to reaching endpoints before metastasis reaching levels required for obtaining the experimental goals and/or statistically sound data.

To discover what causes treatment resistance in cancer, the use of tumour models together with therapeutic approaches is required, whereby repeated imaging serves as a very powerful method to inform on time-dependent changes in the very same animal. Therapeutics include chemo-, targeted-, and immuno-therapeutics as well as radiotherapy.

Common to all currently available imaging methodology is the requirement of the animals remaining motionless during imaging, which renders general anaesthesia essential. General anaesthesia is also necessary for surgical procedures (e.g. orthotopic tumour implantation in the liver or lung lobe, or intracardiac administration of cancer cells for some metastasis models).

Why can’t you use animals that are less sentient?

Mice are the species of least neurophysiological sensitivity that provide the capability to support the growth of human-derived tumours (xenografts) and present with an immune system sufficiently similar to humans (for syngeneic murine cancer models). Mice also present with the minimum size compatible with the scale of resolution/movement associated with the imaging techniques we plan to use (resolution of the whole-body imaging techniques is of the order of 0.5-1mm).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be humanely killed and their tissues used for downstream analyses once the experimental goals or predetermined humane endpoints are reached. If the experimental goals can be reached earlier through a procedural refinement, e.g. through the use of imaging or through the use of an improved drug formulation, then we will implement this as a refinement.
For example, we have very recently developed an in vivo cancer cell tracking method that reports the tumour mass of living tumour cells in 3D at depth; this enabled us to quantify the primary tumour volumes occupied by living cancer cells much more accurately compared to superficial calliper measurements or luciferase measurements, and it enabled us to quantify tumour burden at distant metastatic sites such as lymph nodes and the lungs. This increase in accuracy permitted earlier termination of experiments as significant differences in distant metastasis and on the primary tumours were detected earlier by this non-invasive imaging technique. This meant that none of the animals in the study reached a humane endpoint and all were sacrificed well before the manifestation of clinical signs in this study.

To minimise any transient pain from injection, we will use inhalation anaesthesia whenever feasible. Furthermore, we will use pain relief after surgical procedures, which are necessary for the establishment of some tumour models.

To minimize distress from handling and/or stemming from procedures normally performed while animals are awake, we will combine these steps with procedures that require anaesthesia; for example, while an animal is under anaesthesia after i.v. administration of a molecular probe and awaiting transfer onto the respective imaging device, we will also perform blood sampling, weighing and superficial tumour measurements if applicable.

We will continue to develop and apply such approaches to reduce severity, transient pain and distress of the animals as well as implement approaches developed elsewhere for this purpose if feasible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the principles laid out by the UKCCCR guidelines and by Workman et al (Brit J Cancer 2010) as well as by LASA, for example, when performing surgical procedures (Guiding Principles for Preparing for and Undertaking Aseptic Surgery) and original literature such as for pain assessment in laboratory animals (Langford et al Nat Meth 2010).

Accurate reporting of experiments is an integral part of reliable and reproducible research, hence we follow the ARRIVE framework (now ARRIVE 2.0: Percy du Sert PLoS Biology 2020).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All team members holding PILs also subscribe to the NC3R newsletter (https://nc3rs.org.uk/subscribe- our-newsletter) and will attend NC3R online education/webinars or in-person workshops if relevant to this project. The team is in regular exchange with named persons and animal unit staff, which is another way of being informed about 3R news. When available and if relevant, local 3R symposia will be attended by the team. Relevant scientific literature published in journals such as LabAnimal (Nature Publishing Group) and JoVE are regularly searched by the team for new methodologies, which are then assessed on whether they offer improvements in light of the 3Rs that can realistically be implemented locally.

67. Skin immune responses in inflammation, infection, and cancer.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Skin-inflammation, Innate-immunity, cancer-immunology, Cutaneous-lymphocytes

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand, at the molecular and cellular level, the role of human skin immune responses in mechanisms of disease, potential treatments, and vaccination. As well as contributing to an understanding of disease pathogenesis, we aim to translate our findings to changes in clinical practice.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Skin frequently represents the first point of contact with bacteria and allergens, yet we still know relatively little of the role of the skin barrier and skin immune system in reacting to such challenges. This is crucially important in understanding the mechanisms of skin

diseases and related diseases, and for optimising approaches to drug and vaccine delivery to this important tissue.

Skin is also one of the main organs that is directly exposed to carcinogenic materials and UV irradiation. Understanding the effect of such onslaught on the skin immunology, and the consequence to development of cancer and skin inflammation can set a rational for developing treatments.

What outputs do you think you will see at the end of this project?

Outputs will include publications describing mechanisms of skin inflammation, pathways of antigen recognition in the skin and draining lymph nodes, and intervention regimen for pathological skin inflammation conditions. Outputs will also include patent applications and candidate compounds with therapeutic application in skin inflammation diseases, as well as treatment of subsets of cancers that are either located in the skin or bare similarities to some of the cells that normally reside in the skin.

Who or what will benefit from these outputs, and how?

Novel findings, delineating pathways in skin inflammation and novel reagents used for modulating these pathways will be published within the 5 year duration of this licence. Patent applications and assessment of products that will be developed for preclinical testing and clinical use may extend beyond the time frame of this licence (beyond 5 years). Novel mouse experimental setups may also benefit research in other barrier tissues such as gut and lung. Such traversing applications will be explored within the time frame of the project (5 years).

Where widely applicable new treatments with public interest will be developed, a wider publication audience will be sought through our funders and local communications advisors.

How will you look to maximise the outputs of this work?

Dissemination of new findings will be initially done in lectures, conferences and subsequently in scientific publication. We will use such occasions to draw on expertise from colleagues and set up collaborations in order to take advantage of the most advance technology that we can access.

Where possible unsuccessful approaches will be embedded in publication and discussed in meetings.

Species and numbers of animals expected to be used

- Mice: 18,500

Predicted harms
Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of mice, rather than any other organisms, is based on the balance between similarity with the human immune system versus the availability of transgenic models, the

ability to work with sufficient number of animals to achieve statistical significance, and the large body of published scientific evidence that exists and can be built upon and referenced to.
The diseases that are modelled in mice often differ in some aspects from the equivalent diseases in human (e.g., tumours tend to grow faster in mice. The models of atopic dermatitis is more acute than chronic, as it is in humans). Nevertheless, when examining aspects of the diseases such as response of specific cell types to treatment, there is sufficient similarities to make conclusions that are transferable to human biology and disease.

Typically, what will be done to an animal used in your project?

Two types of models will be used in this licence.

The first involves creating inflammation in the skin that mimics such conditions as Psoriasis, Allergic dermatitis, and Atopic dermatitis. These will be generated by topical application of irritants or allergens or by injection of such compound (and organisms such as bacteria) into the skin (typically the back of the ear or the back of the animal). The symptoms that will develop are inflamed skin, redness, thickening of the skin, flaking skin. Treatments involving novel manipulation of the immune system will then be tested for their ability to ameliorate the symptoms of these diseases. The treatments will be delivered either locally by injection/topical administration, or systemically by injection into the blood, or the peritoneal cavity. Such experiment will typically last two to three weeks and may involve a single injection to induce the disease (or eight daily application of cream to induce the disease) followed by repeated injection (typically two to three times per week) of the treatment. Initial experiments will mainly be conducted on mice with the C57BL/6 genetic background since the progression of the disease in this strain has been consistently shown to mimic several aspects of the human disease. The use of this strain also permits us to make use of extensive range of transgenic and knockout mice that exist on the same background, in order to investigate the effect of specific genes and cell populations that are involved in the development of the skin inflammation symptoms.

The second involves implantation of tumours by injection of tumour cells either in the skin or in the blood. This will be accompanied by treatments that are designed to manipulate the immune system to interact with the tumour and restrict its growth. These experiments will typically extend to three to four weeks while the tumour develops and in cases where growth of the tumour is inhibited by the treatment, experiment will extend further in order to monitor the delay in tumour growth. Treatments may include repeated injection of compounds (typically two to three times per weeks over a period of two to three weeks).

What are the expected impacts and/or adverse effects for the animals during your project?

The main impact on animals will be the local symptoms of the inflammation. These include redness of the skin, thickening of the skin and flaking skin. Small areas may also develop scarification and in some cases first signs of necrosis (this latter will be a humane end point).

In the case of experiment with implanted tumours, the increase in tumour size may reach $1.2cm^3$, however due to the flexible nature of the skin in mice and the location of the implanted tumours on the side and back of the mice, this does not impede their movement or behaviours and does not impact on internal organs. For intradermal implantation where

there is a greater risk of ulceration, the maximum tumour volume is reduced to 0.8cm3 (volume is calculated by measuring three diameters and using the formula: H x D x W x 3.14/6)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

11% Subthreshold

40% Mild

49% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Using a mouse model of skin inflammation allows analysis that complex interaction between different organs in the animal, including migration of subsets of immune cells from the blood stream, lymphatic system and even bone marrow. Mimicking the symptoms of psoriasis and dermatitis disease involves restructuring of the tissue and formation of features such as flaking skin and eczematous lesions. This process involves several cell types and requires the *in-vivo* tissue architecture in order to develop .

Development of tumours in mice is also a multifactorial process which involves not only the growth of the cancer cells themselves but also a creation of microenvironment around the tumour in response to the tumour growth and molecules that it secretes. The presence of tumour in one location also affects the entire animal body in ways that are impossible to recreate *in-vitro*. Since we are interested in the interaction of immune cells with the tumour, the *in-vivo* setting and interaction with distal parts of the animal are vital in the understanding and development of treatment that can be translated into human therapies.

Which non-animal alternatives did you consider for use in this project?

We are using several *in-vitro* experimental methods to analyse skin tissue from healthy individuals as well as patients with psoriasis, atopic dermatitis and contact dermatitis.

We use imaging analysis linked with single cells analysis of gene and protein expression of those human tissue sample and use this analysis to predict gene and proteins that play a causative role in the development and susceptibility of the skin conditions.

We isolate T cells from peripheral blood in order to identify cells that can interact with skin cells under inflamed condition. These cells are cloned and used for in-vitro analysis of their pro-inflammatory, or anti-inflammatory properties.

We experiment with the use of skin obtained from healthy individuals (from discarded tissue from plastic surgery) to recreate in vitro tissue that can retain function for a limited period.

We use skin tissue derived from patients and healthy donors to isolate several types of skin cells that are involved in development of skin inflammation (e.g., Langerhans cells). We can maintain these cells in a functional state for a limited period during which we can co culture them in vitro with T cells to assess the nature of this intracellular interaction.

We use a model of ex vivo suction blister analysis in which volunteers' skin is blistered and allergens are injected in the blister location. Cellular and fluid infiltrates are then recovered for analysis of the response to those allergens.

Why were they not suitable?

These in vitro and ex-vivo techniques are very useful in generating hypothesis about the causes of skin disease and can form the theoretical basis for developing treatments, but they do not allow multi tissue interaction analysis, and development and testing of therapeutic treatments with multi-factorial analysis of symptoms of the disease.

Other limitations include the frequency and amount of tissue that can be recovered from patients, the limitation of tissue recovery at early stages of the disease, before the symptoms develop, and the limitation on the novel experimental treatment that can be tested.

Reconstructed cellular in-vitro systems also suffer from the bias that we introduce by choosing the cell types that we co-culture.

With respect to cancer model analysis, the current in vitro methods for reconstructing tumours do not fully capture the 3D nature of cancer tissue with all the associated structural and functional microenvironment or the gradual infiltration of different cell populations and blood components.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in this project is based on the estimated requirements for experiments in each model as well as the number required to breed and maintain a productive colony.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Web application, Experimental design Assistant (https://eda.nc3rs.org.uk/eda/landing), has been used to rationalize optimal numbers of animals for future experiments.

Shared control groups are used in combined experiments where more than a single question is addressed to reduce the need for repeated control groups. (the simplest example being when using three different blocking antibodies in identical experimental setting, there is only a need for a single Isotype control group).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Best practice is followed for colony management to ensure we do not breed animals that are surplus to our experimental needs. The Establishment has a dedicated colony manager who can advise. There is also a mouse database from which we can source data for our strains that assist in colony management

Pilot studies that determine the parameters for group size calculations will be used to optimise the number of animals used in the experiments. Collection of multiple tissues at the end of experiments (occasionally storing them for later analysis) will reduce the need to repeat experiments for the purpose of assessing different aspects of the experimental conditions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For the analysis of inflammatory skin conditions we will be using several models which differ in the stimulus that triggers the skin disease. These includes a cream containing an inflammatory compound or allergen, or intradermal injection of a bacteria that causes skin disease. In all cases these substances will be localised rather than systemic in order to reduce the overall suffering. Most experiments will be restricted to two to three weeks in order to limit the duration of skin inflammation.

For the analysis of T-cells from Psoriasis patients and dermatitis patients, we will use immunocompromised mice, that do not reject injected human cells. These mice will also be injected with human cell lines, or human tumours or express human proteins, in order to examine the function of the human T-cells with the human cells and proteins. In this model the reaction of the T cells will be assessed by measuring tumour size, or sampling the blood. Typically these experiments will last no more than three to four weeks. The tumours will be implanted subcutaneously at the side of the mouse (near the back) and will not cause the mice any pain or distress due to their location and the fact that they will not

impose on any internal organs. The skin of mice can be quite loose and tumours growth of up to 1.2cm^3 do not cause any pain or distress to the animals. Implanted tumour models will be used in immunocompetent mice in order to test therapeutic compounds. These are well established models which have been shown to cause little to no pain or distress to the animals.

In a few experiments mice will undergo bone marrow transplant which involves irradiation that kills the cells in the mouse's bone marrow, to be replaced by new bone marrow that is injected shortly after the irradiation. This treatment causes some illness but it is short term (about a week) and the mice recover with no lasting harm. This type of experiments is an important tool for assessing the role of the blood cells, and specific proteins expressed in the blood cells, in the progression of the disease.

Why can’t you use animals that are less sentient?

The use of mice rather than other animals, further down the evolutionary development tree, is based on the balance between similarity of the immune system to that of humans, and the availability of transgenic models and the ability to work with sufficient number of animals to obtain statistically significant results.

In particular when working on skin immunology, animals such that are less developed evolutionarily e.g. common models such as zebra fish and drosophila flies, are not suitably close to human skin biology.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experimental protocols are formulated to minimise stress or harm to the animals and are based on the observations in pilot experiments, repeated past experiments and published observations.

We continually refine our methods, including changing humane end points, assessing and adding new monitoring techniques (e.g., equipment for measuring tumour size, or ear inflammations), and reducing number of procedures to the minimum necessary for the desired effect (e.g., reducing the number of injection of compound once a sufficient effect has been observed).

We regularly inspect animals to determine their welfare (e.g., take weight measurements and observe changes in their social behaviour and appearance).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The design of experimental procedure will follow best practices guidance described by ARRIVE guidelines (https://arriveguidelines.org/arrive-guidelines/inclusion-and-exclusion-criteria), and PREPARE guidelines (https://norecopa.no/prepare)as well published guidelines on tumour models (Workman P et al 2010 British Journal of Cancer (2010) 102, 1555 – 1577.) and skin inflammation models(Lowa et al 2018 Exp. Dermatol.27: 478-483), as well as general practice guidance (e.g https://www.rspca.org.uk/webContent/staticImages/Downloads/WelfareAssessmentProtocolsFull.pdf).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review the literature relating to animal models and improved more refined models that relate to our work. We also discuss ways of improving our models with other groups and with the Named Veterinary Surgeon. We also access specific literature on animal welfare through the nc3Rs web site and regular links sent by the 3Rs Information Officer.

68. Novel Biologicals for Tumour Immunotherapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

immunotherapy, cancer, biologics, antibodies, adjuvants

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to investigate novel biologic medicines suitable for immunotherapeutic treatment of cancer patients with the goal to develop safer and more potent strategies based on the use of immunotherapeutic antibodies, nanobodies and adjuvants.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Immunotherapy of cancer has shown to have great potential in the treatment of cancer patients. However, many of the current immunotherapeutic medicines in routine clinical use for treatment of cancer show a high incidence of adverse events. By modifying existing therapeutic approaches, the safety profile and the potency of immunotherapeutic medicines can be improved. Cancer patients will greatly benefit from more efficient biologic medicines with improved safety profiles.
What outputs do you think you will see at the end of this project?

At the end of the project we will have a better understanding of

how to efficiently deliver biologics such as adjuvants to the tumour tissue using antibody conjugates

what biologics are most effective in promoting anti-tumour immunity when delivered to the tumour tissue

what treatment schedules for specific biologics are most efficient in promoting anti-tumour immunity

Who or what will benefit from these outputs, and how?

In the short term, the project will allow us to develop specific antibody-adjuvant conjugates for targeted delivery to the tumour tissue with optimised potency and safety profiles.

In the long term, the tumour immunotherapy field will benefit from these outputs by recognising that existing therapeutic antibodies that target tumours can become even more effective in cancer treatment by combining them with the immunostimulatory properties of adjuvants in form of antibody-adjuvant conjugates. The project may also identify novel biologic products other than antibody-adjuvant conjugates with great potential in tumour immunotherapy. Again, the tumour immunotherapy field will benefit from these discoveries.

How will you look to maximise the outputs of this work?

The outputs will be published in peer reviewed journals and the work will be presented in international conferences including the communication of unsuccessful approaches. New collaborations will be sought based on the findings in order to work on the translational aspects of the treatment approach.

Species and numbers of animals expected to be used

- Mice: 1600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the ideal model organism for this project because of the availability of a large array of tools to investigate immune responses and tumour growth in these animals. There is a huge arsenal of genetically altered mice, anti-mouse antibodies and mouse-specific accessory kits for the investigation of mouse immune responses available to study the mechanistic details of anti-tumour immunity in a variety of mouse tumour models. The induction and the effector arm of anti-tumour immune responses cannot be explored fully in vitro due to the spatial location of different parts of the immune system and the high number of different immune cells and different immune effector molecules that form these responses in specific spatiotemporal patterns.

Juvenile mice (5-8 weeks of age) are used since engraftment of mice tends to be more efficient in younger mice. However, adult mice can be used and will be used depending on the experimental design and availability of specific mice such as gene modified mice.

Typically, what will be done to an animal used in your project?

The mice will undergo immunotherapeutic interventions. Immunotherapeutically treated mice may be injected with tumour cells or may have developed tumours prior to the therapeutic intervention or tumours may be injected or develop after the intervention. In some experiments, mice may not be injected with tumour cells or develop tumours and in other experiments, mice may be injected with tumours without being treated.

For investigation of cellular mechanisms underlying the observed immune responses, mice may receive adoptively transferred cells or may be depleted of specific cell types. Adoptive transfer of cells may require irradiation of the mice in order to create a niche for the adoptively transferred cells.

For monitoring of immune responses and tumour growth, mice may undergo whole body imaging and blood sampling throughout the experiment. In addition, mice may undergo immune testing in vivo to quantify the scale of specific effector functions induced by the therapeutic intervention.

At the end of an experiment mice will be culled by a schedule 1 killing method or mice may undergo terminal anaesthesia in combination with perfusion or exsanguination.

A typical immunotherapeutic intervention experiment (protocol 1) without optional procedures will last 7 days. The duration of tumour intervention experiments (protocols 2-4) depend on the tumour model that is used and can last from 18 days (e.g. B16 pseudo-metastasis model) to 28 days (e.g. humanized mouse model with HER2-expressing tumour cells) or can last several months (e.g. genetic tumour models).

Similarly, the number of procedures can vary from 1 (e.g. most simple immunotherapeutic intervention experiment or protocol 4 without whole-body imaging) to 20 in typical experiments involving several steps (e.g. humanised mouse tumour model with immunotherapeutic intervention and blood sampling and whole-body imaging). However, the number of procedures may exceed 20 for specific experiments.

Different strains of genetically altered mice may be used under this licence depending on the scientific question that will be addressed. In general, we may use

animals with a genetic modification that leads to the development of tumours in the mice

animals with defects in the immune systems e.g. lack of pattern recognition receptors, lack of specific immune cell types, lack of specific cytokines or cytokine receptors

animals which are transgenic for specific antigens or which express specific reporter molecules that can be used for investigating immune responses
animals which are transgenic for specific human markers / receptors that can be targeted with immunotherapeutic molecules.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible unwanted effects of experiments involving the growth of tumours in mice include weight loss, weight gain, tumours impeding locomotion and tumour ulceration. Furthermore, mice with tumours may show signs of general ill health such as inappetence, piloerection and hunched posture, inactivity or diarrhoea. However, the likelihood of any of these adverse effects to occur is very low since animals will be culled when tumours reach a specific size and before tumour burden affects the general well-being of the mice. Any adverse effects of tumour growth are very unlikely to be transient and are expected to become more severe over time when the tumour growth further.

In some cases, adoptive transfer of xenografts such as human peripheral blood mononuclear cells (PBMC) can lead to graft-versus-host disease in mice. The likelihood of mice developing graft-versus- host disease is low since animals will be culled at specific time points before graft-versus-host disease is known to develop. However, should graft-versus-host disease manifest in mice, the adverse effects are not transient and will become more severe over time if mice are not killed.

Immunodeficient mouse strains may be used which are more susceptible to infections. However, immunodeficient mice are kept in a bio-exclusive environment such as individually ventilated caging or isolators and rarely experience infections. Should infection occur immunodeficient mice are unlikely to clear the infection irrespective ofthe pathogen.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of animals (80%), the level of severity will not exceed mild levels due to the timepoints at which the experiments will be concluded (humane endpoints). From experience, approximately 20% of animals under this licence will reach moderate severity levels with the rest of animals experiencing mild severity levels.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The interplay between tumours and the immune system and the mechanisms of immunotherapeutic intervention strategies can only be investigated fully in vivo since anti-tumour immune responses involve a high number of different immune cell types and tissue cells and follow specific spatiotemporal patterns which cannot be fully reconstructed in vitro.

Which non-animal alternatives did you consider for use in this project?

Some limited aspects of immune activation can be investigated in vitro such as for

example the activation of innate immune cells by adjuvants. Whenever possible, we will examine specific aspects of the therapeutics in vitro by performing in vitro activation and in vitro binding assays prior to the in vivo experiments.

There are no other suitable non-animal alternatives for use in this project since investigation of the functionality, potency and safety of biologics for tumour immunotherapy requires to understand the interplay of the immune system and the tumour tissues including intact tissue architecture such as lymphatic vessels, lymph nodes and blood vessels.

Why were they not suitable?

The induction of antigen-specific anti-tumour immunity requires the priming of T cells and B cells in lymph nodes and the induction of anti-tumour immunity requires the migration of effector cells to the tumour tissue where the immunosuppressive tumour microenvironment may negatively affect the functionality of the effector cells. The specific connection between tissue or tumour tissue and secondary lymphoid tissue such as lymph nodes cannot be reconstituted in in vitro assays.

Also, the pharmacokinetics and pharmacodynamics of immunotherapeutic drugs such as antibody- adjuvant conjugates cannot be investigated in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use 30 animals per experiment since this is the maximum number that can be processed experimentally within the laboratory for logistic reasons. We further estimate to perform one experiment per month on average bringing the estimated number of mice to 360 per year and to 1600 mice over the lifetime of the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We sought internal advice from our statistician colleagues to calculate the required group size based on estimated variabilities within groups in combination with estimated differences between groups. The used estimates stem from experience with similar experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We perform pilot experiments whenever necessary as for example when working with a new tumour cell line or a new immunotherapeutic biologic medicine. The pilot experiments are designed to allow us to refine specific aspects of the procedure (e.g. dose of injected tumour cells, dose and treatment regimen of the immunotherapeutic drug, end point of experiment) in order to optimise the experiments. From these pilot experiment we can

calculate how many mice will be required to produce statistically significant results. This largely depends on the variability in the response within treatment groups and the differences observed between treatment groups.

We also work with whole body imaging of bioluminescent tumour cell lines whenever possible in order to maximise the data obtained from the tumour models. However, it depends on the tumour cell line / tumour model whether or not whole-body imaging allows us to make the group sizes smaller.

We analyse different read-outs from the same experiment such as serum levels of cytokines and/or antibody titres, tumour growth profiles, induction of antigen-specific T cells, cytotoxic effector functions and immune cell profiling of blood, splenocytes and tumour tissue. Thereby, we gain in-depth insight for various aspects of the immune response from the same experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using exclusively mouse models during this project. Regarding the tumour models, the project includes syngeneic mouse tumour models and also xenograft tumour models with human tumour cells. In some experiments, we may also adoptively transfer human immune cells. The project may also include the use of genetically altered mouse strains such as for example NSG mice which allow for effective engraftment with human xenograft tumour cells and human immune cells. In addition, other genetically modified mouse strains may be used such as specific knock-out or reporter mice in order to study specific mechanistic aspects.

The mice will be injected with cells and/or immunotherapeutic drugs and may undergo blood sampling, irradiation, immune cell depletion and/or whole-body imaging in specific experiments.

Mice may be irradiated before adoptive transfer of cells to create a niche for the transferred cells and enable efficient engraftment. From experience, we know that sublethal doses of irradiation are sufficient for most of our experiments (e.g. 3.5Gy). At this dose, mice do not show any adverse effects of irradiation. However, the dose of irradiation required for successful engraftment varies between mouse strains and in some rare cases we may have to use the maximum dose of 11Gy. For identification of the most suitable irradiation dose for specific mouse strains the literature will be consulted.

Anaesthesia of mice will be performed with isoflurane whenever possible. From our experience, mice undergoing anaesthesia using isoflurane do not experience any adverse effects. Only on rare occasions when usage of isoflurane is not advisable will injectable anaesthetics be used.

The models and methods were chosen to enable the investigation of tumour immunotherapeutic intervention strategies. For understanding the potency and safety of tumour immunotherapeutic intervention strategies, the model has to include an intact immune system and a tumour in addition to suitable tools such as antibodies, recombinant factors and/or gene-modifications that enable the mechanistic investigation of the model. The mouse model is the most suitable for these investigations. The identification of appropriate humane endpoints will enable the investigation of the efficacy of the immunotherapeutic intervention and its underlying mechanisms while at the time ensuring that the harm to the animals will be kept to a minimum.

Why can’t you use animals that are less sentient?

Animal models for studying anti-tumour immunity induction require animals with an adaptive immune system similar to humans. The immune system of less sentient animals such as fish or invertebrates are too different from the human immune system to provide meaningful insight into immunotherapeutic intervention strategies. Also, mouse models have the great advantage that a wide arsenal of tools such as antibodies and genetically modified mouse strains have been developed to study immune responses in mice. Furthermore, most mouse tumour models are well characterised and thereby enable their use for studying a variety of intervention strategies with minimal need for optimisation of the protocols.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our biological service division (BSD) has a very good track record in minimising harms to animals. Refinement of procedures implemented during the previous PPL include:

single use needles - using a new needle for every animal that is injected

increased observation frequency after specific procedures (e.g. surgery, irradiation and adoptive transfer, injection of immunostimulatory reagents)

supportive husbandry measures e.g. mash diet and additional warmth when anaesthesia is used or upon irradiation

antibiotic in drinking water pre and post irradiation

non-aversive animal handling techniques

various enrichments in the cages

The scientists, the NVS and the BSD staff working on a project have pre- and post-meetings for experiments. During these meetings possible refinements are discussed and jointly agreed.

In addition, experimental endpoints will be adjusted to deliver the minimal average tumour size that allows to achieve the scientific objective and the minimum irradiation dose that allows for good engraftment. Also, endpoints will be chosen to avoid mice showing signs of graft versus host Disease (GvHD).

What published best practice guidance will you follow to ensure experiments are

conducted in the most refined way?

In addition, for planning of the research and the experimental procedures on the animals we will follow PREPARE guidelines (Smith et al., 2018. Laboratory Animals 52(2): 135-141; https://norecopa.no/PREPARE). For experimental design, reporting and publication of study data we will follow ARRIVE guidelines (https://arriveguidelines.org/).
Regarding the tumour models, we will follow the Guidelines for the Welfare and Use of Animals in Cancer Research (Workman et al., 2010 British Journal of Cancer 102: 1555-1577).

Maximum blood withdrawal volumes and dose volumes for specific routes of administration will be adhered to as listed in the action plan. In addition, expert input from NVS and NACWO will be thought for new treatment regimens.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Scientists working on animal experiments receive regular e-mail updates relating to the 3Rs by the Named Information Officer. In addition, scientists, the Named Veterinary Surgeon (NVS) and the staff members performing the experiments in the biological service division (BSD) hold pre- and post- meetings for experiments. During these meetings all aspects of the experiments including the 3Rs are considered and discussed and are documented in the meeting notes. Refinements are jointly agreed on and implemented for future experiments following the same procedures.

69. Preclinical models of haematological malignancies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

blood cancer, targeted therapy, xenograft, preclinical models

Animal types	Life stages
Mice	pregnant, adult, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to accelerate the entry of new and effective treatments against haematological malignancies to the clinic. For this we aim to develop and characterise novel pre- clinical models of haematological malignancies, in particular novel patient-derived xenografts, and to use these models to assess the efficacy of novel treatment regimens.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Haematological malignancies are the fourth most prevalent cancers in the UK, affecting about 40,000 new patients of all ages each year. While chemotherapy has greatly

improved survival in some malignancies such as for example childhood acute lymphoblastic leukaemia, this can be at the cost of huge toxicities such as infertility, immunosuppression, secondary malignancies or cardiac and neurological problems. For others, such as diffuse large B-cell lymphoma, T-cell lymphoma or acute myeloid leukaemia, the overall survival can be as low as few months with most patients failing conventional therapies and has not improved much over the last decades. There is then a clear unmet medical need for patients with blood cancers. There are many reasons for the persistent lack of efficacious therapies such as poor understanding of the biology of the tumour cells, poor understanding of the role of the microenvironment, the broad heterogeneity/variability within one disease, the lack of preclinical models, including access to patient primary samples and the poor viability of primary cells ex vivo precluding assays.

What outputs do you think you will see at the end of this project?

At the end of this project, we aim to have developed forty novel models across the spectrum of haematological diseases. We will focus more particularly on diseases for which preclinical models including cell lines are rare. These models will be characterised in terms of genomics, growth and drug vulnerabilities. We will also try to develop novel cell lines from this xenograft models, which will considerably facilitate drug screening, the study of mechanisms of tumourgenesis and the mechanisms of drug vulnerabilities and resistance. We are aiming to have tested five different drugs ex vivo (explants or suspension cells) and/or in vivo and that the results will support and inform novel clinical trials. Results from this project will be shared to the scientific community as publications (following the ARRIVE guidelines) and/or conferences. All models will be made available.

Who or what will benefit from these outputs, and how?

In the short- and medium-term, the development of novel pre-clinical models will benefit the academia and pharmaceutical communities. In this project, we will particularly focus on diseases for which the development of novel therapeutic agents has been lagging because of a lack of available preclinical models (including cell lines) and a poor understanding of the tumour biology. The developed models will be made available to use as collaborative work to better understand the pathogenesis of haematological malignancies and to develop better and targeted novel therapies.

In the long-term we hope these models will benefit the patient community. Together with data collected from other studies and by using these models, our understanding of the diseases will be improved and we hope the use of these models will have informed the approval of novel therapeutic agents in clinical trials or as novel standard of care, and lead to novel and better therapeutic options available to our patients.

How will you look to maximise the outputs of this work?

We will look to maximise outputs by advertising the existence of our models, our know-hows and the results of in vitro and in vivo experimental work to potential collaborators both in academia and in the pharmaceutical industry. This will include publications in peer-reviewed journals, communications at conferences and as confidential information to our collaborators. Unsuccessful approaches or negative results will be equally shared.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For this project we will mainly use immunodeficient adult mice. Our main model will be the Nod Scid Gamma (NSG) (NOD.Cg-PrkdcSCID Il2rgtm1Wjl/SzJ) immunodeficientmice which have been shown to be the best model for xenograft studies in haematological cancers but we might use NSG variants when appropriate, or the Nod Rag Gamma (NRG) (NOD-Rag1null IL2rgnull) immunodeficient mice model.

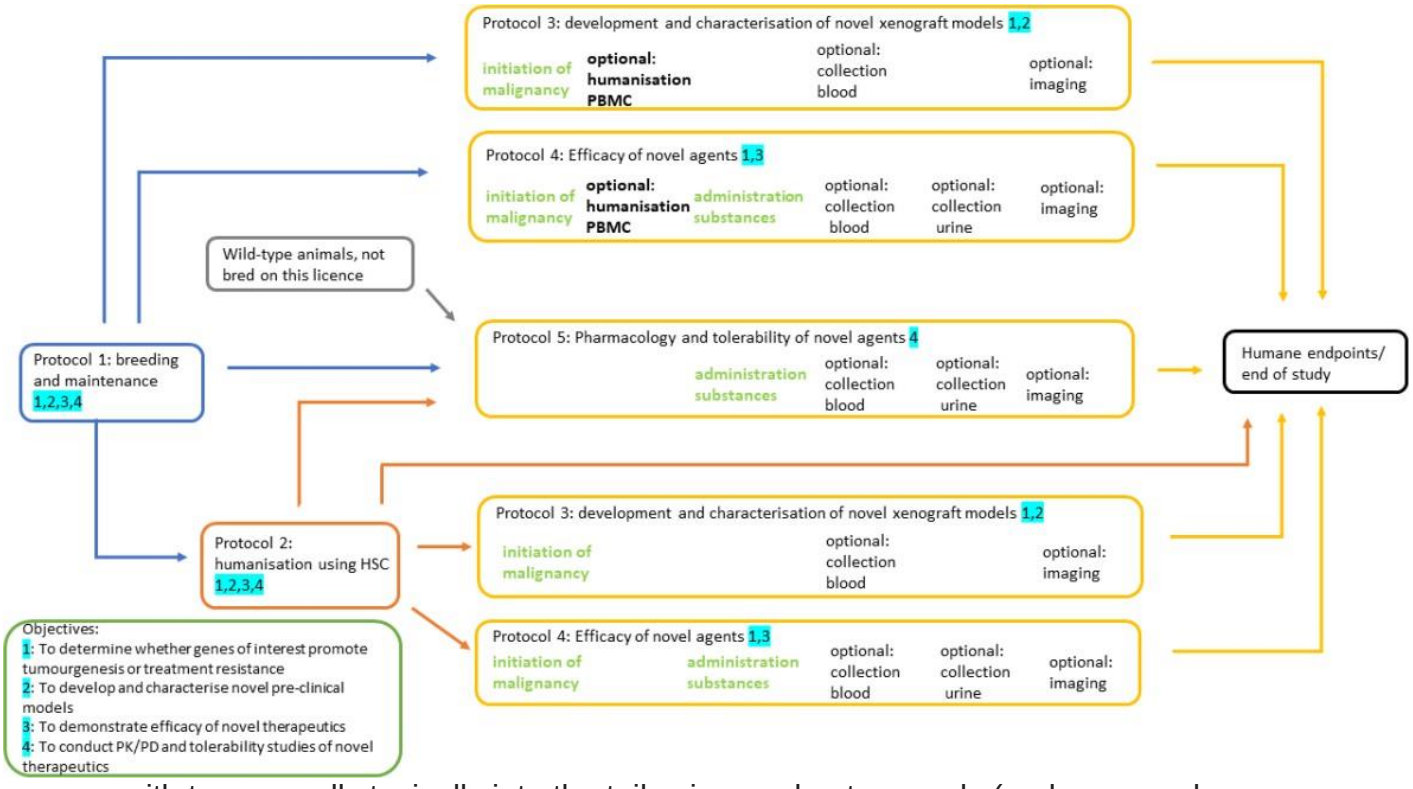
To establish humanised immune system mice, juvenile (5-8 weeks old) NSG, NSG variants or NRG mice will be irradiated to deplete the bone marrow from mouse haematopoietic stem cells (HSC) and to allow engraftment by human HSC after intravenous injection. As an alternative approach we might inject mature immune cells isolated from peripheral blood into adult mice.

Typically, what will be done to an animal used in your project?

A summary of a typical journey of an animal is shown in the figure below:

Throughout this project, we will use primary tumour cells from patients or established cell lines. These cells might be engineered/modified to remove or mutate genes of interest and we will compare their capability to develop tumours or to respond to treatment.

For the development of novel xenograft models, immunodeficient animals will be injected



once with tumour cells typically into the tail vein or subcutaneously (under general anaesthesia), but other routes could be used such as into the intraperitoneal space, into the femur or into the subrenal capsules (both under general anaesthesia). We will only use

these latter routes for the most interesting samples and if engraftment by intravenous or subcutaneous injections has failed. Tumours will be let to grow until they reach the defined humane endpoints (size of subcutaneous tumours, clinical signs, body condition scoring, behaviour, pain). The animals will then be humanely killed, and tumour samples processed for analysis in the lab or reinjected into mice. If six months after injection, animals do not show evidence of tumour growth, they will be humanely killed. Blood samples might be taken to assess the number of circulating human tumour cells. Imaging might be used to obtain further data on tumour growth. If immunotherapy will be evaluated in subsequent pre-clinical trials using these models, we will need to humanise the

mouse immune system and to characterise these humanised models before their potential use. For this, the animals will be injected once, either with human haematopoietic stem cells (after irradiation and before tumour engraftment) or with mature immune cells (no irradiation, after tumour engraftment).

For the assessment of novel therapeutics, established and characterised xenograft models will be used in pre-clinical trials using novel therapeutic agents and we will compare the efficacy of these new agents (or combination) at reducing tumour growth compared to standard of care regimen. These novel drugs will be administered using routes that will reflect the minimum possible harm and distress for the animal in line with the proposed route of administration in patients. We will choose the less invasive route whenever possible and will limit the number of daily administration and the duration of the treatment in line with published guidelines. We might collect blood samples to assess pharmacokinetics (PK) and pharmacodynamics (PD) data in tumour-bearing animals. We might use imaging to limit the number of animals used in these trials. If immunotherapy are evaluated in pre- clinical trials, we will need to humanise the mouse immune system. For this, the animals will be injected once, either with human haematopoietic stem cells (after irradiation and before tumour engraftment) or with mature immune cells (no irradiation, after tumour engraftment).

We expect to have PK, PD and tolerability data for most novel agents we will use in this project. However, if data are not available, we will run small pilot study to evaluate tolerability, and carry out some small studies to determine PK/PD data in immunodeficient animals (without tumour) or in wild- type animals. This will require administration of substances and collection of blood and urine. The routes and frequency of administration will be informed by in vitro and in silico studies. We will choose the less invasive route whenever possible and will limit the number of daily administration and the duration of the treatment in line with published guidelines.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals produced under this project will develop human-like blood cancers, will receive medicines that aim to improve the treatment of disease and reduce the unpleasant side effects of current cancer treatments (chemo and radiotherapy). We expect that the severity will be moderate as animals are likely to suffer moderate impairment of their well-being. This will include the development of tumours and adverse effects linked to the administration of substances and collection of blood samples. A small number of animals might undergo surgery under general anaesthesia as part of the procedures.
Adverse events will be controlled by analgesic when necessary. Any animals that show significant impairment of normal behaviour or signs of distress will be humanely killed.

Humanisation of immune system using human haematopoietic stem cells: Animals will be sub- lethally irradiated to eliminate the mouse haematopoietic stem cells from the bone marrow and to allow engraftment with human stem cells (injection once into the tail vein). Some animals might lose weight about a week after irradiation, this weight loss might reach 15% of the initial weight. We will provide support to the animals such as soggy diet or hydrogel and most animals should recover their initial weight within 3 weeks after irradiation. Some animals might not fully recover their initial weight but their body condition and general behaviour should remain stable.

Humanisation of immune system using human mature immune cells: An alternative approach to humanise the mouse immune system is to inject, once by IV, peripheral blood mononuclear cells (PBMCs) after the initiation of malignancy. The major risk of this approach is the development of xenogeneic Graft vs Host Disease (xGVHD) four to five weeks after injection in NSG strain due to the recognition of the mouse cells by the human T cells. xGVHD is characterised by sudden weight loss, skin fibrosis and hair loss, loss of mobility and increased breathing. We will limit the adverse effects by 1) terminating the study before or on the onset of clinical signs in NSG, 2) using strains that are resistant to xGVHD (NSG lacking MHC system or with humanised HLA system).

Initiation of malignancy will be performed by injection, once, with human tumour cells, typically subcutaneously or intravenously, but for a small number of animals, injection might be intraperitoneally, intrafemorally (under general anaesthesia) or into the subrenal capsule (under general anaesthesia).
The health of animals will be routinely monitored for the apparition of clinical signs such as tumour growth, weight loss, change in appearance, body condition, behaviour, signs of pain, enlargement of internal tissues to follow the engraftment of tumour cells. Health monitoring will be increased as necessary to limit pain and suffering within the moderate severity band.

Administration of substances will be done using routes and frequency that will reflect the minimum possible harm and distress for the animal in line with the proposed route of administration in patients. Maximum volumes for dosing per animal will be ascertained using published guidelines. We will minimise the number of injections when possible. Typically, most animals who will receive drugs by oral gavage, IP or SC, alone or in combination, will receive one or two administrations per day for a maximum of three weeks. However, a small number of animals might require three administrations per day, this will be over a maximum period of one week for IP or SC and over a maximum period of 4 weeks for oral gavage. For intravenous injections, we will limit injections to once per week, with a maximum of 8 injections. Tails will be regularly checked for bruising or infections. To limit the side effects of repetitive injections, we will use the minimum size of needles, rotate sites of injection, assess for bruising or tenderness of the injection areas, allow period of rest if animals show clinical signs (weight loss, lethargy) or signs of pain using the NC3Rs grimace score. For oral gavage, the administered volume will be kept as a minimum to avoid filling up the stomach and weight will be monitored to ensure animals get enough food. Analgesics such as paracetamol might be given to alleviate pain. Whenever possible we will use alternative ways of administration and this could include the implantation of slow release pellet or osmotic pump such as the Alzet minipumps.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals are expected to fall within the mild (40%) or moderate (60%) severity bands.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice offer multiple advantages to help human patient cells grow. Patient cells needs a microenvironment support that has not been fully characterised and cannot be recapitulated in vitro or in tissue culture conditions. We need to use mice to provide the best microenvironment within the different tissues usually affected by blood cancers, ie blood, bone marrow, spleen or lymph nodes for orthotopic models, or to provide blood supply and other support for subcutaneous models.

Which non-animal alternatives did you consider for use in this project?

We routinely use established cell lines and primary patient samples in our investigation. We are holding one of the largest cell line banks in the UK for haematological malignancies and thanks to our close link to the local hospital we have been collecting and using primary samples from our tissue bank for the last twenty years. We are collaborating with many centres in the UK and in Europe to source samples, share best practice and novel technologies. We use a large array of in vitro/in cells approaches, including knockdown/knockout technologies, next-generation sequencing, single cell analysis. We also have access to large sequencing datasets that we interrogate to predict responses to treatment for example and we have initiated collaboration to predict mechanism of resistance using computational systems biology.

Why were they not suitable?

Each model has its advantages and its own limitations. Cell lines are easy to grow, relatively well characterised (even if misidentification and contamination are a recurrent problem), of unlimited supply for diverse mechanistic studies. Cell lines have been an instrumental tool in our understanding of various cancers and the development of novel targeted therapies. However, cell lines numbers are limiting and the scientific community still requires novel cell lines. Some malignancies such as DLBCL for example can be modelled with a bit less than one hundred cell lines, and while this is a great number to work with, this is barely enough to model the heterogeneity and the diversity of the disease seen in patients. Moreover most cell lines have been established decades ago and they don’t represent the tumour cells emerging from patients with resistant/refractory disease to the current therapies. Some malignancies just don’t have enough bona fide model cell lines for researchers to make any significant progress. For example, T-PLL can be modelled by only one cell line, undermining any mechanistic or drug screening studies.

Despite the overall need for cell lines, the cancer community is well too aware of the biological limitations of these models. Cell lines don't fully recapitulate the patient's disease as they have been adapted to grow as a 2D culture on a plastic dish and completely lack the effects of the tumour microenvironment and this could explain in part the high attrition rate in drug development.

Besides cell lines, we use primary patient samples in our studies. While we have a large collection of samples through our Tissue Bank, supply of cells is limited with what we have stored or what we can have access to, with samples that can be limited to few biopsy cores. The low number and low viability of primary cells once put in culture is a major obstacle to any mechanistic or drug screening studies. We have tried to develop patient-derived explants when we had access to lymph nodes or spleen samples but these organs don't seem to be suitable for this type of study as they are of poor viability or too fragile, possibly due to the way they are excised from the patients (blood vessels are first clamped). Moreover, application of drugs is done only by soaking in the pieces of tissue as blood supply is abolished and might limit drug accessibility. We are also trying to develop patient-derived organoids but this approach has its own challenges.

Information gathered from sequencing or multi-omics analysis together with computational predictions are a compelling approach to draw hypothesis but there is still a need to validate those using appropriate models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Breeding: We plan to use about 1000 animals for breeding purposes. We endeavour to use all animals (males and females) issued from the breeding for procedural work.

Development of models: we anticipate injecting 80 different patient samples. From our previous experience, about half of these samples are expected to produce successful xenografts. At the moment we are not able to predict which samples will be successful or not. We thus expect 40 patient samples will only be injected as passage 1 (typically 6 animals) and 40 will be injected for 3 passages, about 20 animals in total for each model. In total we estimate we will use 1000 animals for this part of the work.

Assessment of novel treatment regimens: we anticipate we will carry out about 20 preclinical trials over the 5 years of the licence. A typical preclinical trial will consist of 4 treatment arms (Arm 1: Vehicle, Arm 2: current standard of care, Arms 3 and 4: 2 doses of drug of interest) with 5-10 animals per arm. So in total we anticipate we will use about 400-800 animals

Pharmacology study of novel agents: We expect a maximum of 5 novel agents to be assessed for PK/PD studies with a maximum number of 100 animals to be used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For the assessment of novel treatment regimens and the pharmacology studies of novel agents, number of animals will be determined by using the NC3R Experimental Design Assistant and other power calculation tools such as the 3rs-reduction tool (3rs-reduction.co.uk/html/6____power_and_sample_size.html). All novel agents will be first assessed in cells and only the most promising compounds will be evaluated in xenograft models. This pre-assessment in cells will allow us to determine the expected variability of response (noise) and the expected size of the effect (signal).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The animals will be held in a high health facility minimizing bias from the pathogen status of the animals. We will breed animals depending on our study schedules. We will use both males and females.

We expect that for most compounds we will have access to PK/PD data. In case of novel agents never tested before in animals and for which PK/PD data are not available, we will work with our collaborators from the pharmaceutical companies providing the agents to determine target occupancy and drug-target residence time using biochemical studies, studies in cells and computing modelling. PK/PD studies will be complemented with computational predictions of target engagement to select concentration doses for the studies. Moreover, we will run small pilot studies to detect unexpected toxicity. When possible, we will reduce the number of animals in the non-treated/vehicle arm.

Downstream analysis will be optimised to reduce the amount of tissues required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use adult (8-20 weeks) immunodeficient mice for the xenograft studies. Our main model will be the Nod Scid Gamma (NSG) (NOD.Cg-PrkdcSCID Il2rgtm1Wjl/SzJ) immunodeficient mice which have been shown to be the best model for xenograft studies in haematological cancers but we might use NSG variants when appropriate, or the Nod Rag Gamma (NRG) (NOD-Rag1null IL2rgnull) immunodeficient mice model.

We might generate animals with an humanized immune system by transplanting human CD34+ haematopoietic stem cells (HSC) after irradiation or by injecting peripheral blood mononuclear cells (PBMC) to assess novel immunotherapies. In that case juvenile animals might be used. NSG animals are relatively sensitive to irradiation but adequate support will

be provided when needed. NRG animals are more resistant to irradiation and would be used instead.

Whenever possible, the injection volumes and the size of the needles will be as small as possible.

Sampling will require only small amount of blood (typically 50 microliters) as the downstream in vitro measurement experiments are highly effective.

We have developed a comprehensive distress scoring sheet and health check protocols, which allow us to identify any early signs of disease progression and to control pain, suffering, distress and lasting harm appropriately.

Routes of administration for the therapeutic agents will reflect the minimum possible harm and distress for the animal in line with the proposed route of administration in patients. We will follow the LASA guidelines regarding the routes and frequencies routinely. We will consider using subcutaneous mini pump whenever possible.

Why can’t you use animals that are less sentient?

Recent studies have shown that zebrafish could be used as host for xenotransplantation of human tumour cells, with tumour growth similar to what is observed in mice. These zPDXs have also been used in compound screening. There are some advantages of considering zPDX as an alternative of mouse PDXs, as they are less sentient, easier to maintain, allow high-throughput screening and more cost-effective. However, the current limitations of using zPDX are the need of fluorescent-labelled cells, the need of specialized equipment for imaging and injections. Moreover, most studies have used established cell lines as their source of xenograft and up to now very few studies have used patient cells to establish zPDXs. Moreover, this is a relatively new area of research, which will require further evaluation within the scientific community before being implemented and used widely and convincingly. However, zPDX will be looked into as a possible alternative model and if deemed appropriate an amendment will be made to this ppl in the future to include zebrafish and lower the number of mice used accordingly.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our experimental animals have a daily check and are examined at least once weekly. This examination will include recording of body weight, body condition scoring, behaviour, signs of pain, changes to respiration and mobility, evidence of enlarged internal tissues and examination for visible evidence of tumours with size of tumours recorded if present. A distress scoring sheet has been developed based on our previous experience of leukaemia/lymphoma models. Health monitoring frequency will be increased for animals exhibiting subdued behaviour and on the apparition of adverse events. Communication between PPL holder, PIL holders, NACWO and facility staff is paramount. Animals are trained to be tunnel handled during the health checks minimising stress.

Administration of substances and blood sampling:

Other than in terminally anaesthetised animals, dosing and sampling procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. Maximum volumes for dosing or blood sampling per animal will be ascertained using published guidelines (The

LASA Good Practice Guidelines Administration of Substances (1998) The LASA Good Practice Guidelines Blood sampling (1998), Turner et al., Journal of the American Association for Laboratory Animal Science, 2011, Vol50, No5, pp600-613, Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider; Members of the Joint Working Group on Refinement, Laboratory Animals Ltd. Laboratory Animals (2001) 35, 1-41, Refining procedures for the administration of substances).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Maximum volumes for dosing and blood collection per animal will be ascertained using published guidelines (The LASA Good Practice Guidelines Administration of Substances (1998), The LASA Good Practice Guidelines Blood sampling (1998), Turner et al., Journal of the American Association for Laboratory Animal Science, 2011, Vol50, No5, pp600-613, Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider; Members of the Joint Working Group on Refinement, Laboratory Animals Ltd. Laboratory Animals (2001) 35, 1-41, Refining procedures for the administration of substances).

We will follow the NCRI guidelines for the welfare and use of animals in cancer research (Workman et al, 2010, British Journal of Cancer). If those guidelines are updated within the lifetime of this licence, the updated guidelines will then be used.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have several routes to stay informed about advances in the 3Rs. At our Institution we have a 3R working group which evaluates the procedures and informs us on advances/experience/guidance to improve our compliance to the 3R. For example, we have quickly implemented tunnel handling of mice when this was highlighted as best practice. Users at our facility meet every six weeks and are encouraged to share their experiences. The regional NC3Rs programme manager is a member of our AWERB committee and attend our User Group meetings. We work closely with our Institution’s NACWO and NVS to discuss ways to improve the welfare of the animals, from housing to procedural work. We also received newsletters from our animal facility that highlight webinars, conferences, articles of interest for our perusal. I am also registered to various animal-focused companies (Charles River, Jackson Labs, Crown Biosciences) and organisations (NC3Rs) as they provide webinars and other useful resources.

70. Tumour-bone interactions in skeletal malignancy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

multiple myeloma, prostate cancer bone metastasis, bone microenvironment, metabolism, aging

Animal types	Life stages
Mice	juvenile, adult, embryo, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine how tumour-bone interactions drive tumour growth and bone disease, and therefore how we can disrupt these interactions to prevent or treat skeletal malignancies. The project is focused upon metabolic, aging and obesity-related changes within the tumour-bone microenvironment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Once solid tumours such as prostate cancer bone metastases, or blood cancers such as multiple myeloma, develop within bone they are largely resistant to current treatments and the malignancies are ultimately fatal. A better understanding how and why tumours like to grow within bone is needed, in order to find new ways to combat disease and new ways to identify those patients at greatest risk.

What outputs do you think you will see at the end of this project?

The primary outputs from the project will be new information, which may lead to new drugs, therapeutic approaches or disease markers. This will typically be communicated by scientific publication or presentation (but also engagement with non-specialist audiences).

Who or what will benefit from these outputs, and how?

In the short-term, those that will benefit from these outputs include scientists interested in tumour and/or bone biology and clinicians, in particular oncologists and bone biologists. They will benefit by an increased understanding of how tumours grow and survive within bone, and the mechanisms that drive this.

In the medium-term, we anticipate that scientists and the pharmaceutical industry will benefit, as our mechanistic findings progress to investigating new therapeutic approaches.

In the long-term, we anticipate that our findings will be translated to the clinic, in the form of new therapeutic approaches or markers of disease progression. Therefore, those that will benefit from this include patients with multiple myeloma or prostate cancer.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work by;

Collaboration with scientists and international societies worldwide to share our findings as quickly as possible

Dissemination of our findings by open access publication in scientific journals, use of preprint servers such as BioRiv and presentation at national and international conferences

Any unsuccessful approaches will be published

Any refinements or good practices identified will be shared via local NC3Rs networks

Species and numbers of animals expected to be used

- Mice: 4400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice because they are the most characterized model for tumour response to therapy and have the widest scope for genetic manipulations. The models we use are the models that most closely replicate human disease, with tumour growth within bone and development of an associated bone disease.

We use young and adult mice, as they provide reliable and well-characterised models of tumour- induced bone disease. We will also use aging mice to study how aging contributes to tumour development.

Typically, what will be done to an animal used in your project?

Mice will be injected with tumour cells and tumours will grow within bone. To study the specific role of the bone, it may also be necessary to inoculate mice with tumours at non-bone sites such as under the skin (in separate studies). Mice may be treated with drugs designed to stop tumour growth, or may be placed on a specific diet designed to increase or reduce obesity. Some experiments may be performed in aging mice. During the course of an experiment, blood will be sampled, and mice may be imaged and have bone marrow samples taken. For most models, the typical duration of an experiment is four weeks, with some tumour models requiring 12 weeks for tumour growth within bone.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects are mainly related to the tumour growth, and may include weight loss, pain, temporary lameness/limping or hindlimb weakness. The project is designed so that such adverse effects have an estimated duration of less that 48h.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold; 40%

Mild; 19%

Moderate; 41%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The reason that tumour growth within bone and the associated bone disease is so rapid and aggressive is due to the multiple interactions between tumour cells and host cells within the bone that promote both tumour growth and survival and bone disease. These interactions are impossible to accurately replicate in non-animal means at the present time, and there are no in vitro models available that can model effects on both tumour growth and bone disease.

Which non-animal alternatives did you consider for use in this project?

We have considered using cell culture, including the use of 3D models or organoids. We gain valuable information regarding the biology and drug response of individual cell types using standard cell culture techniques, and all our initial experiments are performed in vitro. We are developing methods to enable the simultaneous culture of multiple cell types found within the tumour-bone environment, however these experiments are in their infancy.

Why were they not suitable?

It is not currently possible to culture together all cell types found within the bone, and so not possible to accurately recreate and manipulate the tumour-bone microenvironment in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the numbers of animals we will use, based on previous experience in doing these types of studies and on statistical calculations to determine the number of animals required. We have considerable familiarity with these experimental approaches and will perform pilot studies in those cases where we do not, to gain understanding of the timing of the tumour development and/or response to therapy and of the statistical variability to ensure that the smallest numbers that can yield statistical significance are used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant to plan our experiments with the minimum number of mice. Where possible, we pool data from repeat experiments for statistical analysis which allows us to reduce the number of mice used in each repeat. Where possible, we use one control group for multiple experimental groups to reduce the number of mice required.

We will be conducting our experiments to comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines) at time of publication.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding is usually managed by support staff specially trained in maintenance and breeding of genetically altered mouse colonies. The MCMS database is used, taking advantage of the efficient breeding and notification systems. This allows us to keep the number of surplus animals to a minimum. Experimental design will be optimised by the use of MCMS study plans. Tissues are routinely shared within multiple research teams, in

order to reduce the number of animals used. Where necessary (e.g. new cancer cell line) pilot studies will be performed to gain understanding of the timing of the tumour development and/or response to therapy and of the statistical variability to ensure that the smallest numbers that can yield statistical significance are used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models that we use are well-characterised, standard and the most refined in the field. We use the most refined model that can answer the scientific question. Typically, this is a model that requires tumour growth within bone, but where possible we use a less-invasive subcutaneous model. Models are selected based upon the development of the tumour cells selectively within bone, thus eliminating the risk of tumour growth at other sites. All models are designed to have a short duration (typically 4 weeks, sometimes up to 12 weeks)i. Where it is necessary to fast animals, we will use the minimum amount of time necessary to achieve accurate measurements of the factors under investigation. For long-term or continuous drug treatments, osmotic minipumps may be implanted to reduce the frequency of drug administration. Taken together, these steps will minimise the welfare costs to the animals, while enabling us to achieve our scientific objectives.

Why can’t you use animals that are less sentient?

Mice are the least sentient animals that have anatomy and physiology similar to that of humans. The reason that tumour growth within bone and the associated bone disease is so rapid and aggressive is due to the complicated interactions between tumour cells and host cells within this microenvironment that promote both tumour growth and survival and bone disease. These interactions are impossible to accurately replicate within less sentient animals. Age is an important contributary factor to tumour development, so the use of aged animals is required to accurately reflect this.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are routinely housed in individually ventilated cages to minimise the risk of infection and supplied with environmental enrichment.

When administering agents to the mice we will use the least invasive route possible, for example administration of viscous substances by gavage rather than injection.

Observed outcomes of initial studies carried out on this licence will be used to revise endpoints in future studies.

Where needed, animals will receive pain relief and/or will be under general or local anaesthesia. Tumour growth and animal behaviour is closely monitored.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will make use of the resources available at the NC3Rs website (www.nc3rs.org.uk), including the NC3R's Experimental Design Assistant where relevant, and the Laboratory Animals Science Association website (https://www.lasa.co.uk). We will follow the ARRIVE guidelines (https://arriveguidelines.org) when planning, undertaking and publishing this work.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All members of the team associated with this licence attend local good practice and welfare meetings, and we are in receipt of regular e-mails from the University's NC3Rs manager. Attendance at the local annual NC3Rs day is encouraged. We will consult the NC3Rs website for the latest updates.

When undertaking a procedure for the first time, we will consult the vets and animal welfare officer beforehand so that any recent 3Rs updates can be implemented.

71. Remodelling of stem cells and niche cells: from development and regeneration to disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words
Respiratory system, Stem cells, Tissue repair, Ageing, Lung disease

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to investigate how the cells of the lung adapt to tissue perturbations (situations driving the tissue away from normal health condition) such as ageing, cell depletion and tumour development. I aim to learn if we can use this information to improve injury repair in lung tissues.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The lung is exposed to external environment and faces with constant challenges by various insults such as allergen, air pollution, chemicals, and pathogens which lead to tissue damage and ultimately developing lung diseases. Lung disease is one of the top three killer diseases in the worldwide. The Asthma and Lung UK estimates that approximately 12.7 million people in the UK have a history of longstanding respiratory illness including lung cancer and pulmonary fibrosis (scarring of the lung tissue). Most significantly, the recent COVID-19 pandemic, caused by SARS-CoV-2, has already recorded more than 300 million confirmed cases, while as of 18th January 2022, more

than 15 million deaths have been reported worldwide (WHO, 2022). The cells of the lung are the main target of SARS- CoV-2 infection. Further, patients with chronic lung diseases are at greater risk of developing severe COVID-19, presumably due to the unresolved lung damage or alteration already present within their lungs or an overactive immune response. Therefore, with the global scale and clinical burden of COVID-19, a deeper understanding of lung repair mechanisms following tissue perturbation (situation driving the tissue away from normal health condition) is urgently needed.

In this project, we will study the way in which the cells of the lung function under normal conditions, evaluate how their behaviour changes in response to tissue perturbations. By addressing these questions, we expect to understand how cells behave in different contexts, and whether this information can be used to change their behaviour to improve the health condition of the lung. We ultimately aim to improve lung injury repair with minimising fibrotic scarring (regeneration) and to treat disease more effectively. By investigating cellular changes from its early stages of lung disease, we expect to identify markers that can assist in the early detection of these diseases, improving the long- term prospect of those patients. We anticipate that our work will identify targets of potential medical relevance that will contribute towards solving the challenges being currently faced in the clinic.

What outputs do you think you will see at the end of this project?

The main output of our work will be in the form of scientific publications that will be of relevance to other scientists in our or other related research fields. These publications will provide novel information on the processes regulating how the cells of the lung respond when not in normal health.

In our publications, we aim to cover a number of relevant aspects:

Identify changes in the damage repair ability of cells during aging, and its implication in chronic lung disease.

Uncover how changes in the immediate environment that surrounds stem cells affect tissue damage repair.

Define how cells return to an early developmental stage when perturbed, and its implication in lung cancer.

As standard practice, the data generated in our work will be made publicly available in free repositories to ensure that it can be used by other researchers and facilitate scientific discovery beyond our own studies. This should reduce repetition of the same work by other laboratories, decreasing the number of animals needed for related research purposes.

Who or what will benefit from these outputs, and how?

Our overall challenge is to identify the processes controlling the ability of a lung tissue to heal (regeneration) and to develop lung diseases including lung cancer and pulmonary fibrosis (scarring of the lung tissue), and translate this knowledge into therapies that benefit the patients and healthcare providers. For this, the immediate aim is to understand how the cells deviate from normal behaviour when they face an injury/damage or develop disease. Then we need to determine which molecular mechanisms regulate the cellular

response. Our ultimate aim is to determine whether we can intervene in these processes, using drugs, in order to take cells back to their normal healthy state.
In this programme of work we will address these important questions. In the short term, new information that comes from this study will be presented through publications and conference presentations, or shared with organisations such as the Wellcome Trust and The Royal Society. This will mostly benefit the scientific community, particularly those with interests in tissue regeneration and chronic lung disease. In the long-term, our findings could be used to devise new strategies for the early detection of lung diseases as well as to develop novel therapies to improve lung regeneration and treat diseases. This will benefit patients suffering from declining lung function, professionals in the healthcare community, as well as companies with an interest either in i) experimental systems to study disease or in ii) in the potential identification of novel drug targets.

How will you look to maximise the outputs of this work?

We maximise the outputs of our work by doing the following:

To increase the outputs of the work conducted within this study, the management of individual project is closely supervised by me. This way I avoid effort duplication and ensure that the resources are maximised and shared between members of my laboratory, where feasible.

By disseminating our observations from early stages, for example via conferences, we create new collaborations with experts in research fields beyond our own. They positively contribute to the progress of ongoing projects and ensure their completion to the highest standards. This has previously allowed us to establish collaborations with researchers interested in samples created as a side-product of our research. For example, samples are currently being shared with other groups examining the cell behaviour in other organs such as the intestine, brain, liver, among others.

Moreover, in our effort to understand the behaviour of cells, we conduct the analysis of large- scale datasets. To maximise the outputs obtained from these complex datasets, we collaborate with experts in theoretical physics, mathematical modelling, and computational analysis, who have the skills to develop theories explaining the results obtained in our experiments. Methods and datasets generated in these types of analyses are made publicly available as part of the relevant research articles enabling new collaborative projects.

Our work will be published in free, public repositories online and in international scientific journals. In our publications, we do not only include positive data, but also experimental results that fail to support our hypotheses. This also prevents duplication by ensuring that other laboratories do not spend resources in ideas that have already been tested.

We will share our work with the public via public engagement activities. This will allow people to learn about novel aspects of regenerative medicine and lung diseases, and will provide the opportunity for a productive exchange of ideas between patients and scientists.

Species and numbers of animals expected to be used

- Mice: 41050

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mice will be used in this project for tracing the changes in behaviours of the lung cells under tissue challenges (conditions away from healthy normal lungs). A crucial reason for using mice is that cellular responses to tissue challenges represent a complex biological process that involves numerous cellular types, signalling pathways and environmental factors. These processes can differ substantially in organisms other than mammals and, specially, in invertebrates. Mice are the smallest species with lowest susceptibility to neurophysiological conditions (situations that affect both physical and conscious functions such as stress, anxiety, and mental activity) that have mammalian lungs. Moreover, stem cells that contribute to lung tissue maintenance have been extensively studied by using multiple mouse models that are readily available and capable of reproducing the human settings. Critically, at the moment, there is a critical limitation to investigate the time-course changes of disease initiation and progression for which human samples are typically unavailable yet mouse disease models are allowed. Our study will focus on the early sequential changes of lung cells upon tissue challenges using mouse models which also allow relatively easy genetic manipulation and tracking the changes of individual cells over time.

We will use mice that undergo different stages of their lifetimes (from birth to aged stages) because we are interested in understanding why we exhibit a different repair response and disease incidence as we age.

Typically, what will be done to an animal used in your project?

Most of our experiments will use genetically modified animals that allow us to follow the individual cells in which we are interested. This will facilitate the tracking of individual cells to study their behaviour in response to perturbations (such as ageing, genetic mutation, or cell ablation). To address our research questions, animals will typically undergo one of three main types of experiments:

Ageing: Animals will be administered various substances to label their cells, by delivering them into their stomach. This will help us track the behaviour of cells at different time points throughout the lifetime of an animal. Samples will be collected after humanely killing mice at different ages from birth and up to 24 months of age. The labelled cells will be analysed to investigate the impact of ageing on cells.

Genetic mutation: Animals will be administered substances to alter genes that are associated with lung cancer, by delivering them into their stomach. Animals will then be allowed to develop tumours in the lung. Since we are interested in early tumour formation, animals are humanely killed before showing any signs of distress or suffering. Tumour samples will be collected at different times to capture the point at which tumours form. The cells will be analysed to investigate how tumours emerge.

Cell ablation: Animals will be administered well-studied substances for local cell ablation in the lung, by delivering them into abdomen or lung. The procedure of lung delivery will be completed under inhalation-mediated anaesthesia for less than 5 minutes so that animals remain in a state of sleep/unconsciousness during the procedure. Some animals may develop mild scar (fibrosis) after cell ablation in the lung. Some animals may be treated with additional substances to label the cells and track their behaviours during

replenishment process of lost cells or development and progress of lung fibrosis. Aged animals may be used to compare these features to the young animals. Subsequently, samples will be collected after humanely killing mice at different stages of replenishment or fibrosis to investigate the sequential changes in cell behaviour. These experiments will shed light on how tissue repair changes as animals age.

For any of these typical experiments we may sporadically treat a small number of animals with drugs that will help us discover the processes that regulate cellular behaviour.

What are the expected impacts and/or adverse effects for the animals during your project?

Please note the adverse effects presented here are based on our previous experience using the proposed techniques. Our work will be conducted in a way that will not lead to long-lasting pain, suffering or distress and have no lasting effect on the animal's health and wellbeing. The genetically modified mice used are not expected to show deviations from normal health.

All animals are carefully checked regularly and if there are any concerns animals are examined and weighed. The majority of the animals will be used in procedures under which they suffer either no, or mild, adverse effects. For example, transient pain or discomfort following an injection. A smaller number of animals (less than 5% of the total) will be exposed to procedures of moderate severity to model different aspects of human lung disease. Some animals sporadically present transient weight loss of up to 15%, which is usually recovered within the next 2-7 days. In some instances, animals become sick from unresolved tissue damage or scarring that causes sustained altered breathing rate and subdued activity, in which case they are humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice.

-Mild: 67%

-Moderate: 33%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal experimentation is required to obtain relevant information on cellular behaviour within the living organism. In order to identify treatments of relevance to improve injury repair and the symptoms of illness, we need to understand the way in which different cell types interact with each other. The lung is complex organs formed by different layers and tissue compartments that contain different types of cells. In response to an injury or genetic alteration leading to lung disease, all these cells need to communicate in order to elicit a coordinated response that results in injury repair or disease development, respectively. Unfortunately, this complex communication network is something that so far cannot be fully explored merely by growing cells outside the animal. Additionally, most techniques that work with cells outside of living animals do not fully reflect their normal behaviour over long periods.
Hence, animal work is necessary to disentangle how different cells communicate and cooperate in health and disease; an aspect of critical importance to understand the basis of tissue regeneration and cancer.

Which non-animal alternatives did you consider for use in this project?

My laboratory is a pioneer group in developing methods, called three-dimensional (3D) organoid systems, to grow tissues outside the animal. These platforms recapitulate physiological features of lung tissues in a dish and thereby significantly replace injury/disease animal models that generally employ moderate to severe animal protocol. Additionally, we have published the details of our methods which can be used by other scientists who can also replace their animal models. Importantly, we have been educating more than 500 scientists from academia and industry to grow 3D lung organoids in a day workshop. Whenever possible, we will implement this technique to obtain preliminary data to inform experiments with animals in this project.

Why were they not suitable?

Tissues are formed by many different types of cells. We are interested in understanding how those different types of cells interact with each other and contribute to ageing, injury repair and disease development over long periods of time. Unfortunately, to date, by growing cells/tissues outside the animals, we are not able to fully mirror the complex cellular interactions and time-course long-term changes in cell behaviour that take place in the animal. Until then, experimentation with animals will still represent the gold standard to unveil these intricate processes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
The predicted number of animals needed for this project has been based on the following:

Animal numbers have been worked out with the advice of expert statisticians. This ensures that our experiments are designed properly and that the results obtained have enough statistical power to draw meaningful biological conclusions.

Animal numbers have been calculated based on the animals used in my laboratory in similar work over the past 5 years. I have also accounted for an increase in the number of members that form my laboratory, something anticipated for the next five years.

We have carefully considered the best way to make sure we keep the lowest number of different types of mice (strains) for breeding, while ensuring we have enough mice to use for experiments.

Test experiments, called pilot experiments (which use a smaller number of animals; typically 3) will be used to calculate the amount of a substance that we can safely inject into the animal. It is important to find the smallest amount of the substance that has an effect but that will not harm the animal in any way. This will then allow us to perform the intended experiment using only enough mice to be sure that the results we obtain are statistically significant.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken advice received from a local, qualified expert in statistics. This will make sure that each experiment produces statistically meaningful data. Where possible, all experiments are designed to get the most information using the least number of animals possible. We will also take into consideration the NC3Rs guidance and experimental design assistant tool (https://www.nc3rs.org.uk/experimental- design-assistant-eda; https://nc3rs.org.uk/3rs-advice-project-licence-applicants-reduction). Additionally, all experiments will be designed taking into account the PREPARE guidelines (a document that gives scientists advice on how to plan animal research and experiments).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We implement different measures to reduce the number of animals used. Among them:

Efficient breeding techniques: We will breed our genetically modified mice in a way to minimise waste. Any types of genetically modified mice (strains) that are not being used for scientific studies will be frozen as embryos for future use.

Experimental design: Critical experiments are designed in collaboration with experts in statistical physics. With their assistance, we determine the number of experimental animals required to answer each of our scientific questions.

Mouse strain management: animals are bred only to fulfil our experimental needs. However, any unavoidable excess of animals is used for in vitro experiments (culturing cells outside the animal), validation or pilot studies (as long as they are compatible). The latter represents a critical consideration in our laboratory, and allows us to ensure that mouse waste is minimised as much as possible. While this approach requires a significant amount of coordination and team effort, it is essential to reduce the number of animals we breed or purchase. We will also take into consideration the NC3Rs Breeding and Colony Management Resource (https://www.nc3rs.org.uk/3rs-resources/breeding-and-colony-management).

Animal and tissue sharing: I have a network of collaborators within the UK who work in my or a similar research field. We exchange particular types of mice (strains) between us to reduce animal imports, the need for additional breeding and its associated excess.

Similarly, to increase the output of our work, we share tissues with members of other research groups and collaborators who examine different areas of the body (tissues), such as the liver and the intestine. Additionally, we are registered in the animal tissue sharing list of our institution.

Growth of tissues outside the animal (3D tissue cultures): Using this method, one single lung can produce sufficient cells to perform at least 3 experiments instead of one. Thereby, this system effectively reduces the number of animals used by two thirds. However, as indicated above, studying interactions between different types of cells remains a limitation when using this technique.

Mathematical modelling: By working with our collaborators, we use our data to develop mathematical models that explain how cells behave and interact with each other. The created hypotheses are then tested in the laboratory. This makes our science more targeted, which allows us to significantly reduce the number of animals needed to understand how cells work.

Advanced imaging and molecular methods: Dissected samples are analysed using state-of-the- art whole-tissue imaging and molecular techniques that require minimal tissue material to obtain meaningful results.

We will also consider subscribing to ATLA (Alternatives to Laboratory Animals) published by FRAME (Fund for the Replacement of Animals in Medical Experiments), in association with SAGE publishing, featuring articles on the latest research relating to the development, validation, introduction and use of alternatives to laboratory animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically modified (GM) mice to carry out our plan of work. Most of our GM mice bear genetic alterations that allow us to label cells and track their behaviour in the tissue. Hence, the majority of genetic alterations we propose are not expected to lead to any adverse effects, except animal models for early tumour formation (please see below).

The animal procedures proposed in this study will inflict minimal pain, suffering or distress to mice:

We administer substances to mice to label and track cells over time. These methods are based on previous studies and our long-term expertise using them. We use the lowest dose needed to observe an effect. Hence, we expect our treatments to cause no harm to animals.

We also use GM mice bearing lung cancer-associated genes to understand how cells work and explore the earliest stages of tumour formation in the lung. Our project mainly focuses on the early tumour development and use well-established GM model system based on our experience and published literature. Therefore, mice rarely show complications apart from developing discrete lesions, and will be killed before the tumours have an impact in any vital process.

Animals receive drugs causing localised short-lasting damage in the lung. These methods affect the limited region of the lung and ablate specific cell types which are typically replenished within 1-2 weeks, depending on cell types and methods. Therefore, effect is both refined and only short- lasting. Animals undergo inhalation-mediated anaesthesia which allow a rapid recovery (less than 5 minutes) from procedures and unconsciousness during the procedure.

Why can’t you use animals that are less sentient?

In our studies, we investigate how different cell types function under normal circumstances, and how they change their behaviour in response to injury and early disease development. Given the differences observed in injury repair and incidence of lung disease, such as lung fibrosis and cancer, as we age, it is important to investigate cell behaviour over long periods of time and at different stages throughout the life of animals (from birth to aging). Unfortunately, these long-term experiments require living organisms, limiting the use of other less sentient animals such as anaesthetised mice or tissues grown outside the animal.

Another critical aspect of our work focuses on investigating how different cell types interact and impact on each other's behaviour. For these studies to be clinically relevant, they need to be performed in mammalian animals, closer to humans. Results in lower species such as fish, worms or fruit flies, would be of very limited medical relevance.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All methods in this project will use techniques that reduce animal stress and make sure the animal does not suffer as detailed below:

General:
We will make sure to use the best care methods to improve the quality of life for the animals. Mice will be placed in cages and will be provided with nesting and bedding material to stimulate mouse activity and provide them with shelter if needed.

Side effects from procedures will be monitored by regularly weighing animals, daily health checks, and the use of scoring sheets, as required. This will prevent animal suffering. Animals showing any signs of suffering will be immediately killed. This is called the Humane Endpoint. We are not expecting animals undergoing procedures under this licence to experience suffering. If an animal does begin to look unhealthy, we will monitor it more frequently and provide pain relief if needed. If it does not improve the symptoms of illness the animal will be killed by a humane method.

Some substances have to be given to animals by injecting them in specific places. We have therefore asked to be allowed to use different administration routes (e.g. intraperitoneal [injection into the abdomen], oral [via the mouth] and intratracheal [into the lung] in this project). We will always use the least harmful route possible to give an animal

a substance. This is to make sure we cause the smallest amount of discomfort or pain to the animal.

All animals that are brought into the animal facility will be allowed at least 7 days to get used to their surroundings. This process is called acclimatisation. We will also allow them to get used to the animal technicians prior to use. This will reduce the amount of stress the animal experiences and will improve their well-being.

To improve the quality of life of our animals, we always house them in groups, unless strictly necessary due to experimental reasons or unexpected husbandry issues such as fighting.

Animals have enrichment in their cages (such as wood sticks, bedding and nesting material) for extra comfort and enhanced mental and physical health.

We will carry out pilot studies when new substances or genetically altered (GA) mouse lines are used for the first time. These preliminary experiments will be guided by the relevant literature.

Conditions are first validated in reduced cell culture pilot studies using less than 3 animals to perfect the experimental design required to satisfactorily address a particular experimental question.

Surgery procedures:

Surgery will be carried out in a clean manner (using aseptic technique). We will make sure to meet the level set out in the Home Office Minimum Standards for Aseptic Surgery and the LASA Guidance on Preparing for and Undertaking Aseptic Surgery (2017).

We will ensure that animals suffer as little as possible during surgical procedures by giving the animals medication to manage their pain under the advice of the Named Veterinarian Surgeon. We will also consider the use of medicated palatable substances for voluntary treatment such as flavoured jelly, paste or milk shake liquid.

Animals will be monitored before and after surgery to ensure that any deviation from normal health is picked up. Observations will be monitored on a chart. Animals will receive additional pain relief medication as needed, and advice from the Named Veterinarian Surgeon will be sought if animals show any deviation from normal behaviour.

Surgical procedure will be completed under inhalation-mediated anaesthesia for less than 5 minutes so that animals remain in a state of sleep/unconsciousness during the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the guiding principles on good practice for Animal Welfare. Our experiments are planned following the "Planning Research and Experimental Procedures on Animals: Recommendations for Excellence" (PREPARE) and "Animal Research: Reporting of In Vivo Experiments" (ARRIVE) guidelines. We attain to the LASA (Laboratory Animal Science Association) guidelines, as well as the NC3Rs published strategy for improving animal welfare (see publications details below):

Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217

LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. A report by the LASA Education, Training and Ethics section. (E Lilley and M. Berdoy eds.). http://www.lasa.co.uk/publications/

Smith D, Anderson D , Degryse A, Bol C, Criado A, Ferrara A, Franco NH, Gyertyan I, Orellana JM, Ostergaard G, Varga O, Voipio H (2018) Classification and reporting of severity experienced by animals used in scientific procedures: FELASA/ECLAM/ESLAV Working Group report. Lab Animal 51(1S): 5-57. doi: 10.1177/0023677217744587

Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T (2018) PREPARE: guidelines for planning animal research and testing. Lab Animal 52(2): 135-141. doi: 10.1177/0023677217724823.

For surgical procedures we follow the Laboratory Animal Science Association (LASA) Guidance on Preparing for and Undertaking Aseptic Surgery (2017) and the Home Office Minimum Standards of Aseptic Surgery.

For the breeding of genetically altered mice, we will follow the guidelines provided by the Home Office and the NC3Rs Resources on 'Genetically altered mice' detailed in:

https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_da ta/file/773553/GAA_Framework_Oct_18.pdf

https://www.nc3rs.org.uk/GAmice

Additionally, for cancer studies, we will refer to:

Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double AJ, Everitt J, Farningham DAH, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA, Committee of the National Cancer Research Institute. Guidelines for the welfare and use of animals in cancer research (2010). Br J Cancer 102(11): 1555-1577. doi: 10.1038/sj.bjc.6605642.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

At our institution, we count on with the outstanding support of our Biofacility Service. They keep us informed (through their central team) about new developments on 3Rs and offer us expert advice on how to implement them in our ongoing studies (via our very experienced team of animal technicians, Named Animal Care & Welfare Officer (NACWO), Named Veterinary Surgeon (NVS) and Named Information Officer (NIO) all of them experts in animal experimentation).

We follow the website of the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs, available at https://nc3rs.org.uk/resource-hubs). This allows us to stay up-to-date on the most relevant information.

We also use our Institutional 3Rs search tool. This contains an up-to-date database with information on the best ways to reduce or replace animals in our experiments. It also contains advice on how to refine methods in order to reduce animal stress.

Additional guidance and information on the most appropriate and refined techniques for our studies may be obtained from external sources, including:

Laboratory Animal Science Association (LASA) Institute of Animal Technology (IAT)

ARRIVE Guidelines

72. The role of the RASSF family in development and regeneration

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

tissue architecture, development, cell polarity, tissue growth, regeneration

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to understand how the complex architecture of tissues and organs is built during animal development. In particular, we will study the RASSF (Ras association domain family) proteins, which have been implicated in this process, by generating knockout mouse models for these genes and studying the impact of these genes on development and tissue regeneration. We are particularly interested in how cell identity and polarity are precisely orchestrated in highly polarised organs such as the placenta, skin and kidneys.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to build functional organs, each cell within an animal has to adopt the right fate,

shape and orientation to yield the appropriate tissue architecture. This organisation has to be maintained during adult life, and restored after injury through tissue repair. Normal tissue organisation is essential to prevent cells from becoming cancerous and disrupted tissue architecture is a hallmark of cancer.
Studying how tissues are organised during development and maintained in adult life is therefore key to understanding not only how complex organs function, but also how to prevent tumour formation.

What outputs do you think you will see at the end of this project?

The main objective of our work is to generate new knowledge and promote a better understanding of how complex organs are built during development and maintained throughout adult life. The primary output will be publication of our results in peer-reviewed journals and deposition of raw data in the appropriate repositories to make our findings available to other researchers to build on.

Our work will also generate new lines of genetically altered mice that can be distributed and used by others in the field, for future research.

Who or what will benefit from these outputs, and how?

In the short term, new knowledge on the mechanisms of organ development will be beneficial to scientists working in developmental and stem cell biology.

In the longer term, we anticipate our findings will inform future work on several disease states. Unravelling how normal development proceeds is essential to understand how organ function fails in pathogenic conditions. For instance, our work on placenta development will promote a better understanding of how placenta failure or insufficiency occurs, which is a major cause of complications during gestation. Given the strong link between tissue architecture and cancer, as well as the genetic evidence pointing at a role for the RASSF family and the Hippo pathway in cancer formation, we also anticipate that our work will benefit the cancer research community. For instance, although the RASSF family is frequently lost in a range of human tumours, there is little insight into why these genetic losses are favourable for cancer formation. Understanding the consequences of RASSF loss in tumours might lead to improved therapeutic options. Finally, our work on tissue regeneration may lead to improved strategies for tissue repair.

How will you look to maximise the outputs of this work?

In order to maximise outputs from this research, we will ensure the timely publication of our findings and we will promote our work on social media and by presenting it at international research conferences. To make our work available as early as possible, we will release pre-peer reviewed versions of manuscripts on appropriate preprint servers such as bioRxiv upon first submission to peer-reviewed journals.

Through internal and external collaborations, we will share both positive and negative results and best practice with our peers. We will share our mouse transgenic lines or tissue extracted from these models with others in the field in order to accelerate the progress of research and reduce overall animal usage.

Species and numbers of animals expected to be used

- Mice: 15600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our aim is to investigate how complex organs develop in mammalian systems, therefore mice represent the best available model, due to the many similarities with human development and the wealth of genetic tools available. The majority of our work will be performed during embryonic development and we will endeavour to focus on the earliest developmental times where a phenotype becomes manifest. For our work on tissue regeneration, we will also need to use adult animals, as the mechanisms for tissue repair during embryonic development and in adult animals are radically different.

Typically, what will be done to an animal used in your project?

Most of our experiments will involve the breeding of genetically altered animals, both for generating experimental animals and for maintenance of genetic lines for future experiments. For experimental animals, breeding will be followed by injection of a gene expression-modifying reagent (tamoxifen or doxycycline) and/or tracer dye if necessary. Upon reaching the appropriate stage, the animals (and the mother in the case of embryonic stages) will be killed and tissue will be harvested either for analysis (e.g. immunohistochemistry) or placed in ex vivo culture conditions.

For a small number of animals, adults of the appropriate genotype will undergo a standardised technique to create a small (4mm) shallow wound in loose skin on the back using a sterile biopsy punch. The aim of these experiments will be to evaluate the role of RASSF family members or functionally related proteins in tissue regeneration. Analgesia will be provided and the animals will be closely monitored to ensure their full recovery.

To generate new transgenic lines if necessary, a small number of animals will undergo surgical procedures to transfer embryos into the uterus of adult female mice. These animals will be closely monitored, and anaesthetics/analgesics will be used as appropriate.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the phenotypes will be analysed at embryonic stages, less than two thirds into gestation, when the animals are not considered sentient. We will generate genetically modified animals, the vast majority of which are expected to display either no phenotypes or moderate phenotypes such as hair loss.
Animals undergoing the punch wound or embryo transfer protocols will experience mild to moderate post-operative pain which will be controlled with analgesics. Full recovery is expected within one or two weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity is expected for up to 14% of animals. The rest of the animals will reach a maximum of mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our project aim is to understand the precise cellular interactions that allow the development and maintenances of highly complex organs. In order to tackle this question, we have used and will continue to use simple models such as fruit flies, mammalian cells in culture, computational models and different types of ex vivo cultures systems such as gastruloids. However, in order to fully recapitulate the complexity of organ development, it is necessary to observe how this occurs in an animal model, as there are currently no cell culture models that fully reconstitute this process. Since ultimately our aim is to gain insights into human development, mice are the in vivo system of choice due to the close similarities between mice and humans during development and the number of genetic tools available in the mouse system.

Which non-animal alternatives did you consider for use in this project?

As outlined above, we have used several less complex systems (fruit flies, cell culture, computational simulations) to minimise the number of vertebrate animals used in our experiments. We will continue to monitor the rapid progress in ex vivo differentiation and organoid models with a view to incorporating as many of these emerging technologies into our research as possible.

Why were they not suitable?

Cell culture-based models such as blastoids and gastruloids are showing a great deal of promise to study development, particularly its early phases. However, these models remain imperfect and fail to capture the complexities of organ formation, which involve complex interactions between many different cell types, and in many cases communication between different organs. One example relevant to our work is the interplay between the mother and embryo during the development of the placenta. Although we will take full advantage of cell culture, it remains necessary to use animals to capture the real complexity of development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our animal use projections are based on several factors:

Number of genetically modified lines we are currently maintaining.

Complexity of the crossing schemes to generate experimental animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We carefully reviewed the cross schemes required to generate the desired genotypes in order to ensure we use the minimal number breeding steps to generate the maximum number of experimental animals. We regularly review our mouse colony and freeze sperm and embryos in order to archive lines that are not immediately required. To achieve efficient colony use, we work closely with the mouse technicians in our animal unit and our institution's colony management team. Our institution also supports sharing of useful genetically modified animals such as Cre lines with other licensees in order to minimise animal usage at the institutional level. This is enabled by our sophisticated electronic colony management system.

The RASSF gene family contains 10 members, which likely perform redundant function, making the analysis of all possible mutant combinations using standard genetic approaches hugely costly in terms of animal breeding. To circumvent this problem we will screen for phenotypes in mutant combinations using mouse embryonic stem cells and in vitro differentiation protocols such as gastruloids. This will allow us to screen for combinations that elicit phenotypes prior to generating mouse lines and will therefore allow us to focus only on informative combinations. This approach will considerably reduce mouse usage for this project. Whenever possible, we will use established protocols to derive stem cells from mutant and control animals, and differentiate them in vitro into the cell types we want to study. For instance, to support our work on placenta development, we will derive trophoblast stem cells and differentiate them in vitro to compare gene expression profiles between mutant and control animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In addition to the measures outlined above, when we generate genetic combinations for analysis, we will maintain as many of the genetic elements as possible in the same line without causing harmful phenotypes in order to minimise the numbers required to generate experimental animals. Where we generate a new mutant line to investigate its phenotype, we will perform pilot studies with a small number of animals in order avoid generating a large cohort that will not present any phenotype we want to study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen to use mice for these studies for a number of reasons. They are ideal model organisms to investigate mammalian development and regeneration - their biology is close enough to that of humans for our findings to be relevant to human disease. Mouse embryonic development and biology are well described, so we will be able to identify and characterise abnormalities easily. As our primary interest is development, we will seek to study phenotypes at early developmental stages where the animal is less sentient in order to minimise suffering. Our analyses will primarily be performed on dissected tissue following the killing of the subjects via humane methods.

To study regeneration, we have chosen a punch wound protocol that induces relatively little discomfort compared with many other injury models such as liver regeneration upon partial hepatectomy or toxic substance ingestion. This protocol was chosen because the Hippo signalling pathway, which we are investigating, has been shown to affect epidermal regeneration using this experimental system.

Why can’t you use animals that are less sentient?

Most of our work will be carried out on embryos prior to two thirds of gestation, which are not considered sentient. Wherever possible, we will derive stem cells from our animals in order to reduce the number of animals we need to breed for our experiments (e.g. trophoblast stem cells for out placenta work). For our regeneration work, we need to use adult animals as the wound healing process is very different in adults compared with embryonic stages. Our work on mice will continue to be guided by our work in fruit flies and cell culture, which allows us to reduce mouse usage.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our close collaborative relationship with the staff in our animal facility ensures that animals having undergone procedures such as our epidermis regeneration protocol are closely monitored. New genetic combinations which may develop unanticipated phenotypes will also be closely monitored. In these cases, the animals will be monitored daily or twice-daily depending on the situation. Animals exhibiting unexpected harmful effects will be killed using an approved method, except in rare cases where these animals are essential for an experiment, in which case we will seeks advice from the Home Office Inspector.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow guidance and best practice provided by the NC3Rs, as well as our animal unit and scientific colleagues.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our animal unit communicates best practice and new advances in animal handling through regular newsletters and annual refresher sessions for project and personal license holders. In addition, we will keep abreast of new advances in ex vivo culture experiments through conferences and publications.

Finally, we will regularly monitor the NC3R web site for updates (https://www.nc3rs.org.uk/3rs- resources).

73. Determining what happens to intestinal T cells

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

T cells, Intestine, Memory, Infection, Inflammation

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine the nature of the memory T cell populations that are formed following intestinal infection. We will define what these cells are doing, what they are making, whether they are migratory and how they contribute to local (intestinal) versus systemic (the rest of the body) immunity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our immune systems are taught to distinguish between molecules encoded by our own DNA (termed 'self') and everything else (termed 'foreign'). Immune cells are therefore poised to respond to all foreign molecules in our body, whether they come from the food we eat, harmless bacteria that colonise different surfaces in our body or disease causing organisms (bacteria, viruses, fungi, collectively termed 'pathogens') that enter our body. The immune system is able to establish an acceptance of certain molecules that do not cause us harm, which is termed 'tolerance'. In responding to organisms that cause disease, our bodies seek to establish 'immunological memory' which refers to an improved ability to fight off a previously encountered infection and underpins vaccination. The mechanisms that dictate whether a state of tolerance is formed versus responses that

generate memory populations are key to maintaining normal functions within the body as well as keeping us healthy.

The intestinal tract is largest surface in our bodies at which we encounter foreign molecules and so the immune system is constantly active, suppressing responses to everything that is harmless (e.g. food and commensal bacteria) while suitably responding to pathogens seeking to enter the body to prevent infection. To achieve this, what happens to different immune cell populations (their ‘fate’) must be carefully controlled. While we know some of the details of this process, details of what happens to key immune cells called 'T cells' during this process remains unclear.

Crucially, when the regulation of immune responses in the intestine doesn't work properly, patients suffer intestinal inflammation. This is very common, can be life-long and highly debilitating and affects nearly 7 million people in the world. This inflammatory state is associated with an expanded population of T cells with altered functions, suggesting that something has gone wrong in regulating appropriate T cell responses and the formation of memory populations. Why these abnormal T cells have formed and how best to either control these cells, or the processes regulating their formation needs to be worked out. Therapies that seek to limit intestinal inflammation remain a work in progress, successful in only a proportion (~50%) of patients, meaning that there is a huge need for other treatments.

Through defining how different intestinal T cell populations form and what happens to them over time, basic research can help identify pathways that should be targeted in new therapies. Importantly, understanding the regulation of intestinal T cell responses is highly relevant to oral vaccination. This represents significant potential refinement to current injectable vaccines, particularly in terms of ease of delivery and required expertise, storage and distribution in less developed countries. Importantly, a lack of understanding of the memory populations that form following intestinal exposure to antigen and how this is controlled, undermines the development of oral vaccines.

In this Project we will determine what happens to the T cells generated in response to intestinal infection, how and why this affects their functions and what this means for our immune system. T cells lie at the very heart of our immune system, coordinating what many other cells in the immune system do. While our research is at the basic discovery stage, through defining the fate and function of these cells in fine detail, alongside mechanistic insight into how this is controlled, our research can influence the development of new therapies and better inform efforts to develop effective oral vaccines.

What outputs do you think you will see at the end of this project?

The key outputs of this project will be

a detailed understanding of what happens to T cells after intestinal infection, determining the types of memory cells that are formed, what they do and what kind of protection they can provide. This information will be published in scientific journals and potentially influence the design of oral vaccines.

detailed characterisation of the inflammatory T cells that are formed, why this occurs and what this means for the health of the intestine. This information will again be published in scientific journals and will support efforts to better disrupt the generation or persistence of inflammatory T cells in patients.

We have consistently published all our findings in high impact immunological journals and we will continue to do so as the best way of advancing understanding from our research. In addition we will continue to present our research findings at scientific conferences, invited seminars, interactions with industrial partners and public engagement events.

Who or what will benefit from these outputs, and how?

Short-term benefits: Our detailed in vivo research will directly benefit researchers, particularly mucosal immunologists, seeking to better understand intestinal inflammation and how to best limit or control this. It will also benefit researchers including immunologists and vaccinologists investigating how and why memory cells are formed from intestinal responses and how the factor that control these processes can be best manipulated. In addition to academic research, research teams within industry, e.g. pharmaceutical companies, can exploit our research findings to refine their efforts to manipulate key pathways operating in the intestine.

Medium and long-term benefits: Our research outputs and observations will feed through into both academic and industrial efforts to develop anti-inflammatory therapies targeting the intestine. This will feed through into better therapeutic options for patients with inflammatory bowel conditions and potentially other inflammatory conditions that are linked to intestinal health (e.g. rheumatoid arthritis). Through better defining the mechanisms controlling how different memory cells are formed in response to intestinal infection, our research can influence the refinement and improvement of oral vaccines, which ultimately can have wide reaching benefits to humanity through improved vaccine uptake.

How will you look to maximise the outputs of this work?

Throughout my research career I have actively collaborated with many researcher in my field and shared expertise, research tools and models widely and prior to publication. I think this is an essential part of maximising the outputs from basic research. I will continue to do this and further continue to instil this philosophy in the researchers of my lab. Publishing our work in high impact journals with broad readerships provides an effective means of disseminating experimental data and findings. I am also very active in presenting research findings from my lab nationally and internationally through invited seminars and conferences. Finally, I have established collaborative interactions with pharmaceutical companies and will continue to develop these to maximise the influence of our research activity.

Species and numbers of animals expected to be used

- Mice: 12,700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will use mice to further our understanding of what happens to T cells after intestinal infection. The intestinal tract is far too complex to accurately model through non-animal methods currently available (e.g. in vitro cultures). This is because not only are

there many different immune cells that must be considered due to their interactions, these cells also move between different areas of the tissue and even between tissues, which further changes what they do and why. On top of this, the epithelial lining of the intestine plays a key role in controlling the response and furthermore, all of this is influenced by the commensal bacterial populations of the gut. In summary, such a collection of cells, which exist in their own dynamic microenvironments cannot be recreated with the complexity required using cell culture systems. This really means that the only way to control for all these parameters is to study what T cells do within the intestine of a living animal. This ensures that the data we acquire is of maximum relevance to human patients suffering from intestinal inflammation and the better development of oral vaccines.

We have chosen mice as our animal study for the following three key reasons:

The main components of the mouse immune system shared by humans, making the mouse an excellent model of the human immune system.

The mouse immune system has been extensively studied already, meaning that there are an extensive range of reagents available to help careful study of what mouse immune cells do and why. This is important because it means we can use pre-existing data, we don't have to validate evidence in a new species and our research is not restricted by a lack of experimental tools.

There are many genetically modified mice available which enable detailed information about what cells do or how they behave. This is hugely important, particularly in this Project as it means we can understand cell functions, which cannot be captured by other approaches - for example tracking the movement of cells within the intestine and between the intestine and other tissues. The immune system alters over the course of development, and our research is focussed on functionality in the adult. For this reason we will use adult mice.

Typically, what will be done to an animal used in your project?

In a typical experiment on this licence, mice will be infected via oral gavage with a natural mouse bacterial infection that colonises the intestine. Most infected mice will additionally be injected (typically by intraperitoneal injection) with reagents (maximum frequency of daily, maximum number of 14 injections) to try to manipulate the response to the infection. The bacterial infection lasts approximately 3-4 weeks and is then naturally cleared by the mouse.

In some experiments we would test whether the initial infection had successfully caused the formation of a memory response by re-infecting the mice 6 wks after the initial infection, again by oral gavage and testing whether they make a better response. During the experiment we would measure how well the mice were controlling the infection by analysing bacteria in the mouse faeces.

In other experiments, we will induce intestinal inflammation to model that experienced by IBD patients. TO do this mice will be given water containing 3% dextran sulphate sodium which causes damage to the lining of th intestine and induces local inflammation. Mice undergoing this procedure will experience up to 2 periods (each of 1 wk duration) of drinking water containing 3% dextran sulphate sodium.

In some experiments we would directly assess the intestine using a mouse endoscope inserted into the rectum of the mouse while it was anaesthetised. This would typically only

be done once. Using this endoscopic approach we use light to trigger a label in the intestinal cells so that any subsequent movement into other tissues can be identified post-mortem. Mice will only undergo this labelling approach once. The vast majority of experiments would last for less than 8 weeks and at the end all animals will be humanely killed and tissues taken post-mortem for analysis'

What are the expected impacts and/or adverse effects for the animals during your project?

All mice on the project will experience temporary discomfort and stress from the handling and process by which the mice are infected. Our typical intestinal infection model does not cause overt clinical symptoms and is naturally cleared by mice without inducing adverse effects such as pain from intestinal inflammation. In mice that are given drinking water containing 3% dextran sulphate sodium, these animals will experience local inflammation in the colon and will suffer weight loss (typically up to 10% body weight). Mice on experimental protocols will continue to experience intermittent stress from restraining them (for injection) and discomfort from further injections, which we will keep to the minimum required and the least painful injection route. Mice undergoing endoscopy will do this under anaesthesia, limiting stress and discomfort from this procedure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum expected severity on any protocol is moderate. For approximately 60% of the mice this reflects the cumulative effect of several interventions which individually would be considered mild (e.g. infection by oral gavage, intraperitoneal injection, re-infection) but as the mice will experience these interventions several times an overall severity of moderate is appropriate. Approximately 20% of the mice will experience moderate severity where we will induce intestinal inflammation. Approximately 20% of the mice are expected to only experience procedures of a mild severity, through only a very limited number of interventions.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To investigate what happens to T cells following intestinal infection, which includes understanding of what cells they become, where they go, what they do and why, it is impossible to study this without study a living animal and the different tissues and conditions that exist. The intestinal tract is hugely complex mixture of many cell types (immune cells, epithelium, commensal bacteria) and these cells constantly interact and regulate what happens to each cell type. Furthermore, the majority of these cells are not

static and both move between areas of the intestine and even between the intestine and other tissues. In addition other parameters change regularly over time (e.g. nutrients, metabolites) in relation to the 'body clock'. It is not possible to effectively model this environment nor the cells within it in a way that captures even a fraction of the normal cellular behaviours and interactions. Findings from only non-animal experiments would still then require extensive validation in an animal model before there relevance to human patients could be assessed and confirmed.

Which non-animal alternatives did you consider for use in this project?

We do exploit in silico (computer-based) approaches to capture existing information from previous studies. With the advent of sophisticated cell sequencing and bioinformatics approaches, which we will continue to use throughout this project, in silico studiesform the major non-animal approach we use. These experiments can provide clear direction in which molecules to try to manipulate to control what happens to intestinal T cells.

We also considered organoids, which can enable the study of single cell types in a more 3D environment and even multiple cell types for example intestinal epithelium organoids. We further investigated 3D culture approaches using a 'framework' approach where cellular interactions are enhanced. One type of cell culture approach, where we push T cells into different developmental states can be used to initially test potential interventions before some are then validated in mouse models.

Why were they not suitable?

We concluded that neither organoids nor 3D culture models would be appropriate as they completely fail to accurately model so much of the intestinal environment. Organoids cannot recapitulate the intestinal architecture, which we know has huge influences on the immune response. Currently, no in vitro model (3D culture nor organoid) can recreate the complexity or dynamism of the intestinal immune system. Furthermore, this approach would ignore the microbiome, which dramatically impacts the intestinal system and many bacterial species found in the gut cannot be cultured in vitro. Modelling all the communities of cells within the intestine and how they interact is currently not possible.

In silico models are excellent at capturing descriptive data and we will continue to inform our in vivo projects where possible, but they do not provide the means to test 'cause and effect' nor determine functional outcomes. We will screen initial candidates using in vitro T cell cultures and this will enable us to rule out some pathways/approaches that do not function as predicted from the in silico approaches.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In calculating the number of mice we will use, I have reviewed data over the last 10 years of my animal returns on my existing and previous PPLs. The number here reflects the

need to maintain an extensive breeding colony to generate sufficient experimental mice across multiple genetically modified strains.
Furthermore, efforts to reduce experimental variability, for example through using age and sex- matched animals within an experiment, or the correct use of littermate controls in conditional knockout mice experiments, means that a large colony of mice for each strain is required to ensure that sufficient numbers of the desired mice are available. For individual experiments, the number of animals required is calculated based on data obtained from previous experiments, pilot studies, and information in the literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In designing this experimental body of work, we considered our previous experience of experimental models to investigate T cell responses and have also utilised the NC3R's Experimental Design Assistant. It is our extensive experience in using the approaches described here that really enables us to keep the number of mice used in this project to a minimum. We have selected only those experimental models that gave the most robust and quantitative analysis of the intestinal T cell response and eliminated other experimental approaches where there was greater experimental variability or less clear means of definitively testing T cell function.

Through extensive research in the lab we have further optimised our understanding of the infection models underpinning this project and identified the key time points that need to be assessed. This reduces the number of analysis points when mice might be killed. Furthermore, we have developed robust means of monitoring the infection over time through counting bacteria within the faeces and extensively validated this approach. This means that infections can be tracked over time through a completely non-invasive (faeces sampling) method, eliminating the need to kill mice at specific time points to capture information regarding the progression of the infection. Through establishing and sustaining a productive collaboration with industrial partners, we are able to acquire reagents that have been extensively validated in vivo and generated to extremely high standards. This massively reduces the numbers of mice needed to test new compounds that we want to use in our studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continue to monitor mouse usage on our projects by constant and careful consideration of the data and its appropriateness in addressing our experimental objectives. In developing our models we reassess group sizes as our experience develops and we will continuously look to use the minimal number of mice that provide robust experimental data adhering to standards of experimental reporting laid out in the Arrive 2.0 guidelines. In our publications we endeavour to fully report our data adhering to these guidelines to ensure experimental transparency and ensure that experiments do not need to be further repeated due to any ambiguities in their interpretation.

While our experimental models are all established and optimised, we will likely test new reagents in targeting pathways that might regulate T cell function. When this occurs, we will use small scale pilot experiments (n=3) to first test the novel reagent. Furthermore, through many years of active collaboration with industry, we typically acquire reagents from these collaborators (e.g. blocking antibodies for in vivo). This ensures numbers of mice used can be kept to a minimum as these items have been extensively validated previously and we adhere to the recommended dosing regimen in our pilot study, ensuring

less animals need to be used in establishing the experimental setup in our models. Furthermore, the purity of these reagents is often substantially higher than what is provided through commercial sources ensuring less experimental variability and smaller group sizes.

Over many years of supervising my own mouse colonies, I have developed extensive experience in efficient breeding strategies. A key approach in our experimental models is that through tracking endogenous antigen-specific responses, the data is highly consistent between experiments (rather than in models where TCR transgenic T cells are transferred for example). This means that data from different experiments can be pooled to reach the desired number of mice per experimental group. Therefore we use mice as they become available, rather than trying to generate large cohorts and this is a considerably more efficient means of breeding the mice with less mice generated and not used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In all of our experiments we use mice to study intestinal immune responses and in most experiments we only use genetically modified mice. We have selected genetically modified mouse models that enable robust testing of our experimental questions with minimum further manipulation (to reduce stress and discomfort through procedures) and minimum pain through tissue inflammation or damage. We have developed refined infection models and ways to assess the response to these infections.

For example:

To definitively test the role of specific pathways within intestinal T cells, we have developed models in which the responding T cells delete key genes involved with the process during their development - i.e. they do not require further manipulation/intervention such as injection of a compound to induce gene deletion.

We have developed experimental infection models that use either natural mouse pathogens which cause robust immune responses in the absence of extensive tissue inflammation, or attenuated infections where the side effects (pain through tissue damage and inflammation) experienced by the mice are substantially reduced. This means that we can drive the T cell responses we need to study using infections that cause very limited symptoms for the mice.

We use approaches to label cells within the intestinal tract using an endoscopic approach rather than surgical approaches used by other groups in the UK. This means that highly invasive surgery is not needed and the approach massively refined to cause at worst only temporary discomfort from having the endoscopy (done under anaesthesia).

We can track the progression of the infection through counting bacteria from the faeces, which can be easily collected without any discomfort to the mouse. This is substantially more refined than trying to monitor the progression of the response by analysing immune cell status within blood samples taken during the course of the infection.

Why can’t you use animals that are less sentient?

Mice are the least sentient animal species we can use. The only other model that could conceivably be used that are less sentient would be zebrafish and here the immune system and physiology is considerably different to that of humans and the relevance of our findings would be much less clear (and likely would need testing in another animal model before being relied upon for translational work). Furthermore, many of our experiments exploit the genetic modifications available in mice to maximise the detailed functional questions we can ask to provide critical new insight of relevance to human patients with intestinal inflammation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have extensively refined our experimental approaches over the last PPL and continue to review our methodology. We have consistently worked with staff in the animal facility to refine experiments and will continue to seek their advice on this project. We have reduced the need for surgical interventions through developing ways that label cells without the need to expose the target tissue. We have tested and then started to use infection models that can be monitored using analysis of faecal samples (which can be acquired with no harm or distress to the mice). Model refinement is an active and continual process that requires careful consideration of all stages of the experiments. This ethos is instilled within researchers in my lab.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All the researchers in my group are aware of the revised Arrive 2.0 Guidelines developed by the NC3Rs and recently published. We have consistently endeavoured to publish our research to the original ARRIVE standards and will continue to maintain this publication standard to ensure experimental transparency and reproducibility. In planning our experiments, we work to the PREPARE and LASA guidelines. This is taught to members of the lab when they arrive and actively discussed as researcher learn how to plan and then conduct in vivo experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Within our lab we continuously scrutinise the literature for experimental advances that might enable further refinement of our models, reduction in the number of mice used or ways to entirely replace in vivo experimentation. All members of the lab are actively encouraged to engage with this. We also engage with presentations and symposia organised by the animal facility and the NC3Rs and receive their emailed news updates. Both I and members of my lab have presented in 3Rs themed sessions, highlighting experimental refinements we have developed to try to benefit other research groups.

74. Viruses and viral vaccines research

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

virus, viral vaccines, developmental vaccines, immunogenicity, infectious disease

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult
Guinea pigs	adult
Ferrets	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To study viruses of consequence to public health to better understand their biology, natural immunity to the viruses, surveillance and health control mechanisms. The information informs the development and refinement of vaccines against viral diseases, enhances our understanding of the immunogenicity induced by vaccines, allows us to develop reagents and tests that can assess the biological quality, safety and stability of vaccines, including the vaccine viruses, vaccine formulations and viral vectors that are used in their manufacture.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK alone, an individual will be offered circa 11 individual vaccines to afford them with protection against 8 viral infectious diseases by the time they are an adult, more if they are immunocompromised. The adult vaccination programme adds further protection, the annual influenza vaccination campaign is designed to minimise serious illness from this underestimated disease, and travel vaccines can prevent serious mortality or morbidity as a result of contact with viruses such as Yellow fever virus, Dengue virus and Japanese Encephalitis virus. While many of these diseases seem inconsequential in modern times, influenza is the cause of 1000s of deaths annually in the UK and it is not so long ago that measles and polio caused significant mortality in this country - elsewhere in the world, these and other viral infections remain significant threats to human health, particularly in vulnerable populations such as neonates, the elderly and those living in impoverished situations.

In 2020, the WHO declared a pandemic resulting from the SARS-CoV-2 virus which causes COVID-19. This is the third pandemic of this century arising from a Coronavirus; there have been significant outbreaks of Ebola, Ziika and influenza.

Vaccines are a proven defence against infectious disease. The research and development of vaccines requires significant understanding of the natural biology of the virus causing the disease, such that vaccines are fit for purpose. It is essential that the quality of vaccines that will be used in healthy individuals and patients can be assessed by accurate and sensitive assays for specific properties - immunogenicity, safety, activity, biological quality et cetera. The work under this Project Licence will allow us to assess candidate vaccines for these properties.

What outputs do you think you will see at the end of this project?

Scientists at the Establishment participate in scientific conferences, meetings of scientific consortia etc, often including key international establishments and institutions. Here, data are discussed such that knowledge sharing can be accelerated, resulting in scientific advances in vaccine development and evaluation, with a view to bringing these nearer to licensed use in humans.

We expect to publish scientific papers in open access journals (i.e. available without the reader needing to pay) describing some of the studies that have been undertaken and the ensuing results. This dissemination of results can also help to avoid unnecessary duplicate testing using animals in other establishments.

Who or what will benefit from these outputs, and how?

Ultimately, the benefits of the work in this licence is any individual in the world who receives a vaccine against a viral disease. Such vaccines will have gone through extensive research and development phases. The work undertaken at the Establishment is critical to the collective knowledge of the potential utility, immunogenicity and safety of candidate vaccines.

How will you look to maximise the outputs of this work?

Scientists work collaboratively both nationally and internationally, which can incorporate research supported by funding bodies. Information is shared through these networks of scientific research as well as at scientific conferences.

Whenever possible, scientists publish data in scientific journals - these are 'Open Access' so that anyone can access them free of charge online. Key outputs are made available on the establishment's public-facing website.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 6000
- Rabbits: 100
- Ferrets: 550
- Guinea pigs: 20

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are tractable models for understanding key aspects of an immune response to in- development vaccines. Guinea pigs are small animal models for production of antiserum. Rabbits are a well-recognised model for the production of a broad ("polyclonal") immune response and with a greater body size, it is possible to generate volumes of antiserum that would require multiple rodents.

Ferrets are among the few animals other than primates whose response to infection with influenza reflects that of humans; both the immune response and the clinical signs closely resemble that seen in humans.

Animals in which immune responses are required are selected as adults since very young animals may have an immature, and therefore incomplete, immune response to the virus or other immunogen - this would possibly lead to a sub-optimal product.

Typically, what will be done to an animal used in your project?

The studies require inoculations and boosters of antigenic material (including but not limited to virus, virus components, nucleic acid for example) with or without adjuvant into animals using a range of administration routes including but not limited to oral, intramuscular, intraperitoneal, intradermal, transdermal, intranasal or subcutaneous. The most appropriate route would be selected based on the nature of the antigen. It may be necessary to determine the most appropriate delivery route to induce the optimum immune response from a new candidate vaccine.

Animals may have a maximum of 2 boosters (total of 3 immunisations), typically at weekly intervals;

Ferrets and mice may be challenged with influenza viruses, typically lasting 3 weeks, to assess the protective nature of candidate vaccine materials.

Blood collection will be undertaken, typically weekly.

Nasal washes, oral swabs and ocular swabs may be taken to assess antibody secretions, typically weekly.

Immunogenicity studies will typically be no longer than 6 months in duration; challenge studies may be shorter in duration.

Administration of antivirals orally to ferrets to ameliorate infection and symptoms due to infection by virulent influenza, and to reduce the likelihood of disease progression to the severity limit. Delivery will be twice daily for 7 days. The experiment will not typically exceed 3 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Experience with the procedures in this Licence has been gained over previous 5-year iterations of the work at the Establishment.

General:

Typically the majority of animals used are not expected to experience significant ill-effects.

For any animal being immunised there may be some local irritation at the site of inoculations particularly where adjuvants are used (adjuvants are chemical compounds that increase the immune response to an inoculation). Exudative skin lesions at the site of inoculation are very rare, are expected to respond to local treatments and would be expected to improve within 24 hours: if the status does not show signs of improvement with minor interventions such as those advised by the NACWO and/or NVS,within 24 hours the animal will be culled.

Blood sampling procedures are expected to cause no more than minor transient discomfort. Very rarely haemorrhage, bruising, or haematomas may occur – the incidence of these will be minimised through good technique, use of needles of appropriate size and by applying continuous gentle pressure to the site after sampling. Single-use needles are employed. Maximum blood draw volumes will be adhered to and are based on Laboratory Animal Science Association (LASA) guidelines with expert input from NVS and/or NACWO.

In the unexpected / rare case where any animal is unable to readily feed or drink as a result of their condition will be killed immediately. Any animal with deviation from normal health or behaviour which can’t be alleviated with minor interventions such as those advised by the NACWO and/or NVS, within 24 hours will be culled.

Any animal displaying neurological clinical signs, which may include symptoms such as ataxia or seizures will be culled immediately: this is expected to affect Nil to a minority of animal only.

<u>Mice, Ferrets:</u>

The adverse effects of influenza include rhinitis, fever and lethargy. Animals infected with virulent influenza viruses such as potential pandemic avian strains will usually develop

fever, loss of appetite and reduced activity levels. Sneezing, nasal discharge, partially obstructed breathing due to mucous production and diarrhoea may also occur, as can be observed during human illness. Piloerection may be seen in mice. Anti-viral drugs will be administered to ameliorate infection and symptoms. The virulence for ferrets of these viruses is variable and unpredictable, but if any symptomatic state persists for more than 24 hours, or an animal develops further signs of ill-health, action will be taken to minimise the adverse effects and suffering of the animal. There may be weight loss: a loss of up to 10% (Mild Protocol) or 15% (Moderate Protocol) which does not appear to be resolving (possibly by making available different food stuffs to encourage eating) will result in the animal being terminated. While analgesic and anti-virals may be used, if humane end points are reached, the animal will be terminated to ensure no further suffering.

Rabbits:

The use of a specific adjuvant in rabbits has been reported by this Establishment and informally by others to be associated with the risk of developing granulomas approximately 1 week post inoculation. To minimise this risk, the maximum number of inoculation sites for rabbits has been increased from 2 to 4 to minimise the inoculum volume at any one site. The areas of inoculation are depilated by clipping to improve accuracy of inoculation. Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The overall severity under this licence ranges from Mild (Protocol 1) to Moderate (Protocol 2, 3).

For the animals that will be infected with virulent influenza, the severity may be moderate. Since the outcome of these infections can be unpredictable the animals will be monitored very closely for signs of, reduced food intake, reduced water intake, lethargy, and will be treated with antiviral medication to limit the symptoms they experience due to the infection, with particular review of the control groups (where used).

Protocol 1 will be the most applied Protocol: this incurs the least clinical impact (Mild) thus total number of animals expected to experience moderate severity is likely to be far less than the maximum indicated for the PPL.

Mice - Mild or Moderate (approx. 60:40 ratio)
Rats - Mild
Guinea pigs – Mild
Rabbits - Mild
Ferrets - Mild or Moderate (approx. 65:35 ratio).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The data to be achieved concern the immune response and, in some cases, the protective immune response to viruses and vaccines and the pathogenesis of disease. The components of the immune response are complex and need to have a broad activity against the viruses and vaccines candidates that can mimic what might be observed in higher vertebrates - humans. Because of the complexity of the vertebrate species immune system, these can only be generated in protected animals. The same biological complexity and quality cannot be achieved in a non-animal system currently. Should the immune response to a specific antigen/antigen mix be fully characterised it might be possible to mimic this with monoclonal antibody cocktails – this will require significant research, with consideration of scientific data published in the literature, to ensure the in vitro approach is representative of the in vivo one for each antigen combination. While this is not the focus of this PPL, this would provide information that could support in vitro methods for future regulatory approaches for approved vaccines.

In some cases, data will be generated to validate in vitro assays with a future view to eliminating the use of protected species.

Which non-animal alternatives did you consider for use in this project?

Since the project licence covers activities to better understand the immunogenicity of vaccine candidates, the use of animals cannot be avoided. However, the generation of antibodies in species such as guinea pigs and rabbits will allow us to generate materials that can be produced in volumes sufficient for preparation and storage, such that they do not need to be produced fresh for each experiment.

The establishment is engaged in research into developing antibodies and nanobodies in vitro, e.g. by phage display, which would ultimately be able to replace the use of animals. However, it would be necessary to first understand the natural immune response before it can be reliably replicated in vitro. Equally, the establishment reviews the scientific literature and scientific collaborators etc should advances be made in other laboratories that can influence the animal studies and reduce the requirements for animals.

The use of cells to produce the candidate vaccine that is then used to immunise an animal removes the need for propagation of the material through an in vivo system.

Why were they not suitable?

As above, since the project licence covers activities to better understand the immunogenicity of vaccine candidates, the use of animals cannot be avoided since a fully-functional, complete immune system is required.

The elucidation of the broad immune activity of antibodies is not predictable, thus for the different novel, in-development, vaccine / virus preparations under consideration, challenging a complete vertebrate immune system will yield the necessary polyclonal response that would mimic that raised by a human if infected or vaccinated. Understanding fully the immune response in an animal is required to be able to develop in vitro alternatives (using methods such as that above) that simulate the response needed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The work under this project licence has been undertaken for many years. The numbers reflect previous years' use and allows for some flexibility should additional work need to be undertaken.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The numbers are based on previous experience and for the most part are unchanged since similar testing requirements are anticipated over the next 5 years.

During the course of the previous iteration of work covered by this PPL, the number of rats was adjusted given the increase in testing required for a range of enterovirus candidate vaccines. This is reflected in the absolute number of tests undertaken whereas the group size remained the same. This represented an increase in the overall number which has been reflected in this current PPL.

Statistical advice is available in-house to optimise appropriate group sizes based on the proposed study scientific outputs.

WHO guidelines indicate the numbers of ferrets to be used to test the safety of pandemic vaccine viruses and we can refer to this for establishing the studies under this PPL.

Higher inoculum volumes used to infect mice and ferrets with influenza viruses produce more reproducible clinical disease. Use of higher inoculation volumes will reduce the numbers of animals required for challenge studies with influenza virus. Maximum volumes will only be used where virus pathogenesis and disease are critical to the study design.

We will use archived materials, such as antiserum, from previous experiments and as far as possible these will be used in place of new animal studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers of animals used under the Protocols will be the minimum required to obtain sufficient biological materials and data as based on historical scientific data and experience with the species.

The individual project plans will include a pre-study meeting to identify the number of animals required per group, in cases where the experiment has not been previously undertaken. In-house statistical expertise is available for this purpose.

Where we may undertake collaborative or contract work, we maintain dialogue with vaccine developers to determine if (and when) they can use less volume of sera to test their products, and if so we will be able to reduce the amount we provide and thus reduce the number of animals in any one study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents (mice, rats) - these animals typically will be used for the majority of the studies to investigate immunogenicity of candidate vaccine viruses. These are the least sentient animals for this purpose and are well-established in the literature for their suitability.

Rodents (guinea pigs) - generation of antiserum; Guinea pigs will be anaesthetised and bled by an appropriate blood vessel prior to and/or following immunisation: they will be bled on not more than three occasions with typically 2 weeks between bleeds.

Mice and Rats are housed in socially compatible groups. Guinea pigs will be housed in socially compatible groups whenever possible and always in floor pens.

Rabbits - generation of antiserum. Experience on an earlier licence has refined the inoculation of rabbits and thus exudative skin lesions at the site of inoculation are not expected.

We have refined the method of delivery of adjuvanted antigen during the course of a parallel and current PPL to minimise the risk of granuloma. The use of a specific adjuvant in rabbits has been reported by this Establishment and informally by others to be associated with the risk of developing granulomas approximately 1 week post inoculation. To minimise this risk, the number of inoculation sites for rabbits has been increased from 2 to 4 to minimise the inoculum volume at any one site. The areas of inoculation are depilated by shaving to improve accuracy of inoculation. Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin. By adapting the inoculation process the likelihood of granuloma is reduced and thus the potential for lasting harm is likewise minimised. Should granuloma form, it is possible to pause the protocol until the animal recovers sufficiently, and then select an alternate site for inoculation if needed.

Rabbits will be housed in socially compatible groups whenever possible and always in floor pens.

Ferrets - infection with influenza viruses and generation of small volumes of antiserum. In order for the ferrets to seroconvert they must be actually infected with the influenza virus, which can lead to clinical signs, and be kept alive long enough for antibodies to be produced by B cells. For animals infected with virulent influenza we will use antivirals to

reduce the clinical effects of infection: animals can be given antivirals by the oral route twice daily for 7 days beginning 2 days following an initial intranasal administration of antigenic material. It is recognised that group housing is preferable for optimum well-being of ferrets and wherever possible they will be group housed. Where possible, the use of remote measurement of body temperature will minimise the amount of animal handling required and thus keep stress levels to a minimum.

For mice and ferrets that will be infected with influenza viruses: a clinical scoring spreadsheet is in use to best monitor the clinical severity of any one animal such that interventions can be made to minimise pain, suffering, distress or lasting harm. These might include access to more palatable foodstuffs where weight loss is increasing, or the application of analgesics to ease the effect of symptoms (see below). For all animals: analgesics will be administered where needed and where their effect will not interfere with the scientific outcome of the study.

Throughout, experiments will be kept to the minimum duration to gather meaningful scientific data.

Why can't you use animals that are less sentient?

Mice and Rats are well-established in the literature for their suitability as infection models to assess immunogenicity of antigens / candidate vaccines. A mammalian model is required to present a complete immune system response to an antigen. An immature response (i.e. from a more immature development stage) may not reflect fully the requirements for a vaccine.

Ferrets are among the few animals other than primates whose response to infection with influenza reflects that of humans: both the immune response and the clinical signs closely resemble that seen in humans. Methods for more frequent observation of clinical signs have been developed for earlier recognition of onset of disease allowing earlier intervention with the use of medication to relieve symptoms or termination as appropriate. Data accumulated over the years indicate that the specific immune response is highly predictive for when a strain is sufficiently different from those that have gone before to warrant a strain change in the vaccine. The relationship is far less clear-cut for other species such as mice where infection is usually more restricted.
Rabbits are suitable for large volumes of polyclonal antisera. To generate the same amount of serum in rodents would require substantially more animals.

Guinea pigs will be used where only small amounts of serum are required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals are habituated prior to commencement of study, typically for 7-10 days.

Inoculation volumes are based on those recommended by LASA and others; they are the minimum required at any administration site. These have been shown to be appropriate over the previous licence.

We have made changes to practices under the previous PPL such as refinement of inoculation of rabbits to minimise the risk of granuloma formation. The number of inoculation sites for rabbits has been increased from 2 to 4 to minimise the inoculum volume at any one site. The areas of inoculation are depilated by shaving to improve

accuracy of inoculation. Attention is paid to delivering inoculum with no seepage from the needle prior to inserting needle and on removal, thereby minimising irritation to the skin. Reinoculation (boost) of rabbits that do develop granuloma can be paused until the animal is considered recovered.

Haematomas can occur following withdrawal of blood. This has led to routine use of needles of a shorter length and smaller gauge reducing the risk of bleeding without compromising the quality of the sample.

We have a programme of continual improvement to animal housing, husbandry and handling aimed at minimising stress in animals and encouraging natural behaviours.

Animals undergo thorough pre- and during-study checks. Analgesics will be administered where needed and where their effect will not interfere with the scientific outcome of the study. Clinical signs can be ameliorated by the use of antivirals (ferrets) or analgesia (ferrets, rabbits, rodents), for example.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance is available through Home Office including newsletters via the ASRU.

LASA and FELASA guidelines will be applied to guide dose volume/route per laboratory animal subject and surgical procedures.

NC3Rs documents on husbandry, housing and procedural work will be met or exceeded.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment's AWERB circulates up to date information on the 3Rs through the Named Information Officer (NIO). Similarly, the licence applicant is on the email circulation list for the NC3Rs bulletins.
The PPL holder will work closely with the NACWOs and NVS to ensure that changes to the animal studies are improved wherever possible. This may be reflected in changes to husbandry and animal handling practices, refined procedural activities, and advances reported in the scientific literature or at scientific conferences/meetings that could result in use of a less sentient species, fewer animals in experimental groups, or non-animal alternatives.

Information exchange between PPL holders at the Establishment, in concert with the animal facility staff at the Establishment, will be used to refine the work programmes as necessary.

75. Efficacy of veterinary medicines, biologicals, feedstuffs, feed additives, residues and vaccines in the target species, including first use.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Efficacy, Antimicrobial, Vaccines, Infection, Parasiticides

Animal types	Life stages
Cattle	juvenile, adult
Sheep	juvenile, adult
Pigs	juvenile, adult
Domestic fowl (Gallus gallus domesticus)	adult, juvenile
Domestic poultry	juvenile, adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to assess the efficacy of compounds that may prevent animal diseases from developing or progressing. There is a constant need to combat the development of drug resistance by parasites and microorganisms. Novel and existing compounds need to be developed, tested for efficacy and brought to market and evaluated appropriately eg. against current field strains to ensure that they are effective.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

It is important to conduct animal studies looking at the efficacy of a new or existing medicine, biological, feed additive, feedstuff or vaccine to ensure they are effective against established field strains of microorganisms and parasites. Efficacy tests are a crucial step for new or repurposed pharmaceutical and other products on their journey to market, including being approved by the appropriate regulating authority.

What outputs do you think you will see at the end of this project?

Multiple scientific reports for the sponsoring organisation that will potentially lead to new treatments for animal diseases, illnesses and conditions that cause economic and animal losses each year. Our continuing input into fundamental animal health research and scientific papers is published in high impact journals. We also play an active role in maintaining and updating guidance on animal health and wellbeing and best practise for these types of efficacy studies.

Who or what will benefit from these outputs, and how?

Animals, pharmaceutical and other companies, farmers and the wider economy will all benefit from the research carried out by our company. The testing facilities provided may result in new and novel products being brought to market to help alleviate many different animal diseases and conditions. Therefore, this benefits the animal’s wellbeing and health, farmers see improved yields and less expense for veterinary treatment and pharmaceutical companies see profits by marketing their product. These factors combined stimulate and help the wider economy to grow within the UK.

How will you look to maximise the outputs of this work?

We will work with companies, institutes and charities to disseminate the study findings, publish research papers, attend relevant conferences and play an active role in creating guidelines in this area of research.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 4000
- Other birds: No answer provided
- Sheep: 200
- Cattle: 300
- Pigs: 125

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Many of our efficacy studies are conducted in the target species for authorisation and/or support of a veterinary medicine, biological, residue, feed additive, feedstuff or vaccine and such testing is required by the regulatory authorities. There is an internal policy of checking whether non-animal alternatives are possible, for example by regular visits to the NC3Rs website (http://www.nc3rs.org.uk) and attending relevant conferences. Where there is a validated and appropriate in vitro model then the client would be informed and the in-vivo work refused unless there is a specific exemption and it is agreed with the Home Office.

Typically, what will be done to an animal used in your project?

Administration of substances / vaccine via; oral gavage, inclusion in the diet/drinking water, injections (either subcutaneous, intramuscular or intravenous), topically to the skin (e.g. plunge dipping, spraying, impregnated ear tags, collars or similar devices), implanted subcutaneously, by ear piercing e.g. an ear tag, intranasally or intramammary (via the teat canal).

Animals may be singly housed and veterinary or husbandry treatments may be withheld or varied.

The target animal may be challenged with infective parasite larvae, protozoa, bacteria or virus particles which may be administered by; mouth, nasally using a pipette (or similar device), topically to the skin (e.g. spray or pour on or by skin scrape), the mammary gland (via the teat canal), exposure to infectious agents in the environment, intravenous injection of blood borne pathogens, exposure via insertion in the cloaca. Probes may also be placed in the vagina and/or rectum.

Animals may be dried off.

Animals may have blood samples taken pre and post mortem with the possibility of cannulas being inserted into superficial blood vessels.

Percutaneous secretion sampling by needle aspiration from the dry and lactating mammary gland to allow aseptic sample collection avoiding the streak canal. This will be used once in the last 24 hours of a study. Faeces may be collected by manual removal from the rectum or sample collection from the cloaca.

Environmental temperature may be varied (protocol 7 only).

Feed may be withdrawn up to 24 hours before post mortem. Biopsies or scrapes of superficial tissues may occur.

What are the expected impacts and/or adverse effects for the animals during your project?

Likely adverse effects:

Veterinary medicines:

There may be signs of local or systemic treatment intolerance. These include:

local reactions either injection site reactions or site of application reactions (including signs of pain associated with the area, swelling, skin changes)

systemic reactions to the substance (behavioural changes, mobility changes, feed intake and weight gain changes, organ system changes)

The volume of blood removed could result in anaemia or systemic signs. Guidance table will be used to prevent this.

Vaccines:

There may be signs of local or systemic treatment intolerance particularly where multiples of normal or proposed vaccination dose rates are used during target animal efficacy studies.

These include:

local reactions either injection site reactions or site of application reactions (including signs of pain associated with the area, swelling, skin changes)

systemic reactions to the substance (behavioural changes, mobility changes, feed intake and weight gain changes, organ system changes)

Vaccination could result in an anaphylactic reaction. Artificial Infection:
The levels of infection chosen should not cause clinical disease of beyond moderate severity.

the severity limit could reach the upper border of moderate e.g. in sheep when conducting ectoparasite studies e.g. with Lucilia sericata.

normally, mastitis-causing bacteria will be chosen that would not be expected to cause systemic disease, however the upper border of moderate could be reached.

infection levels could build up e.g. on pasture during a grazing season, depending on climate and other factors.

Withdrawal of feed could result in stress in individual animals.

Increased stocking density (only birds) potential adverse effects are:

Heat stress

Pododermatitis

Lameness

Increase in sparring behaviour in cockerels Necrotic enteritis (Clostridium perfringens)
Severe depression

Diarrhoea

Dehydration

Decrease in feed consumption
Ruffled feathers

Reluctance to move Salmonella spp.

Diarrhoea (often white and watery)

Dehydration

Decrease in feed consumption

Decrease in egg production

Reluctance to move Campylobacter spp.
Up to 15% mortality rate

Decreased egg production

Rapid death due to hepatic necrosis Bacterial enteritis
Diarrhoea

Stable feed intake in growing birds

Depression

Ruffled feathers

Huddling

Sudden increase in death rate

Likely incidence:

The compounds may have undergone preclinical studies in rats or mice but these may be the first studies in the target species. It is expected therefore that, on occasion, there may be either transient clinical signs or mild lasting clinical signs that may reach the moderate severity category. For example, injection site swelling or tissue changes and swelling.

Repeated blood sampling could result in clinical signs after either a large volume is taken on a single occasion or repeated sampling over a period of time. This is very unlikely to occur as the guidance in the table within this document will be followed.

Anaphylactic reaction should be a rare result of vaccination with a product that is intended for commercialisation and would not be expected to occur in these studies.

Measures to prevent, recognise and control occurrence and severity:

prior knowledge will be reviewed to ensure that doses and dose-rate multiples are unlikely to exceed moderate severity. If they are deemed likely to exceed moderate, the work will be declined or the work will be discussed with the Home Office Inspector

the individual study protocol will include adverse events that might be seen with the substance or substances together with an assessment of their severity and a cut off limit of moderate

Animals will be closely monitored throughout the study to ensure that there are no adverse effects and should these occur they will be monitored and veterinary advice and treatment sought or the animal euthanased if the upper border of moderate severity is reached. Monitoring will focus particularly on periods when disease is likely to appear and directly after administration of test substance or challenge. Typically hourly for the first 4 – 6 hours after treatment, then at 24 and 48 hours.

Close clinical observation will be particularly necessary in key stages of some infections e.g. in fly strike to ensure removal of larvae before the 2nd instar stage of development. Similarly close clinical observations will be necessary when challenging with e.g. Staphylococcus aureus or other mastitis inducing bacteria.

should any observations approach the predetermined cut offs then a veterinary surgeon or NVS will be consulted and the animal euthanased, treated and/or removed from the study as appropriate

anaphylaxis is a rare but possible event. To handle this veterinary assistance, treatment and means of euthanasia will be available in the hours after administration

dose volumes and blood sample volumes will follow guidance

Literature review will focus not only on systemic signs, but also specific organs affected so that potential symptoms of any organ related issues can be observed as early as possible.

If possible, in a first use situation, a ladder approach will be used whereby, one animal will be infected and/or treated/vaccinated and assessments will be made on this animal before moving onto the same procedure with the next series of animals. In this way, data from a complete group will be used but it minimises the risk of a group of animals all suffering adverse effects if there are any.

Where appropriate pilot studies will be made to define scientifically valid criteria including early markers of developing severity so that these can be defined.

If an animal approaches the upper limit of moderate severity it will be treated or euthanased, as appropriate. Others in the herd or flock will be monitored and appropriately treated, removed from the study or euthanased as necessary.

Removal of feed will be assessed for scientific need against animal health and welfare. Where deemed necessary the impact will be minimised e.g. by withdrawal of feed gradually over several days with a maximum time with no feed of 24 hours.

Increased stocking density (only birds) potential adverse effects are:

Heat stress

Pododermatitis

Lameness

Increase in sparring behaviour in cockerels Increased stocking density (only birds):
Litter is checked daily and new litter added as necessary throughout the course of a study

At body weight checks, foot pad score checked

Staff are used to regularly checking birds for lameness and assessing the severity of this

Staff are used to observing this behaviour and any signs of injury will be treated appropriately. Isolation facilities will be available.

Foot pad scoring as follows (expect no more than 50% of birds to have a score of 1 for mild severity): Score Description
No lesions; no or very small superficial lesions, slight discolouration on a limited area of the footpad, mild hyperkeratosis (thickening of the outer layer of the skin) or healed lesion.

Mild lesion; discolouration of the footpad, superficial lesions, dark papillae and hyperkeratosis.

Severe lesion; epidermis is affected, ulcers or scabs, signs of haemorrhages or swollen footpads The studies are typically of short duration (1 – 3 months typically)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 40% moderate. (see full breakdown in protocols)

Animal type	Est. numbers (mild)	Est. numbers (moderate)	Life stages
Cattle	180	120	Adult and Juvenile
Sheep	120	80	Adult and Juvenile
Pigs	75	50	Adult and Juvenile
Farmed birds	5000	3350	Adult and Juvenile

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Veterinary medicines, biologicals, feedstuffs, feed additives and vaccines must be trialled in the target species for initial efficacy purposes before taking forwards to larger trials. Unless otherwise recommended or if there is an established and validated in vitro model available, the target animal will need to be used in these studies.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use a combination of tools to estimate the numbers of animals needed. This normally includes the NC3Rs Experimental Design Assistant, Veterinary International Conference on Harmonization (VICH) and World Association for the Advancement of Veterinary Parasitology (WAAVP) guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used.

Peer-reviewed journals and advice from external peers together with in-house experience and historical data over a number of years is used to ensure that animal numbers are adequate.

We are fully committed to reduction, nonetheless the exact numbers of animals required will vary with the particular study needs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have many years of experience of working with veterinary medicines, biologicals, feedstuffs, feed additives, residues and vaccines in the target species. This ensures the minimum number of animals are being used for any particular study. Due to our experience we have highly optimised our processes which enables us to maintain high welfare standards whilst delivering our clients requests. We also utilise the NC3Rs Experimental Design Assistant, VICH and WAAVP guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature.

Studies are normally negatively or positively controlled, parallel studies.

Expert statisticians will be involved in study design as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used that are needed for a valid statistical result.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where appropriate pilot studies are used to establish an appropriate and consistent infection level that will ensure meaningful results are obtained. Dependent on the type of organism, there may be very well established in-house models which can easily produce consistent results. However some organisms respond differently to the host immune system which then can lead to unpredictable models, which may require varying the infection dose levels, the use of immunosuppression or different methods of infection e.g. in feed, water or by oral gavage. Some parasitic organisms (Ascaris suum) for example, need larger numbers of animals for successful infection, therefore a larger control cohort is required to compensate for the over dispersion of the parasite. For every model; age, immunological status, breed and strain of animal may affect the outcome of the infection negatively or positively.

Studies may be exploratory and use small numbers in a standardised design, enrolling further animals one at a time as it is established that the adverse reactions to the drug are mild or moderate and not severe, therefore slowly building up the data to a full set.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species of animals used are the intended target species for each veterinary medicine, biological, residue, feed or water additive, feedstuff or vaccine. Regulatory bodies require efficacy data from the target animal species. To satisfy the EMEA CVMP/VICH GL 7 efficacy criteria, an overall effectiveness of over 90% is required. The species involved are: cattle, sheep, pigs, domestic poultry and other farmed avian species (e.g. ducks, pheasants, geese).

Challenge models are designed to minimise severity as far as possible whilst achieving meaningful results. The numbers chosen will normally be within the guidelines set by the appropriate guideline e.g. VICH GL12.

In some cases, naturally infected animals may be brought in for testing veterinary medicines or biologicals. Under good husbandry circumstances these animals would be given appropriate commercially available treatments to control infections. However, for scientific reasons, this is withheld in both control groups or prior to test treatments.

If the study involved mastitis causing bacteria strains would be chosen that would not be expected to cause systemic disease.

We will seek to link physiological criteria with behavioural signs in a heat stress model.

Why can’t you use animals that are less sentient?

We have to use these animals as hosts due to the research being directly related and utilised in real world farm animal and bird environments. However we regularly refine and/or validate existing animal models in support of 3Rs initiatives

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We minimise suffering by examining each study plan to identify opportunities to improve welfare by, for example, using experienced and knowledgeable staff, handling and habituating animals to procedures where necessary, meeting or exceeding codes of practice and current guidance or literature suggestions for enrichment.

The animals used are the target species for the veterinary product on trial. Any models will have welfare at the centre of their design. In addition, animals on these studies will have a heightened level of observations immediately after and in the days following administration of any substance. Our standard level of monitoring is a minimum of twice daily. Frequency of observations are increased on an as needed basis based on animal observations and behaviour. For example, observation frequency could increase to hourly monitoring following the appearance of clinical signs associated with mastitis.
Observations would normally be general health observations but these are supplemented with clinical observations by our NVS (or similar), monitoring of temperature and other parameters as necessary.

If a treatment is to be administered over the course of a number of days, such as in feed or water, then we would aim to administer at the same time daily to allow the animal to become accustomed to the dosing regimen. We may also associate dosing and administration with feeding times as positive reinforcement for the animal If it is believed an animal is approaching and likely to breach the predetermined severity category then we have a well-established process. This includes seeking veterinary advice from our NVS or another veterinary surgeon, discussions with the NACWOs, PELh, PPLh, PILh and Study Investigator. This group of people decide the best next steps in terms of animal welfare. This could be either, immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, and increased monitoring if the animal is unlikely to breach the severity limit by the conclusion of the study if appropriate.
If an animal breaches the predetermined severity category for the study then immediate action is taken. This often includes rapid discussions with the NVS, PELh, PPLh and PILh alongside the study investigator. We would also if possible contact an ASRU inspector. The course of action could be immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, maintaining and closely monitoring the animal if the scientific need is justified and the end of the study is within a short time frame, if agreed by an ASRU inspector. All decisions are taken on a study by study basis and differ with treatments and species.

We will also continually review our procedures and refine as much as possible with guidance from, for example, VICH, EMA, WAAVP and other relevant organisations and published literature.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

WAAVP guidelines for best practice in parasiticide related work. These guidelines are now seen by most regulatory authorities as the standard by which parasite-related protocols are written, and consider numbers of parasites required for study purposes. Similar guidelines will be utilised for bacteriological, virological and other types of study.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly reference the NC3Rs website, published literature, attend relevant conferences and employees are members of The Royal Society of Biology and other relevant organisations.

76. Investigation of Thymus Degeneration and Regeneration

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

T cells, Thymus, Immunity, Repair, Atrophy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to study the cellular and molecular mechanisms that result in the loss and regeneration of functional thymus tissue and T cell development following damage or disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The thymus is the primary organ responsible for supporting T cell development. T cells form an essential component of the immune system, providing protection against both infection and tumour formation. In addition to supporting the development of T cells that protect against infectious challenges, the thymus also limits the development of T cells that may otherwise drive autoimmune disease (a process termed central tolerance). Continuous production of new T cells is important to maintain effective immune protection by replacing T cells that can be gradually lost from the peripheral circulation. However, thymus activity is not constant throughout life with a loss of thymus tissue (termed thymus

atrophy) occurring in response to numerous challenges including: acute damage (e.g. irradiation exposure), obesity and therapies used for treatment of blood cancers such as high dose irradiation. Therefore, while the thymus is critical for the recovery of T cell immunity following such challenges, the sensitivity of the thymus to induced atrophy can create severe immunodeficiencies, for example dramatically heightened susceptibility to life-threatening infections following treatment for blood cancer. Further, alterations in the ability of the thymus to control the development of autoreactive T cells may also lead to the development of autoimmune disease following thymic atrophy. Interestingly, the thymus possesses an inbuilt regenerative capacity to counter such effects, importantly however the mechanisms that control both thymus degeneration and regeneration, including how this impacts the development of functional, self-tolerant T cells are very poorly understood. In addition, although different challenges such as low or high dose irradiation and obesity all lead to thymus atrophy, the mechanisms involved in each appear to include unique elements, including how and the degree to which the thymus is able to recover following degeneration. These limitations therefore hinder the creation of new approaches to improve thymus recovery and T cell driven immunity. This basic science project aims to investigate the cellular and molecular networks in the thymus that control recovery after induced atrophy and examine whether such mechanisms are either shared or unique to the different atrophy-inducing stimuli of either irradiation or obesity.

What outputs do you think you will see at the end of this project?

Work performed under this licence will:

Generate basic science data that will enhance our fundamental understanding of the cellular and molecular mechanisms controlling thymus atrophy and regeneration.

Provide a platform for the identification of new pathways and targets that may inform follow-on future studies targeted towards the development of translational approaches to manipulate and enhance thymus function.

Generate scientific findings that will be communicated to the wider public and scientific community through presentation at scientific meetings, public engagement activities and publication in high impact peer-reviewed scientific articles.

Who or what will benefit from these outputs, and how?

The outputs from this will be of interest to a wide range of individuals and groups interested in understanding thymus function, and exploring the potential for manipulation of thymus tissues in order to enhance T cell development and output. For example following the use of ablative therapies used to treat patients with blood cancers that amongst other outcomes, can lead to the depletion of T cells, will be of interest to both clinical and non-clinical colleagues. It is anticipated that the immediate beneficiaries of this research will include basic research scientists within the field of biomedical research interested in T cell biology and the impact of perturbed T cell development on immune protection. At a local level, interactions with colleagues will ensure discussion and distribution of data and findings from the project. Wider beneficiaries will be engaged through sharing of information through attending and presenting data at national and international meetings. Results from the project will be published in free-to-access scientific publications.

Importantly, this is a basic science project. It is essential that such exploratory projects are undertaken if we are to identify novel mechanisms that regulate thymus function and T cell development and thereby make new discoveries that further our understanding of thymus

biology that may ultimately inform approaches to manipulate the immune system for improved health. Although outputs from the project may be of interest to the clinical community, the likely potential for any outputs to directly inform future therapeutic approaches should be viewed in the long term. In addition to individual beneficiaries, the ultimate potential long-term goal to translate research findings into methods to improve immune function in humans may include socio-economic impacts due to health and wellbeing implications of poor immune function occurring as a result of reduced thymus function.

How will you look to maximise the outputs of this work?

In order to maximise outputs from this work, we will continue to maintain existing and develop new collaborations with colleagues at both national and international levels. Such collaborative interactions are anticipated to enhance sharing of both knowledge and materials that will provide added value to both this programme of work and others. Outputs from this programme of work will be shared with the scientific community through communications of results and technical approaches at meetings and conferences e.g. by both oral and written presentation. Such dissemination of work will raise the profile of work and allow sharing of data outputs that will enhance knowledge exchange and support development of our projects via feedback from experts in the field. In addition, we will continue to publish our results in high-impact journals. Importantly, in line with the requirements of our funding bodies published results will be in open-access scientific journals in order to make our research as accessible as possible. We also aim to publish negative results where these will provide important data that may inform other studies or prevent replication of experiments elsewhere. In order to communicate outputs with wider audiences we will continue to use additional platforms, including social media to maximise exposure of results and publications. Where possible we will also engage with the wider public through public engagement events in order to communicate our work to wider audiences.

Species and numbers of animals expected to be used

- Mice: 15,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The immune system is formed by a network of cells and inter-connected organs (termed lymphoid organs) that are spread throughout the body. In this programme of work we aim to look at how the thymus, a primary lymphoid organ that supports development of T cells, undergoes degeneration and subsequent regeneration following challenges such as irradiation damage or in settings such as obesity. Importantly, T cells exported from the thymus are critical in the maintenance of immune protection against bacterial, fungal and viral infections and for the prevention of tumour formation. Therefore, loss of thymus tissue and reductions in T cell development and output from the thymus can have serious implications for immune protection throughout life.

In particular, this project aims to study thymus atrophy and recovery at adult stages of the life-course. In order to investigate these aims, this project will use mice, including genetically-altered animals as an experimental model. The mouse represents the lowest order of placental mammal that possesses an immune system of similar make-up and function that can be used to effectively model the human immune system, including the thymus. Importantly for example, one of the primary aims of this project seeks to model and study thymus atrophy and regeneration that occurs following the use of therapies used to treat human patients for blood cancers. The treatment of such disease involves exposure of patients to radio- and/or chemotherapies in order to deplete cancerous cells in the bone marrow, followed by transplantation of donor bone marrow containing stem cell populations. The use of mice therefore represents the lowest order placental, mammalian species that possess a corresponding system of lymphoid organs. In addition, mice represent the lowest order species where haematopoiesis (blood cell development) occurs within the bone marrow, and subsequently leads to a programme of T cell development and output from the thymus and can therefore can be used to model this process of thymus damage and T cell recovery in humans.

Typically, what will be done to an animal used in your project?

Under this basic science licence, we will undertake investigations to study the mechanisms that can result in both the loss of functional thymus tissue (thymic atrophy), and subsequent regeneration, including the impact of these processes on T cell development. All animals will undergo a procedure to induce thymus atrophy in order to understand the cells and molecules that drive this process. Thymus atrophy will be induced by either exposing animals to a low dose of irradiation on a single occasion, feeding a high fat diet for up to 20 weeks, or exposing animals to a higher dose of irradiation on up to two occasions accompanied by a transfer of donor haematopoietic (blood) stem cells delivered by a single intravenous injection. In order to study the role of defined cells or molecular pathways in either atrophy or regeneration, some animals may then receive a single intravenous injection of cells on one occasion, whilst other animals may receive an injection of substances such as proteins, peptides or antibodies via either intravenous or intraperitoneal injection on up to 6 occasions over a maximum period of two weeks, with injections separated by a minimum of 24 hours. In order to investigate outcomes of such procedures on thymus and T cell recovery, animals will subsequently be humanely killed, and cells/tissues isolated for post-mortem analysis.

In order to study the functionality, including self-tolerance of T cells generated in atrophied/regenerated thymus, in a small number of experiments T cells, isolated post mortem from mice having undergone induced thymus atrophy, will be transferred to host mice via a single intravenous injection. Animals will then be maintained and subsequently humanely killed , and cells/tissues isolated for post-mortem analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Potential adverse effects that animals may experience include:

High fat diet: Increase in bodyweight and greasy coat due to feeding animals a diet with a high fat content (typically over 8-12 weeks).

Irradiation exposure and stem cell transplantation: Animals may experience temporary weight loss (1-2 days) following exposure to irradiation. Animals may also display signs of

radiation sickness between day 6-14 post-irradiation before donor stem cells are able to reconstitute haematopoietic compartments (blood cells).

Delivery of cells OR substances e.g. via either intraperitoneal or intravenous injection: temporary stress and discomfort due to handling and insertion of needle for the duration of the injection (less than 1 minute).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate 100%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The analysis of thymus atrophy and recovery relies on the coordinated activity of diverse cell types and molecular signals that require the use of whole animal models to investigate in detail. For example, the thymus does not contain haematopoietic (blood) stem cells that develop into T cells. Rather, in the adult, blood stem cells are located in the red marrow of skeletal bones and migrate from these distant sites in the body through the bloodstream and subsequently colonise the thymus. Importantly, this is a continual process meaning that the study of T cell development relies on an interconnected system of skeletal and circulatory blood vessels with the thymus. Following development in the thymus, a further step is the export of T cells into the peripheral circulation in order to provide effective immune responses. Similar to thymus colonisation, in order to study this critical process it is necessary for the thymus to be fully connected to an intact circulatory system. In particular, under this project we aim to study how the thymus undergoes atrophy in response to challenges such as obesity and irradiation and subsequently how the thymus recovers. Importantly, thymus recovery occurs over an extended period of time (>8 weeks) and as yet no in vitro experimental systems exist that can effectively model this complex, interconnected network of circulatory, skeletal and lymphoid tissues systems including the thymus over a protracted period of time.

Which non-animal alternatives did you consider for use in this project?
We routinely use in vitro (in a dish) models in our research, including cell and thymus organ culture systems. These approaches include reaggregate thymus organ culture systems that allow for the study of thymus biology without using intact whole animal models. These models therefore help to reduce the need to perform experiments in whole animals, and provide a key system where we are able to validate experiments in vitro e.g. screening and testing the ability of defined molecular pathways to influence thymus function. Although such in vitro systems provide an invaluable approach to explore the role

of defined cells types and molecular pathways, thereby reducing the need to use experiments in animals, they are currently still limited in their application to the study of thymus degeneration and regeneration. Current limitations to such models, such as lack of a connected blood supply and therefore an absence of immature T cell recruitment from the bone marrow, currently restrict the use of such models as a complete replacement for whole animal models. A further current limitation to the use of non-animal models for thymus research remains the lack of information regarding stem cell populations that are capable of generating functional thymus tissues. Although our previous work, and that of other research groups, have sought to identify stem cell populations that can form complete thymus tissues as yet no specific markers have been identified that allow for the isolation and propagation of such cells in vitro, thereby precluding their use in alternatives to animal models.

Why were they not suitable?

The thymus contains a unique three-dimensional network of cells that support the development of T cells. At present, attempts to use cell culture models to recapitulate normal thymus structure and function, in particular use of 2-dimensional cell culture models has met with limited success. The lack of specific markers to isolate stem cells from thymus tissues in order to attempt generate thymus tissues has also hampered efforts to replace animal models. Recent efforts have also been made to utilise organoid systems to study aspects of thymus biology, although as yet the effectiveness of such systems remains limited and have failed to effectively model normal thymus development and function. Critically, the need for a fully integrated immune system that communicates and directs the migration of immune cells through a system of blood vessels is essential for the study of the thymus atrophy and recovery. As such, alternative models to study thymus function currently remain limited. However, we will continue to study the scientific literature for any emerging models that may facilitate reduction and replacement of animal models, and will continue to utilise and refine our current use of non-animal models such as thymus organ culture systems wherever possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This programme of work is a continuation of work performed under our previous project licence. We have estimated our numbers based on our experience of animal husbandry and use of wildtype and genetically altered animals using such protocols and procedures over the last 5 years of our previous project licence. Numbers of animals are therefore based on previous Home Office data returns for the use of animal numbers, in-house data from pilot studies and ongoing/published studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase we use power calculations (e.g. using G* Power software) to estimate the predicted group sizes necessary to determine statistically significant results. In order to reduce animal use, we routinely use robust approaches to ensure standardisation of experiments in order to make them directly comparable for example where an individual scientist repeats an experiment across different days, or where experiments are performed by more than one individual. We adopt standard experimental approaches within our research group to ensure reproducibility via the use of shared experimental techniques and regular lab meetings to ensure that all research lab members are performing experiments in exactly the same way. We also perform regular calibration of our scientific instruments again in order to reduce the need to repeat any experiments due to variability in the acquisition and recording of results.

Wherever possible we use control animals from the same litter as experimental mice in order to both reduce unnecessary animal breeding and to reduce the potential for any observations occurring as a consequence of differences in genetic and/or age-related factors. Where undertaking a new series of experiments we will perform pilot experiments coupled with power calculations to estimate the number of animals that we need to breed, maintain and subsequently use in experiments. We will also make use of NC3Rs resources for 'Experimental Design and Reporting', including the experimental design assistant, (https://nc3rs.org.uk/experimental-design-and-reporting) to support our studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to optimise our use of animals, we will use a combination of approaches:

Efficient animal breeding and husbandry. Mouse colonies will be maintained at a size necessary to generate animals required for robust experimentation. Resources such as those provided via the NC3Rs' Breeding and Colony Management Hub will also be used to support this. Wherever possible, we will use litter-mates as control mice in order to optimise maximum use of animals generated under this licence.

Pilot studies. These will be undertaken whenever we commence a new series of experiments or use new reagents etc. Outputs from such experiments will allow us to accurately plan animal breeding and subsequent experiments for example through the use of power calculations.

Sharing of materials. We undertake regular team research meetings at the start of every week where we discuss experimental plans. Here we are able to maximise use of every animal by combining experiments and sharing tissues/cells taken from each animal.

Archiving materials. We regularly archive cells and tissues by freezing and storing materials. Such archived tissues provide a valuable resource for future experiments, for example gene expression and microscopy analysis of cells/tissues. Using such approaches we are able to maximise use of tissues and reduce the need to breed additional animals.

As described above, we will make use of NC3Rs Experimental Design and Reporting Resources to guide our studies, and will ensure experimental design and conduct is performed and reported in line with the ARRIVE 2.0 and PREPARE guidelines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This programme of work will be supported by the use of both genetically-normal (termed wildtype) and genetically-altered mice in order to explore the cells and molecules that control thymus degeneration (atrophy) and regeneration.

The thymus undergoes a process of atrophy in response to numerous damaging stimuli such as exposure to irradiation, including: 1) low dose irradiation, 2) high dose irradiation, for example as used in ablative therapies used for treatment of haematological (blood) cancers and 3) obesity. Importantly, the response and recovery of the thymus may differ in response to these varying types of challenge. We therefore propose to study thymus atrophy using complementary models that are relevant to human conditions and that cause the least adverse effects to animals whilst addressing our scientific questions.

Irradiation models.

In this project, we will expose adult mice to two different levels of irradiation:

Low level irradiation. Here mice will be exposed to a low dose of whole-body irradiation that whilst sufficient to induce damage to highly radio-sensitive tissues of the thymus, does not lead to depletion of peripheral cell types, including stem cell populations in the bone marrow. This model has been selected as a model of acute thymus damage that is capable of driving thymus atrophy, whilst sparring overt adverse/damaging effects on other more radioresistant cells in other parts of the body. Of note, the sensitivity of irradiation exposure is linked to the genetic background of mice. In order to ensure the least possible adverse effects are experienced by any given animal, the minimum possible dose of irradiation is tailored to the genetic background of mice in each experiment performed.

High level Irradiation and stem cell transplantation. In order to model therapies used in human patients for treatment blood cancer, we will expose mice to a higher dose of whole body irradiation. This approach induces cell death in haematopoietic stem cells that generate all cells of the blood system, including T cell progenitors. All mice undergoing irradiation in this model will receive a transplant containing haematopoietic stem cells that will subsequently restore haematopoiesis (blood cell development). All animals are expected to make a full recovery following infusion of donor stem cells via a single intravenous injection.

Importantly, it is again appreciated that the genetic background of inbred mice can lead to differences in sensitivity to irradiation. We will therefore ensure that irradiation doses are tailored to the known radiosensitivity of different genetic backgrounds of mice used in this study in order to minimise the impact of adverse effects.

Diet-Induced Obesity

In order to model obesity driven impacts on thymus, we will use a diet-induced model that involves feeding mice an altered energy diet (up to 60% kcal coming from fat). The delivery of such diets to mice have not been associated with the development of physical or behaviourial abnormalities, and as such are not typically anticipated to cause pain, suffering or distress. However, the coats of animals fed diets high in fat content may become greasy and lead to excessive grooming with associated irritation skin irritation.

Why can't you use animals that are less sentient?

In this project we will use mice as an experimental model. The mouse replicates the mammalian placental pattern of human development over a gestation period of 21 days and provides the closest model that replicates the development, maintenance and loss of thymus function with increasing age. Of note, placentation in mammals is associated with the development of specific properties of the immune system that are not present in lower order species. For example, this includes the evolution of cellular and molecular mechanisms of the immune system that aid in preventing maternal rejection of the developing fetus eg regulatory T cell development in the thymus. Importantly, the mouse represents the lowest order species that contains a similar full makeup of primary and secondary lymphoid organs and tolerance mechanisms that regulate autoimmune activity that collectively replicate those observed in humans. The mouse is also the only species that provides a wide range of natural and induced mutants with defined genetic alterations that allow the study of target molecules crucial to the function of the immune system. A large body of published data has been generated characterising the immune system in murine models, and the vast majority of knowledge regarding thymus development and function is solely based on the use of murine models since the first formal description of the critical role of the thymus in T cell development in the 1960s using mice as an experimental model. Importantly, the use of species that are less sentient remains limited. For example, Drosophila fly models do not possess an equivalent of the lymphoid lineage, including T cells nor do they possess a thymus which is evolutionarily restricted to jawed vertebrates. While fish models e.g. zebrafish possess a thymus, notable differences preclude their use as a model to fully replace the use of mouse models, particularly in regard to studying thymus biology in relation to bone marrow transplantation due to these animals lacking bone marrow haematopoiesis with blood cell development taking place in the kidney of adult fish. Although this project will use embryonic models wherever possible, we will however need to extend use of animals to adult stages in order to track postnatal stages of thymus development and maintenance that include critical stage specific roles for the thymus in T cell production.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our research group has played a significant role in refining experimental approaches to study thymus development and function in mouse models. For example, we have played a major role in developing novel in vitro models for the study and manipulation of thymus tissues. Such approaches have been widely adopted within the international research field and have provided an essential model to validate candidate cellular/molecular pathways without the need to use complex in vivo models.

We will always aim to keep our experiments to the minimum possible duration to meet our experimental end-points, and will always use the fewest possible interventions (e.g. injections) that are needed. Best practice in animal husbandry e.g. refined handling techniques and provision of enrichment items will also be adhered to, and as guided by the NC3Rs'. In order to minimise welfare costs, as is required, all relevant work will be

carried out under appropriate aseptic conditions which will be of particular relevance if strains exhibit immunodeficiency following treatments such as irradition exposure. Where mice have for example undergone irradiation exposure, animals will undergo increased monitoring to ensure appropriate recovery and haematological reconstitution. In addition, where larger doses of irradiation are used to model stem cell transplantation, we will use split doses of irradiation (e.g. two separate low dose exposures) as opposed to a single high dose exposure to minimise the impact of irradiation-associated adverse effects.

Where mice are fed a high fat diet, coats of animals will be carefully monitored, and soft bedding will be used to avoid skin irritation. In addition, high fat food will be placed on the floor of the cage to avoid any pellets dropping on the coat from suspended food containers. Where any mice show signs of pain or irritation, animals may be treated using analgesics following consultation with appropriate staff NACWOS and/or the NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experiments will be planned, conducted and reported in line with the PREPARE (planning) and ARRIVE (reporting) guidelines. We will also make use of the NC3Rs Resource hub e.g. 'Breeding and colony management' and 'Experimental Design' to inform our approaches. LASA guidelines will be adhered to and used where appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to make good use of NC3Rs resources both through the NC3Rs website, and also at a local level via communications and activities driven by a local 3Rs group e.g. regular distribution of the NC3Rs newsletter. We will seek to engage with relevant seminars, conferences and webinars where available, and will maintain contact with NACWOs, and the NVS where appropriate. As described elsewhere, we will also continue to review the scientific literature to ensure that we are able to identify and potentially adopt any new approaches and/or models that may supplement or replace our current animal models.

77. Improving treatments for brain tumours

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain cancer, Glioma, Radiotherapy, Radiosensitisers, Toxicity

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to test the effects of new treatments that may improve the outcome for patients with hard to treat brain tumours, especially aggressive primary brain tumours in adults.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The most common primary brain tumours in adults are aggressive, high-grade gliomas. They remain extremely challenging to treat and do not respond to conventional treatments including surgery, radiotherapy and chemotherapy

What outputs do you think you will see at the end of this project?

Publications describing the effects of new treatments or new combination treatments that may be useful to test in patients.

New information about how different treatments may be best combined to improve how well they work. New information about how to avoid toxicity of new treatments or new combinations.

Who or what will benefit from these outputs, and how?

In the long term (5-10 years) patients with brain tumours may benefit from having access to new treatment approaches.

In the short and medium term the specialist community in brain tumour research will benefit from increasing knowledge of which new treatments may work and how they work for brain cancers.

How will you look to maximise the outputs of this work?

Effective dissemination of new knowledge through local, national and international meetings.

Working with national and international collaborators including in established consortia to bring new treatments to the clinic as quickly as possible.

Feedback to the relevant research community about challenges and unsuccessful aspects of the project.

Species and numbers of animals expected to be used

- Mice: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice for these experiments as they are the smallest species that can be used in our pre- clinical imaging and treatment equipment. Mice models of glioma, especially using injection of tumour cells into brain, have been well validated as effective models of the human disease in terms of tumour and normal tissue responses. We will use adult mice for the majority of these experiments. In some cases, particularly when we are assessing the effect of treatment on normal brain we may also use younger animals to model the effect of treatment on survivorship in young patients.

Typically, what will be done to an animal used in your project?

In a typical experiment animals will be injected with tumour cells direct to the brain while under anaesthesia using a stereotactic guidance technique. Animals will then be monitored over a number of weeks (typically 3-6) until tumour growth is expected. At this point animals may be imaged, for example by MRI or bioluminescent imaging to assess tumour size. In each case animals will be under anaesthesia for the period of imaging. Animals will then be allocated to treatment groups, commonly a short course of radiotherapy (3 doses per week over 1 or 2 weeks) and/or drug treatment given by gavage or ip or tail vein injection.

Following treatment animals will be closely monitored for signs of ill- health over the subsequent weeks and may also undergo further imaging (MRI, bioluminscence) at specific time points. We have set limits for interventions so that there is at least 24 hours between imaging sessions and no more than twice per week and no more than 6 imaging sessions will be performed within any one month period. A typical experiment would last 2-3 months.

Less commonly we will implant tumour cells under the skin and monitor tumour growth directly by caliper measurement across treatment groups described above.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected effects of surgery on these animals include pain from craniotomy or subcutaneous injection and/or from problems with wound healing, which may last from hours to a few days after surgery.

The expected effects of tumour growth on these mice include poor feeding and weight loss, reduced or abnormal mobility, reduced interaction with cage mates, undergrooming. The expected duration is a few days, after which animals will be sacrificed if these signs do not resolve or worsen.

The expected effects of treatment include poor feeding, pain (from injection) and after-effects of anaesthesia including reduced mobility and low body temperature. These effects are expected to be short lived (hours).

The expected effects of other investigations include pain from injections of contrast for imaging, which is expected to be short-lived (minutes or hours)

Animals with subcutaneous tumours may also experience discomfort from tumour ulceration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities for mice are moderate in the majority of animals. Predicted severe in <1% due to exceptional circumstances

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although in vitro (2D and 3D) as well as new organoid models provide useful means to test

specific hypotheses and/or validate findings from screening experiments, in vivo models are a vital addition in clinical translation. They are the only means of assessing the impact of tumour micro-environment on response to treatment, which can often have a powerful modifying effect. In addition these models bridge the gap between biological end-points such as tumour cell killing and clinically relevant outcomes including symptom-free survival. They also permit investigation of clinically relevant biomarkers, for example new imaging approaches to monitor tumour responses which cannot be applied outside of a full organ model. In vivo work is also critical to assess the effects of treatment on normal tissue since this depends on the interplay between different cell populations that cannot be recapitulated in vitro.

For some glioma models, especially patient-derived tumour models, cells cannot be maintained in vitro so direct implantation to mouse brain is necessary to maintain them.

Which non-animal alternatives did you consider for use in this project?

We have used 3D spheroid models for initial proof of concept and would also consider tumour/normal brain organoids, which may allow us to focus the in vivo work on fewer agents and reduce animals needed for pharmacodynamic or tissue based end-points of drug/combination effects.

We are working with collaborators to introduce a combined normal brain/tumour organoid which may permit assessment of effects on tumour and normal tissue simultaneously and further reduce the numbers of mice needed for definitive experiments.

We also have links to labs developing tissue on chip or tumour on chip devices which would support efficient and relatively high throughput assessment of novel agents. We will utilise all of these models when appropriate.

Why were they not suitable?

3D spheroid models do not incorporate normal tissue components and cannot be used for clinically relevant translational end-points.

Organoid and tumour on chip technologies are still in development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
This estimate is based on numbers used previously and the likely balance of work going forwards, which is unlikely to change significantly. I have taken in to account the reduced experimental work carried out 2020/21 during the Covid pandemic when access to in vivo work was severely restricted.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We always use models with high take rates and reproducible growth characteristics (eg the mouse tumour CT2A) unless there is a specific indication for a different model, for example due to expression of a specific target or an indication to use patient derived material. This very significantly reduces the number of animals required per treatment group (usually 5) compared to when we use patient-derived material to establish tumours (usually 12).

As far as possible we design experiments so that we can cross-refer between control/standard treatment groups, reducing the groups necessary across a series of similar experiments using the same model. We use standard radiotherapy/chemotherapy regimes across experiments to facilitate this approach.

We also use data from previous experiments, including serial tumour imaging/monitoring data to inform study time points, for example for histological assessment so that the numbers of animals included for these end-points are minimised.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use efficient breeding in house as well as use of external suppliers to prevent animal wastage.

As above, we use models that we are familiar with and for which we have significant prior data as far as possible. For experiments using new or unfamiliar models we routinely use data from the literature to design small pilot experiments before embarking on large treatment/efficacy work to ensure efficient experimental design.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the lowest sentient animal that can be used for these experiments for clinical translation.

We use established syngeneic and patient-derived xenografts for much of this work, for which we have high quality data on tumour growth, expected symptom-free survival and treatment effects. This allows us to design experiments in which mice undergo treatment at early time points prior to tumour-induced symptoms and to monitor them closely to ensure minimal duration of tumour-induced symptoms.

We also use state of the art technology to administer treatment, including highly targeted radiotherapy, to minimise the side effects of treatment since only the tumour and small volume of normal tissue receives a high dose. We routinely design experimental protocols

to ensure that post-treatment effects can be monitored during the normal working day, for example by treating cohorts early in the day rather than spreading treatment through the day.

Whenever possible we will use imaging-based end-points (MRI, bioluminscent imaging) in place of survival/symptom based end-points to reduce animal distress and suffering.

Why can't you use animals that are less sentient?

Mice are the smallest animal species that can be use in our pre-clinical imaging and radiotherapy equipment. We need to use models that fully recapitulate the human disease as far as possible and we have selected models that reflect this. These models include a relevant tumour micro-environment and allow assessment of effects of treatment on both tumour and normal tissue.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will work with local and national groups who are developing relevant technologies for these experiments. This includes local collaborators who are working on novel imaging approaches for tumour monitoring including small animal PET.

We also work with the CRUK Rad-Net pre-clinical radiotherapy group who are developing an integrated radiotherapy-MRI imaging bed set up to allow MRI-based radiotherapy planning to further refine the accuracy of this treatment and further reduce unnecessary radiation exposure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow current guidelines including:

The updated (2020) guidance on animal testing and research.

UKCCR guidelines for the welfare and use of animals in research (British Journal of Cancer (2010) 102: 1555-1577).

LASA guiding principles for preparing and undertaking aseptic surgery

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We run a local user group for all researchers involved in in vivo work and for our husbandry and in vivo unit staff. This reports to the institution- wide committee who are responsible for in vivo work across the whole campus. New approaches to procedures/husbandry etc are discussed at these meetings. All researchers all also circulated regular updates from for example the NC3Rs unit (Replacement, Reduction and Refinement guidance).

All practitioners are encouraged to maintain/improve their skills through regular courses as well as meetings with researchers in other units.

Specifically for this project we work closely with other institutions doing similar work through radiotherapy research networks and are members of the pre-clinical drug-

radiotherapy working group. This ensures that developments in technology, in model development and in experimental approaches are shared across the UK.

78. Breeding and maintenance of genetically altered (GA) animals, re-derivation, and GA embryo/gamete storage

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Transgenic, Conditional expression, Cancer, Neurodegeneration, Re-derivation

Animal types	Life stages
Mice	adult, neonate, juvenile, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Genetically altered (GA) rodents are of great value in understanding the function of genes and pathways important in physiological and pathological processes and to produce models of human and animal disease. The purpose of this work is to breed, maintain and generate mice with defined genetic alterations and supply them or their tissue for research into the control of disease, ill-health or abnormality and/or the study of normal and abnormal physiology, biology or behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The mice produced will be used for the understanding of basic biology and the discovery and development of new medicines for the treatment and prevention of diseases. This licence will also allow us to provide GA tissue for laboratory use, store lines in a frozen state (cryopreserve) when not required and send or receive frozen embryos from academic and commercial suppliers in accordance with the principles of the 3Rs.

We currently breed approximately 100 GA breeding lines used by around 20 different research groups. A single service project allows a person with expertise on the breeding and husbandry of GA animals to be in full control of the GA breeding programme with anticipated welfare benefits and is efficient where several research programmes may use the same animal strain. The experience and expertise available in animal husbandry will ensure that breeding programmes are co-ordinated to ensure optimal animal husbandry and minimal wastage producing only animals as needed. Minimum numbers will be used to maintain colonies, further embryo cryopreservation will ensure that strains are not lost or bred unnecessarily. The scientific justification for the animal usage is provided by the receiving project licensees or by the scientists receiving tissues.

What outputs do you think you will see at the end of this project?

The output will be to efficiently produce GA mice of a high health status while minimising the number of unused animals. These will be supplied to other project licences or used to supply tissue for laboratory research within the university. The mice supplied to other PPLs or tissue produced will be used to research into the control of disease, ill-health or abnormality and/or the study of normal and abnormal physiology, biology or behaviour. This will produce novel publications giving information on the pathways controlling these processes and will be used for the discovery and development of new medicines for the treatment and prevention of human and animal disease.

The licence will also enable us to produce embryos and sperm from GA mice which can be used to cryopreserve breeding lines in house and to send and receive frozen lines from academic and commercial suppliers.

The outcomes of research using either tissue or live mice produced on this licence will be circulated through publications and presentations at conferences, and go on to inform new therapies and treatment strategies. Researchers will participate in public outreach activities to inform the public about their research and its relevance to disease.

Who or what will benefit from these outputs, and how?

Over the five years of the licence, the mice produced are expected to be used in research that will advance research in the control of disease, ill-health or abnormality and/or the study of normal and abnormal physiology, biology or behaviour, and will be used for the discovery and development of new strategies for the treatment and prevention of human diseases. This includes cancer therapeutics, neurodegenerative and metabolic disease.

How will you look to maximise the outputs of this work?

Outputs will be maximised by carefully designed breeding programmes in collaboration with the end users of the animals or tissue, combined with efficient running of the biomedical research facility

Species and numbers of animals expected to be used

- Mice: 88450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

GA animals, particularly rodents, are currently in widespread use in biological, medical, and veterinary science and have been shown to be of great value in elucidating the function of genes and pathways in a wide variety of biological, physiological, and pathological processes. The human genome has been sequenced, as have a number of other genomes (partially or completely), notably the mouse. However, the function of many genes is not known or is not fully understood, either individually or in the ways they interact to produce their intended effects, or how they are dysfunctional in disease. To better understand normal physiological processes and abnormal disease processes requires, when necessary and justified, the use of whole animal models.

Within biomedical research generally and at this institution the use of GA animals in many stages of research are well established. Their value has especially been demonstrated, for example as research models for cancer, neurological, metabolic, and inflammatory diseases and their therapy, as well as aiding fundamental research into human physiology.

Typically, what will be done to an animal used in your project?

There are two protocols (4,5) for the breeding of GA animals. Protocol 4 covers the breeding of GA strains that do not have any physical (phenotype) consequences, or where the phenotype is within the mild severity band. Protocol 5 will allow breeding where the phenotype causes adverse effects of a moderate severity. In both protocols a tissue biopsy maybe taken from the animals to determine their genetic status. Typically, the animals produced on both protocol 4 and 5 will be transferred to another PPL for experimental use or culled for tissue for laboratory research

Protocol 6 will allow administration of substances to modify gene expression by suppressing, enhancing, or switching on or off genes. These may be given by injection or orally. This includes administration of gene inducing or gene deleting substances to pregnant and lactating females as well as their offspring. Substances will be administered in diet or water, subcutaneously, or intraperitoneally. Implantation of a slow-release pellet subcutaneously may also be used. The purpose of this protocol is to produce animals for use on other project licences or tissue for laboratory research.

Protocols 1,2,3 and 7 are used to introduce animals into our specific pathogen free unit by embryo transfer or caesarean section, and to produce sperm/ embryos for cryopreservation (Protocol 1).

Protocol 1 is used to produced increased numbers of preimplantation embryos or eggs, mice will receive an intra-peritoneal injection of hormones, typically twice before being killed by a schedule 1 method and embryos/ ova harvested.
Animals on protocol 2 will produce surrogate mothers, after being rendered pseudo pregnant by mating with a sterile male, they will undergo surgical or non-surgical implantation of embryos whilst under general anaesthetic and receiving peri-operative analgesia.

Animals on protocol 3 will be vasectomised under general anaesthesia via cutting of the vas deferens by a scrotal approach.

Animals on protocol 7 will be mated and once pregnancy is confirmed receive a subcutaneous injection of progesterone up to three times, typically on pregnancy days 17-18 and then schedule 1 killed on day 19 and embryos harvested, and pups cross fostered to a recipient mother. This protocol will only be used for animals from trusted suppliers with a high health status to bring animals into our SPF unit.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the animals on this licence will be bred on the mild severity breeding and maintenance protocol (protocol 4) and will only ever suffer mild and transient pain or distress. A small number of lines will be bred on a moderate severity breeding and maintenance protocol (protocol 5). Some of these have the potential of developing tumours or neurological changes and weight loss. These animals will be monitored and at any signs of these adverse effects will be either transferred to another authorised project licence or culled for tissue.

Animals used on embryo recipient (protocol 2) and vasectomy (protocol 3) protocols will receive pain relief and are expected to make a full recovery within 24 hours of surgery. We do not anticipate adverse effects from the administration of transgene inducing or deleting agents (Protocol 6), but they could be affected by the genetic alteration. If any adverse effect is observed guidance from the NVS and the Home Office will be sought.

Animals on protocols 1 and 7 are expected to remain in the mild severity band, having received parenteral injections of reproductive hormones, and we do not anticipate any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

85% of all mice allowed on this licence are expected to reach no more than a mild severity. 15% of the mice are expected to reach no more than a moderate severity.

What will happen to animals at the end of this project?

- Used in other projects
- Killed
- Rehomed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Many of the research projects will initially involve the use of studies within the laboratory such as cell culture, human tissue assays, computer modelling to complement the animal work. Such details will be expected in the justification for the animals' use to be reviewed by the Animal Welfare and Ethical Review Body (AWERB).

However, studies within the laboratory cannot adequately model the complete array of molecular, cellular, physiological, and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes. To further understanding the pharmacological efficacy of human disease therapies and where studying such complex systems it will be necessary to follow events within a live animal model.

Which non-animal alternatives did you consider for use in this project?

Cell culture methods and computer models are used whenever possible; however it is not possible to replace all animal models and therefore this requires breeding of animals. Where replacement methods become available for projects supplied by this licence, this data is shared and disseminated by the Named Information Officer.

Why were they not suitable?

This project licence provides various GA animals that will be used under other project licences for research in live animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers have been estimated based on the usage over the previous 5 years on the licence this one will replace while taking into account the levels of work which are expected to be seen over the coming 5 years. The overall numbers have been reduced compared to the estimate given on the previous licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Mice will only be bred to order after discussing researchers' requirements for both mutant and appropriate control animals. The studies that the animals are transferred to are reviewed by AWERB to ensure that they are suitable, properly planned and are not using unnecessary numbers of animals. When breeding animals, online resources and guidance such as https://nc3rs.org.uk/breeding-and- colony-management will be used to ensure best practice is being followed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The strain and genetic background used for generating a new colony will be carefully considered to avoid producing unwanted mice. Animals will only be bred where a user requirement has been established, and the breeding programme will be subject to regular review to optimally meet demand.

Breeding will be optimised, wherever possible, to produce only the genotype required e.g. Homozygous breeding pairs. Spare animals will be made available for use on other scientific projects.

Only small numbers of animals within a breeding line will be kept. Expansion breeding will only take place to order and adequate time to produce the animals must be given.

Researchers will be encouraged to use male mice where possible.

Cryopreservation of sperm and embryos to archive lines will avoid wastage from the need to maintain colonies by continuous breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are widely used for work involving genetic alterations. The standard protocols, methods and reagents have been optimised for this species and there are acknowledged benefits from their use particularly as models for human disease as they share physiological pathways and almost all their genes are conserved with humans.

The methods chosen are all standard for this type of work.

Why can’t you use animals that are less sentient?

While other invertebrate models (Drosophila, C. elegans) maybe used to obtain information on basic physiological and pathological processes they lack the complexity seen in vertebrates. Mice offer tractable models with far closer anatomical, physiological, and genetic similarity to humans.

To maintain GA breeding lines, the animals used need to be of sexual maturity and therefore cannot be at a more immature life stage. A significant number of the animals bred undergo schedule 1 killing to produce tissue and should only suffer transient harm, and a proportion of these will be used for embryos production. Some of the animals will be used under terminal anaesthesia. Many animals will be used under other project licences that will be justified in their own right.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

GA strains will be managed, particularly those of a potential moderate severity to ensure they are not kept alive beyond their severity limits. Staff will be made aware by regular staff meetings, clear cage labelling, and training in how to detect any adverse effects.

Cage enrichment will always be provided, and cup handling has been introduced to reduce the stress caused to the animals during health checks, cage changing and procedures.

Monitoring post-operative and providing peri-operative care/pain management is required for all surgery animals. The anaesthetic used has also been refined from injectable to inhalation to reduce the amount of time the animals need to be under anaesthetic and to improve recovery times.

Needle use has been refined by introducing a policy of single use needles. Needles are now changed between mice during hormone injections.

Tissue obtained from identifying animals via ear punch is used to genotype most animals. Only where tissue cannot be used to genotype due to the requirement to know the expression level of the genes will blood sampling be used. Blood sampling has been refined from tail tipping to lancing to minimise the suffering caused to the animal. Due to these refinements in using the biproduct of identification methods and tail lancing, the requirement for tail tipping is now very rare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the N3CR and Home Office guidance on best breeding practices at the following websites:

- https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/7735 53/GAA_Framework_Oct_18.pdf
- https://nc3rs.org.uk/breeding-and-colony-management

As well as keeping up with best practices on the following sites:

- https://wellcome.org/sites/default/files/wtd040017.pdf
- https://science.rspca.org.uk/documents/1494935/0/GA+passport+booklet.pdf/7050500f-4b6d-13ce- 9a6d-93fb01743ca9?t=1552661824197

Webinars and meetings will be attended on best breeding practices and colony management where relevant and available.

Best practice information is also disseminated by our Named Information Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Published guidelines for best practice will be followed where possible, including:

- Home Office Efficient Breeding of GA animals assessment framework

https://www.nc3rs.org.uk/3rs-resources

- Norecopa EU ECVAM
- Animal Welfare and Ethical Review Body (AWERB) Home Office Animals in Science Regulation Unit RSPCA Animals in Science Department
- Understanding Animal Research
- Following and attending relevant seminars, meetings, and reading papers User groups

79. Targeting the tumour microenvironment of epithelial cancers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Epithelial Cancer, Tumour microenvironment, Immunotherapy, Extracellular matrix, Macrophages

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new ways of treating cancer by targeting the cells and molecules that control the tumour microenvironment. The term tumour microenvironment means all the cells that are found in a cancer, not just the malignant cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancers are not just collections of malignant cells but complex rogue tissues that contain many normal cells and molecules that are recruited and corrupted to help a cancer grow

and spread. This complexity, called the tumour microenvironment, can best be reproduced in animal systems such as mouse models of cancer. Over the past 10 years or so scientists and clinicians have learnt that treatments that alter the behaviour of these normal cells in the tumour microenvironment (e.g. immune cells, blood vessel cells) can shrink and, in some cases, eliminate cancers, even when they have spread around the body. These types of treatment are called biological therapies.

However the biological therapies are only effective in a minority of cancer types and patients. We need to understand how to improve on this. For instance, during the current project licence we have found that in patients and in mouse cancer models, standard chemotherapy drugs can stimulate immune cells to fight cancer but this is often not sufficient on its own; we need to find ways to enhance this.
Another example would be to 're-programme' some immune cells in the tumour microenvironment, that currently help malignant cells to grow and spread, into immune cells that destroy malignant cells.

Therefore, as part of our research, we need to use carefully selected mouse models that replicate as closely as possible their human cancer counterparts.

What outputs do you think you will see at the end of this project?

At the end of this project we aim to obtain new knowledge about the tumour microenvironment of cancer, especially some types of ovarian and breast cancer. We also aim to find new treatments, single, combination or sequential, that eliminate tumours or prevent relapse. This information will be translated to new clinical trials - for instance we are currently working on a 'window of opportunity' trial that will allow us to see if the anti-cancer effects we see in our new mouse ovarian cancer models are replicated in patient tumours. The patients will be given the experimental treatments for 2-3 weeks before surgery with a pre- and post-treatment (at surgery) sample that can be analysed and compared to the results in our mouse cancer experiments. The experimental treatments that we study are called 'biological therapies' and they include drugs that stimulate the body's immune system to attack the cancer and drugs that stop blood supply to cancers.

We will publish our work in international journals and present our work at national and international meetings (In the past 5 years there have been 12 publications that have resulted from work carried out completely, or partially in collaboration with others, under the current project licence).

Finally, we will make all the new information that we obtain freely available as well as any new mouse cell lines we develop. During the current project licence we have so many requests for the new mouse ovarian cancer cell lines we generated that we have handed them over to ximbio.com who are making them freely available to the scientific community.

Who or what will benefit from these outputs, and how?

Patients with cancer - we aim to have a least one clinical trial, based on our results, underway in advanced ovarian cancer by the end of the new Project.

Scientists and clinicians who study the tumour microenvironment from reading our publications and from listening to presentations at meetings.

Ovarian cancer researchers who are already obtaining our new malignant cell lines but will benefit from the new information about them that we obtain in the next five years.

How will you look to maximise the outputs of this work?

Collaboration is an important way to maximise our outputs. For instance we are currently working with collaborators on more efficient ways of imaging tumours in the mice. We plan to collaborate with experts on genetic changes in ovarian cancer to find new ways to combine the drugs they are developing with the biological therapies we are studying. We are also discussing a collaboration which will allow to understand how different clones of malignant cells change during growth and therapy.

We will publish unsuccessful as well as successful approaches and, importantly, we will make clear any differences between our mouse cancer models and the human tumour microenvironment that may influence our interpretation of the data.

Species and numbers of animals expected to be used

- Mice: 3000 female adult mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our work is entirely based on mouse models of cancer that most closely replicate the human tumour microenvironment. As the cancers we are modelling (e.g. breast and ovarian cancers) are generally found in females we will use adult female mice. We have developed several ovarian cancer cell lines that can be implanted into animals that are not genetically altered. We will also be using well- characterised breast cancer cell lines that grow in mice that are not genetically altered. Therefore approximately 80% of animals in this project will be normal healthy mice.

As we believe that the tumour microenvironment of different cancers share many similarities, the most promising treatments may be tested in models of other cancers, including some that affect men as well as women in which case we would use male mice.

Sometimes we may use immune deficient mice to understand the role of components of the immune system in the tumour microenvironment or response to biological therapies.

Typically, what will be done to an animal used in your project?

The most common experiment we will carry out in this protocol (>60% of studies) is the study of different drug combinations. In this type of experiment, tumour cells will be injected into the abdomen of adult female mice. Based on our experience with each tumour model, treatment will be started when tumour cells start to grow in the abdomen. Tumour growth will be typically detected by palpation (a method of feeling with the fingers for tumours during a physical examination of the mice), but an imaging session might be used at this stage.

In some of our experiments, we will use chemotherapy as a means of treating cancer. The minimum number of cycles of chemotherapy will be administered, typically three or six

cycles, depending on the model, by abdominal injection, once weekly. Other treatments will typically be administered sequentially for 6 weeks orally (generally once/day) or by abdominal injection (generally once/twice weekly). In slower growing tumour models where we see a therapeutic effect with certain biological therapies, providing there is no adverse effect, we may continue treatment for a maximum period of 16 weeks (i.e. up to 6 weeks of chemotherapy plus an additional 16 weeks of maintenance therapy totalling a maximum of 22 weeks). In some cases of experimental ovarian cancer, where we are interested in treating relapsed disease, we would stop treatment if all the cancer has been eliminated and recommence if the cancer returns.

Extended treatments will only be carried out where there is a clinical benefit to the mice. As we believe that the tumour microenvironment of different cancers share many similarities, the most promising combinations may be tested in several models and, in time, in models of other cancers, including some that affect men as well as women (in which case we would use male mice).

Some animals may be re-challenged with tumour cells injected in the abdomen. This experiment will be carried out rarely. Imaging will confirm that the mice are tumour-free before the tumour cells are re- injected. The aim of this type of experiment is to determine whether the mice have developed an anti- cancer immune response during the first course therapy, and that this twill prevent tumour growth when mice are re-challenged. Mice will not receive a therapy after the second challenge but will only be monitored for tumour growth according to our standard protocols.

To briefly outline a typical experiment in our breast cancer models, tumour cells will be injected under the skin of adult female mice. Mice are expected to develop solid mammary fat pad tumours, which can be measured using calipers. Caliper measurements and mouse weighing will be conducted three times a week to closely monitor tumour growth and allow us to collect and analyse the tumours when reaching a maximum volume of 1000 to 1250mm^3.

In addition to administration of cancer cells alone we also plan to give the mice combinations of cancer cells and normal cells called fibroblasts (the 'builder' cells of the body) as a way to control the way the tumour microenvironment develops. These fibroblasts may be genetically edited using molecular biology techniques in the laboratory prior to administration, in order to modify specific substances that we think may have an impact on anticancer immunity. Overall, by injecting different cancer and fibroblast cell combinations, we aim to build up a number of mouse breast tumour models, which reproduce distinct immune tumour microenvironment profiles.

Imaging may be incorporated to any study carried out in this protocol and will generally be used to confirm that most animals are developing detectable tumours before the start of a treatment. Imaging may also be used to follow up the response of the tumours to treatment. This would also reduce the number of mice we use, as it will allow us to study, in the same experiment, short term and long term effects of a therapy.

A blood sample may be collected to monitor the animal's health or the effect of the treatment. Generally, we would expect to run these checks up to once weekly over the course of an experiment. A volume of twenty microlitres (a small drop of blood - one microlitre is one millionth of a litre) is sufficient for this purpose. The blood sampling will not exceed what is indicated in the guidance from NC3Rs https://www.nc3rs.org.uk/blood-sampling-general-principles.

Mice bearing any of our cancer models will be culled at a pre-determined time-point whenever possible, or followed up until humane end-point is reached if the aim of the experiment is to find out if treatment prolongs life.

What are the expected impacts and/or adverse effects for the animals during your project?

From our past experience we predict that the planned studies will cause only mild or moderate discomfort. Animals are expected to return to normal activity within minutes after treatments such as cell injections or drug administration. We do not expect any adverse reaction related to drug treatments or their administration. Some distress is likely to occur in the advanced stage of tumour growth which could interfere with normal bodily functions. Indications of minor distress include weight loss up to 10%, reduced food and/or loss of appetite, hunched posture or hair standing on end. When animals have been subjected to minimally invasive surgery to administer cells in to the mammary fat pad/duct the recovery time is usually longer (2-3h after administration of anaesthesia and pain medication).

Animals in the protocol will be observed daily to assess for normal behaviours and general condition of the cages and their environment. If an animal appears to suffer, for example by demonstrating subdued behaviour when provoked, weight loss of 15%, small amounts of weight loss over a period of time without improvement, or continuous hunched posture, it will be humanely killed. An animal showing several repeated phases of intermittent hunched posture of a period of 48hr will also be humanely killed. At the end of each study when all results have been collected, all animals will be killed by humane procedures and their tissues used for analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

A majority of the animals used in this project (90%) will be tumour-bearing and most will be subjected to single agent or combination therapies with the aim of eliminating their cancers or preventing return of the cancer. 25% of the animals will, in addition, undergo some form of imaging to assess their tumour burden. For these reasons, a majority of procedures will be of moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We study the tumour microenvironment which is a complex 'rogue' tissue that contains many other cell types, not just malignant cells. Cancers also evolve with time with the

different 'normal' cell types changing and being further 'corrupted' to help the malignant cells grow and spread. This is very difficult to model in a petri dish or tissue culture flask.

Which non-animal alternatives did you consider for use in this project?

Over the past 7 years we have been developing multi-cellular human models of the tumour microenvironment that grow in the lab and we have just published the first two papers on these models. Alongside the malignant cells we can add some types of immune cell, fibroblasts and cells that usually line surfaces in the body, to the models. These models now have five cell types in them and are proving to be complementary to our mouse models. However, we do not think we can ever totally replicate the complexity of the human or mouse tumour microenvironment and we do not think the multi-cellular models will ever replace mouse models. However, as will be described below, the multi- cellular models are part of a platform of cancer models that will allow us to reduce the use of mouse cancer models during this project licence period.

Why were they not suitable?

The multi-cellular models cannot replicate the cellular complexity of the mouse cancer models, nor can they be grown over the longer periods of time needed for some of our experimental treatment schedules.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimates are based on our knowledge of the natural history of the mouse models we use and experiments (published and unpublished) that have given us statistically significant results. We have extensive experience of murine cancer models and over the past 15 years have collected data on the most suitable models and number of animals per group to generate reliable data. The studies in this project will utilise these models while advancing our work to improve on both models and therapies. The work is now at a stage where we need to focus on the interactions of our novel therapies with the tumour microenvironment and the host immune system. We estimate up to 3000 animals will be sufficient for testing efficacy and bio-distribution of various combination therapies (including novel therapies and conventional therapies). However, these are the maximum estimated number of animals for the duration of the project licence and in each study an exact calculation will determine the numbers to achieve statistical significance.

We will also refer to the NC3Rs Experimental Design Assistant: https://www.nc3rs.org.uk/experimental-design-assistant-eda

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are reducing the number of mice used in our experiments because we have now developed a 'platform' of cancer models, where the mouse cancer models are only one resource. For instance we now have extensive human *'in silico'* (computer) databases from our own research projects and publically available sources. We have similar data for some of our mouse models. These sets of information allow us to test hypotheses using computer-generated programmes and guide our mouse and other types of experiment. Then we have the multi-cellular models described above, and finally we have developed a 'tissue slice' technique where we can, over short periods of time, treat human tumours with an intact tumour microenvironment. We also use tissues in which we have removed all the cells to help study immune cell interactions with the cancer extra-cellular matrix (the stiff protein network that binds our tissues together).

The impact of of all these models can already be seen in the reduced number of mice we will use in the next Project period, and the fact that because of our new models we have eliminated the breeding aspects of our experimental designs. For instance there is 60% reduction in the estimate of the number of mice we will use in Protocol 1 and we will not use any mice for breeding purposes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be very important in terms of reduction, especially when we are assessing combination therapies. As we now have extensive data on the molecules, cells and extracellular matrix of the cancers we study, we can first conduct computer-based studies and work in the other human tumour microenvironment models in the lab before moving to the mouse experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are studying the tumour microenvironment therefore we need mouse models that develop cancers in the correct microenvironment. These are called orthotopic tumours. For instance, for ovarian cancer models we inject the malignant cell lines into the peritoneum and for breast cancer models we inject into the mammary fat pad/duct. We continue to seek improvements to our techniques, this includes using ultrasound echo-guided injections to deliver treatments and cells directly in to target organs or tissues reducing the need for surgical manipulation that can result in pain or distress to the animal, which may affect the immune system and potentially confound experimental results.

This project will mostly use not genetically altered animals, however we do not exclude the potential use of immuno-deficient mice to compare tumour development and profiles in the presence or absence of a functional immune system.

Why can't you use animals that are less sentient?

We cannot use animals that have been terminally anaesthetised because some of our models evolve over several weeks and months. We try to replicate as closely as possible human cancers that generally grow slowly. Also tumour microenvironments do not develop in days; it takes time to recruit the other cells and for important components such as extra-cellular matrix and blood vessels to develop in cancers.

We can only use mice for these models as the malignant cells will only form tumours in mice and it is not relevant to do these experiments on immature life stages of mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The best way we feel to minimise harm is to refine our non-invasive imaging methods. This means that we will be able to find out at a very early stage when a tumour is growing too fast or has spread somewhere that will cause increased suffering. We are collaborating with a number of scientists to refine our experiments in this way.

Increased monitoring is also a vital component of our procedures to minimise suffering. We have and will continue to refine our palpation scoring method for the growth of internal tumours in our ovarian cancer models. We have also developed a single sheet that provides a clear overview of the mouse's welfare record including a history of body weight, palpation scores from first detection to the most current as well as a place to indicate if there are any other noticeable health issue to monitor. Having all of this information available at any time to all technicians and researchers involved with the study allows for a more accurate, informed decision to be made more efficiently. Health issues requiring action are reported to relevant Named Persons and the responsible personal and project licence holders using the BSU database management system. We are exploring this further to see if/how we can effectively incorporate detailed monitoring records including observations on to the database as this would help greatly, enforcing efficient communication and notification of health issues between all those involved in a study.

When interventions are repeated, we are looking in to the potential for acclimatisation, which may reduce severity including positive reinforcement training, or 'rewards' following procedures.

We also strongly believe in the benefit of a consistent approach to monitoring. Elements contributing to consistency include:

Incorporation of multiple expertise, experience and priorities – a 'team approach'

Training in using the day-to-day assessment protocol (including the common terminology used to describe observations)

Expertise on animal health, welfare and behaviour

Regular review of outcomes

Communication between all those responsible for conducting the study and monitoring the animals (top-down, bottom-up, between and within)

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have an effective 3Rs network through the NC3Rs and attend our establishment 3Rs events as well as those within our network. Staff attending conferences (such as the IAT Annual conference) will bring back best practice in terms of the 3Rs and new techniques and we will keep abreast of the literature to ensure that we use the best and most reproducible methods.

An example of an advance highlighted to us by NC3Rs and our resident Named Veterinary Surgeon which we have implemented is tunnel handling. Tunnel handling has had a noticeably positive effect on reducing animal stress and anxiety prior to carrying out procedures.

80. Understanding host-pathogen interactions in zebrafish models

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Infection, Immune cells, Zebrafish, Antimicrobial resistance

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, adult, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand how our immune defence system fights infections and what goes wrong when it can’t control infections leading to disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infectious disease is the world’s biggest health problem. Bacterial and fungal infections are beset by the growing problem of antimicrobial resistance where the germs are becoming resistant to existing treatments (eg, antibiotics). This project will advance our knowledge of the immune system and how infections happen in people whose immune systems to not work correctly. Using this knowledge, we will try and find new ways of treating infections by helping the immune system. Boosting the immune system is a treatment strategy that could work alongside or replace existing antibiotics, reducing the need for new antibiotics.

What outputs do you think you will see at the end of this project?

Infectious disease is still the world's biggest health problem, and the speed of emergence of antibiotic resistance has vastly outstripped our ability to identify new antibiotics. The consequences of this reach well beyond the confines of infectious disease – without antibiotic therapy, we could not safely perform anything other than the most simple of surgery, nor give anti-cancer chemotherapy. A return to pre- antibiotic healthcare is a real threat and amongst the gravest threats to human health.

In vivo visualisation and manipulation of host-pathogen interaction will allow considerable advances in our understanding of how pathogens attempt to evade their killing by host phagocytes, how the host tries to prevent that evasion. This area has considerable potential for identifying completely new ways of treating infectious disease, and critical in an age of widespread antimicrobial resistance. For example, blocking pathways that bacteria and fungi use to prevent host killing could lead to new treatments for infection, ones that might avoid the pitfalls of resistance associated with traditional antibiotics.

As with our previous work, we will publish our findings in as journal articles in an open access manner with maximum impact and will present our work at national and international scientific meetings. We will also disseminate our findings to the public to improve the public awareness of science.

Who or what will benefit from these outputs, and how?

Groups that will benefit from this research programme include:

Scientists directly involved with the project

The short-term benefits will be to our research group and to other researchers in our fields and in closely allied areas e.g. immunology and microbiology. Immediate beneficiaries of this project will be the scientists working on the project (PI, RA and PhD students). With the opportunity to apply new approaches and techniques with Zebrafish models there will be career development opportunities. Researchers will be trained in the priority skills areas of whole organism physiology, quantitative skills (proteomic analysis), and interdisciplinary (particularly imaging).

The scientific community

Academic researchers in several research areas will benefit from this work including those working on pathogenesis of infections, inflammation and researchers in immunity diseases field, zebrafish research community and researchers in cell signalling and molecular biology fields.

Patients and wider public

In the medium-term our programme of work may identify potential targets and leads for further development that, in the long-term, may result in new ways of treating infections disease. Patients and the wider population will benefit from this research if we can identify novel pathways for future research and ultimately, targets for therapies to lessen the burden of infectious diseases.

Industry

There may also be short term benefits to industry through the availability of new knowledge in how pathogens evade killing. This work will identify drug targets that could be used to treat a huge unmet clinical need. It is likely that this will be of interest to pharmaceutical companies, large and small. We will develop strong collaborative links to enable commercialisation of any targets as they arise.

How will you look to maximise the outputs of this work?

We will maximise our outputs by:

effective collaboration with experts in the field of zebrafish inflammation and immunity, which will extend our skill set and facilitate access to advanced technologies and ensure that we are using the most cutting-edge transgenic/mutant tools to answer our scientific aims

dissemination of new knowledge at key meetings and conferences

dissemination of our work more widely through press release via university media team

publication and sharing of both successful and unsuccessful approaches where appropriate (eg via F1000, BioRxiv, Wellcome Open Research, or NC3Rs Gateway platforms)

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 21500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish have many properties which make them the only available system to answer the scientific aims of this PPL. Zebrafish are vertebrates that have a comparable genome to humans. Zebrafish larvae are almost completely transparent, enabling unrivalled visualisation of in vivo host-pathogen interaction. Major cellular components of the innate immune system are present in the larvae and share direct homology to mammals. Zebrafish are readily amenable to genetic modification and there are a host of emerging genome editing technologies available (eg CRISPR-Cas9). Larvae are small, allowing pharmaceutical approaches to be performed by immersion in 6-96 well plates format, (akin to a cell model system) while maintaining the benefits of whole-organism investigation.

The zebrafish as a model of infection is emerging as a favourable alternative to traditional mice models. We have previously used the zebrafish model successfully, and have demonstrated modulation of inflammation and infection using many of the assays required for this PPL. Fish are ranked as the lowest order vertebrate used in animal research (in terms of pain and suffering), therefore the neurology and suffering may be considered less than higher vertebrate systems. Under 5.2 days post fertilisation zebrafish embryos could replace current rodent models of infection, thereby contributing to 3Rs.

Zebrafish infection models represent exciting and viable options for investigating the pathogenesis of infection in a whole organism setting.

Typically, what will be done to an animal used in your project?

Zebrafish will be used to generate mutant and transgenic lines of proteins involved in the immune defence against infections. The roles of these proteins during infections will be tested by deletion in zebrafish one at a time using gene-editing technology. Experiments will almost exclusively be performed on animals before they become protected (<5.2 days post fertilisation at 28 degrees Celsius). These procedures involve microinjection techniques to deliver RNA and protein material to induce mutation at 1 cell stage zebrafish embryos. We will then characterise the effect of these mutations in zebrafish on the response to inflammatory response induced by infections. This involves advanced imaging as well as gene expression and biochemical analysis.

The vast majority of zebrafish used (over 20,000) will be used for breeding (up to mild severity) to produce zebrafish larvae for maintenance of transgenic/mutant lines, or to use in experiments before they become protected. Adult animals will be kept for between 2 and 3 years (their healthy lifespan) and culled by overdose of anaesthetic before they show signs of significant aging. Our experiments are designed to understand how infections are cleared from the animal and most animals will therefore experience only mild severity.

What are the expected impacts and/or adverse effects for the animals during your project?

Infections cause adverse effects on larval fish, including excessive inflammatory phenotypes that lead to oedema. Greater than 95% of larval infections will be halted before the onset of protection at 5.2 days post fertilisation.

The generation of mutant lines in the immune system could lead to immunocompromise and susceptibility to infections. To minimise the risk of this, mutants in genes likely to lead to this will be kept as heterozygotes (rather than homozygotes), and closely monitored for infections. These mutants will not be kept to old age, with new generations generated after 2 years to ensure humane endpoints before age susceptibility to infections (that can happen if kept beyond 3 years of age).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: 95%

Moderate: <5%

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Infection occurs in a complex tissue microenvironment milieu that cannot currently be replicated in in vitro systems. Investigation of the innate immune response to infection requires four main cell types (neutrophils, macrophages, bacteria, and endothelial cells) along with the surrounding tissue microenvironment. Emerging evidence also implicates the neural system in infection, further highlighting the need for a holistic approach. To study interactions of these cell types in a non-living environment would not provide the comprehensive environment in vivo research allows.

Although this project involves animal work, the proposed research will have 3Rs impact in the following ways. My proposal uses the well-validated, widely-published Mycobacterium marinum zebrafish model to investigate novel areas of TB research. It has the potential to replace rodent and other mammalian models (eg rabbits) to investigate TB pathogenesis. In order to avoid mammalian models, I will test findings from zebrafish in innovative human cell models. A benefit of the zebrafish Mm model is that Mm is a natural fish pathogen, unlike in murine models of TB, therefore the investigated host response to infection is a naturally occurring one. Further expansion of this exciting model will compliment other excellent TB research currently undertaken in the UK. Publications and dissemination at conferences will increase and enhance the profile of the zebrafish to wider infection and immunity fields. It will highlight the conservation of pathways in mammals and fish and promote the zebrafish as a genuine alternative to mammalian research.

Which non-animal alternatives did you consider for use in this project?

Infection and inflammation occur in a complex tissue microenvironment milieu that cannot currently be replicated in in vitro systems.

In vitro cell systems to investigate neutrophil and macrophage migration towards infectious/inflammatory stimuli are currently available, but are only useful for asking very specific questions about chemoattractants. Where possible, we will use these models using our findings from zebrafish models and to inform our zebrafish investigations, reducing the animal numbers required. For example, we are performing in vitro work using microfluidic chambers on human blood cells migration towards individual chemokines. However, these cannot completely replace in vivo systems as they lack the complex microenvironment that occurs during infections.

We are also performing in silico computer simulations of processes involved in phagocytosis (intake) of pathogens. However, these are only appropriate to answer specific physical properties of the immune cell (eg, how much actin cytoskeleton is required) currently, but further development of these models will help limit animal use and may eventually be a future replacement.

Why were they not suitable?

The approaches above significantly help to provide more concise information on the

genes/proteins needing to be targeted in vivo but they cannot mimic the actual cellular response occurs in the animal to this challenge.

The innate immune response to infection and this requires four main celltypes (neutrophils, macrophages, bacteria, and endothelial cells) along with the surrounding tissue microenvironment. Emerging evidence also implicates the neural system in infection, further highlighting the need for a holistic approach. To study the interactions of these celltypes in a non-living environment would not provide the comprehensive environment in vivo research allows, which is an absolute requirement to understand the cellular mechanisms involved in the immune response to infections.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For experiments that require animals we will use previously collected datasets to predict the minimum group sizes required for statistically relevant results. For any new experimental models we will perform pilot experiments with small numbers of animals to interrogate the biology to inform future work. We will consult with other biologists and statisticians when planning these experiments. Numbers of adult zebrafish required are calculated based on a requirement to have enough healthy adult fish at any one time to generate the larvae required for experimentation. Although large numbers of larvae can be obtained on one spawning, fish cannot then spawn for 2 weeks, meaning a rotating stock of fish is needed to ensure embryo supply. To minimise animal use, once experiments have been performed sperm will be frozen (for future IVF) and stocks will not be maintained.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will aim to use the minimum number of both protected and non-protected animals. Almost all animals will be used for breeding purposes within their healthy lifespan and when these animals are not required we will minimise the number of fish required to maintain the line. For protected/non- protected animals we have used published datasets to predict groups sizes needed to generate data which will produce statistically relevant outcomes. Where appropriate we will use the NC3R’s Experimental Design Assistant to consult on sample sizes for individual experiments to ensure only the minimum number of animals required is used. We have performed pilot experiments in order to ascertain key timepoints. We have searched on-line databases to identify bioinformatic data which will allow us to narrow the range of hypotheses and sometimes to refute them without experimental work.

Most of proposed fish experiments are performed on larvae before the onset of independent feeding– these larvae are not considered protected by the Animals (Scientific Procedures) Act. Procedures for making mutants in zebrafish are mild severity. Genotyping of Adult fish is done on anaesthetised fish (small tail biopsy which regrows).

To minimise animal use, once experiments have been performed, sperm will be frozen (for future IVF) and stocks will not be maintained. Spare larvae are used for other experiments or shared with other members of the laboratory for reasons of efficiency.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Zebrafish are highly fecund, so we are able to obtain large numbers of embryos <5.2dpf from a small number of parents. To minimise animal use, once experiments have been performed, sperm will be frozen (for future IVF) and stocks will not be maintained. Pilot studies are performed initially to inform on the optimum number of animals needed per experiment to see a significant effect. Spare larvae will be used for other experiments or shared with other members of the laboratory for efficiency.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Zebrafish have a comparable immune system to our own, with similar types of white blood cells, meaning findings are relevant to human disease. However zebrafish have a much lower neurological capacity than other animals used in immune studies and are therefore the most refined model for this project.

Fin clipping and gamete expression methods rarely involve discomfort, but for all manipulative procedures animals are suitably anaesthetised (primarily for restraint). Anaesthetic is delivered by immersion (so no instrumentation is required) using an anaesthetic protocol suitable for the procedure and following best practice.

The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Generation of mutant/transgenic animals with tumour propensity will be based on well established techniques for mutation and transgenesis, and the animals will not suffer directly due to the techniques. However, the infections might lead to suffering and needs to be closely followed.

Where feasible, early genotyping using either embryonic fin clipping or a zebrafish embryonic genotyper (ZEG) system will reduce the number of larvae raised as we will only raise those of the required genotypes.

In any infections of protected animals we will minimise harm by culling animals that show excess clinical signs of infection. Over the course of the current licence we have refined our experimental readouts to mainly use <5.2 days post fertilisation for infection work, to minimise pain, suffering and distress. We will closely monitor all animals and will treat or cull by overdose of anaesthetic if needed.

Why can't you use animals that are less sentient?

We have carefully chosen the zebrafish as the most refined animal model for these studies. Fish are ranked as the lowest order vertebrate used in animal research (in terms of pain and suffering), therefore the neurology and suffering may be considered less than higher vertebrate systems, especially at the under 5.2dpf stages that are investigated here. We will only go over 5.2dpf if the biology requires it (eg, if T cell responses are required for the biological outcome being investigated. T cells only develop beyond 5.2dpf). The translucency of zebrafish larvae and transgenic fluorescent lines allow non- invasive imaging allowing collection of dynamic data over time without surgical intervention.

Drosophila (fruit flies), do not have both macrophages and granulocytes (neutrophils) therefore cannot model the human innate immune response to infection fully.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise suffering and discomfort the animals will be monitored and when there is any concern advice will be sought from the named veterinary surgeon and/or the Named Animal Care Welfare Officer and appropriate action taken. I also have access to a NC3Rs regional programme manager with whom I will consult as well as attend relevant workshops/seminars to learn about the latest developments in the 3Rs. This keeps me updated with evolving 3Rs best practice. For any experiments performed beyond the onset of independent feeding, larvae will be monitored regularly and individual experiments will be evaluated before further larvae are used in this protocol. The advantages and risks of this approach will be evaluated after each larva is used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To the best of my knowledge there are no published best practice guidelines for the zebrafish work in this project licence. However we use philosophies of experimental design advocated by the likes of Festing and Wurbel in order to refine our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The research groups will stay informed about advances in the 3Rs through communication channels including zebrafish user meetings, NC3R symposia, updates from NACWOs that attend animal husbandry/welfare conferences, collaborations, and through direct advice and consultation with the NTCO, NVS and NACWOs.

I am a current member of an NC3R funding panel and am therefore a representative of NC3Rs and must stay up to date on current advances of the 3Rs in that role.

81. Discovery and development of treatments for immunological diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Autoimmune disease, Rheumatology, Dermatology, Immunological disease, Gastroenterology

Animal types	Life stages
Mice	adult, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This licence has two aims:

To develop and validate animal models that can further our understanding of basic mechanisms involved in immunological disease and enable us to test new therapeutic agents.

To use the models developed above to identify novel treatments that will impact human immune diseases

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

Despite decades of research, millions of people live with serious immune mediated disease such as colitis, arthritis, systemic lupus erythematosus (SLE) and atopic dermatitis. For example rheumatoid arthritis, which is an autoimmune disease resulting in painful swollen joints and loss of movement, affected nearly 20 million people worldwide in 2017 (Safiri 2019) with more than 1 million new cases being recorded each year. Other autoimmune diseases such as lupus (SLE) can have devastating effects on patients lives, including debilitating symptoms which impact their ability to work. Allergic inflammation can also lead to the development of serious immune mediated disease such as atopic dermatitis, where the inflammation and pruritus (itch) present significant unmet medical need. Current treatment options are not effective in treating all patients, and many have significant dose limiting side effects (e.g. steroids). We believe we can identify novel treatments to address the symptoms and underlying mechanisms which cause these conditions, and addressing this unmet clinical need is a high priority for the medical research community.

Safiri S, et al. Ann Rheum Dis 2019;78:1463–1471

What outputs do you think you will see at the end of this project?

This Licence will enable us to investigate potential new mechanisms involved in multiple immune mediated diseases and test our novel treatments in simple and complex models, with the ultimate output being a new medicine progressing through to human clinical trials. Simple mechanistic models will be used to demonstrate the role of a particular pathway or system, for example using a treatment known to activate a specific pathway, and then using a novel treatment to block the effect. The more complex models, which engage multiple interacting systems but do not necessarily replicate a human disease, will be used to provide additional information about the likely effect of our treatment on a disease. For example, we may gain more information by seeing how a new treatment blocks the development of skin inflammation in an immune driven model, having previously tested it for activity using a selective stimulus. The outputs of these studies will contribute to active decisions to progress projects and novel treatments along the development path towards clinical testing, or to cease work on pathways or therapies which appear to lack benefit. These studies occur very early in the research pipeline and it can be difficult to publish due to concerns about patent life and intellectual property, but we would expect to share our findings as much as we can with the scientific community.

Who or what will benefit from these outputs, and how?

As an organisation our focus is on delivering life changing medicines to patients, and this licence will contribute to that overall goal by enabling us to test new therapeutic hypothesis in vivo relevant to new treatments for immune mediate diseases. Along the journey to delivering that clinical goal, we will also generate new scientific findings, and build our knowledge of the pathways and biological systems involved.

Drug discovery and development can take years if not decades, so novel treatments tested under this licence are likely to enter human clinical trials after the 5-year lifetime of the licence. However, treatments tested under previous licences with the same goal are now in clinical phase testing and we are confident that this will continue.

How will you look to maximise the outputs of this work?

We have an open culture and interactions between our scientists and those from other research organisations are encouraged. Whenever possible we regularly share our

findings at academic conferences and symposia, but due to the commercially sensitive nature of the work we are unable to be open about our very early and novel findings until appropriate patent protection is obtained. We do share openly information regarding our animal study techniques and practices with our peers to maximise animal welfare, and are committed to supporting the 3Rs.

Species and numbers of animals expected to be used

- Mice: 8000
- Rats: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The overwhelming majority of these studies will be performed in adult mice, as this is the species most commonly used in the disease model studies we will carry out. Mice are used in those models as they are a mammalian species with a similar (but not identical) organ anatomy and immune system as compared to humans. Although immunological diseases can affect patients at any age, the majority of rodent studies are performed in adult individuals (ie post-pubertal) as rodent development is very rapid and animals become sexually mature in a matter of weeks. Rats will be used rarely, when the disease model is performed in the rat, or there is some other technical need (such as the target system in the rat being closer to the human in its properties).

Although it will be very rare, we may occasionally need to understand the responses of the immune systems in aged animals, which for mice and rats equates to 1 year or older. This will only be done where there is a clinically relevant question or scenario that requires it.

Typically, what will be done to an animal used in your project?

In a typical simple immune challenge experiment, adult mice would be implanted with identification microchips under anaesthetic and a few days later weighed and dosed (the dose given being related to the weight of the animals). The dose may be an oral liquid, delivered using a round ended dosing tube attached to a syringe which is placed into the throat of the animal to ensure all the material reaches the stomach. Alternatively, the dose may be given as an injection using a hypodermic needle under the skin, or into a vein or into the abdominal cavity. Animals are returned to their cages and then at a set time after dosing, they may have an immune stimulating substance injected into the skin under general anaesthesia. Once the animal has recovered they would be returned to their home cage. At some time later the animals may be taken out and restrained in a small tube for a few minutes while a blood sample is taken from the tail using a small hypodermic needle. Usually no more than 3 samples are taken from the tail vein in the lifetime of the animal, and only if the samples needed are very small.
Blood samples may be analysed for signals such as immune cell activation, or for drug content. The final blood sample is usually taken under deep non-recovery anaesthesia, when a hypodermic needle is placed directly into the heart to take a large volume of blood, followed immediately by killing the animal. At this time, after confirmation of death, the skin would be dissected to allow analysis of the injected region.

Variations on this design may include the injection or topical application of substances which can cause an itch response, and we will monitor the animals to observe the scratching frequency and other parameters in order to determine if our treatment has modulated the response. Alternatives to injection into the skin may be topical application to provoke an immune response and local inflammation.

Some studies may involve another body site such as a subcutaneous air-pouch, which is generated by injecting sterile air under the skin on the back of the animal. Once the pouch is formed, inflammatory cells can be recruited and activated locally in the pouch following injection of an immune stimulating substance.

Stimulation of a pathway present in circulating cells or a specific organ can be achieved by an injection into a vein, or abdominal cavity. Activation and inhibition can then be monitored by peripheral sampling of blood or terminal sampling of body fluid and tissues.

Treatments in the studies above will typically be given by injection or through dosing into the stomach, but in a minority of cases we may also use a surgically implanted drug delivery device (pump) to do this. In some studies we may inject cells from another animal or which have been grown in a test tube, to enable us to track the movement of cells during immune responses, or to have a role in the immune response itself (e.g. using cells which respond to a known allergen).

What are the expected impacts and/or adverse effects for the animals during your project?

Animal dosing may cause some brief pain, such as when a hypodermic needle is used to dose under the skin or into a vein, the abdominal cavity or air-pouch. This is brief in nature and animals are not expected to show any signs of ongoing discomfort afterwards. Similarly, the needle used to take a blood sample is likely to result in fleeting pain or discomfort but should not have a lasting effect.
Injection into the skin (intradermal) is performed using general anaesthesia to reduce discomfort and allow greater control of the injection.

The sensitisation and challenge models we propose are expected to produce local inflammatory responses, which are likely to include swelling and increased sensitivity (hyperalgesia), and in the case of pruritic responses, irritation that evokes scratching (itch). Overt pain is not an intended consequence of these models and animals will be monitored to limit the severity experienced. Animals may exhibit clinical signs associated with inflammation and illness such as reduced grooming (and/or over grooming of inflamed or challenged areas), reduced social interaction and lowered body temperature. These effects may last over several days, for example following sensitisation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In this Licence the severity experienced by an individual animal is a function of the immune modulating steps and the drug delivery steps. The majority (>60%) of both mice and rats are expected to experience a severity of Moderate due to the inflammatory and irritant challenges. We have run most of the proposed studies under a previous project licence

(e.g. HDM induced ear inflammation, agonist evoked itch, air-pouch) and this estimate is based on the potential for therapeutic effect to ameliorate the inflammation, control injections/challenges which would be expected to have minimum impact on animal welfare and the use of drug-dosed, non-challenged controls which are required in many studies. These factors will bring many animals down into the Mild severity band.

A minority of animals (estimated <10%) may experience Moderate severity due to recovery surgery for implantation of drug delivery pumps under the skin.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not yet technically possible to eliminate all animal studies from our preclinical research programmes as the complex interplay of physiological systems including the innate and adaptive immune systems and the nervous system cannot be replicated using in vitro technologies. One reason for this is that we are working with highly novel mechanisms and need to ensure that in vitro findings can be extrapolated to our in vivo settings.

Which non-animal alternatives did you consider for use in this project?

There are multiple stages of non-animal screening of new treatment strategies as well as novel molecules themselves that are in place before testing in rodents takes place. Depending on the type of new therapeutic agents we will have performed tests (both using computer modelling and lab testing) to understand the physical properties which can affect drug absorption and how rapidly it could be broken down in the body. Cell based systems are used to assess how for example liver cells might process and break down a molecule. The biological pathways we are studying are investigated using multiple human and animal cell based systems to ensure that the molecules we are going to test will modulate the target pathway or system.

Why were they not suitable?

The information gained from these non-animal tests cannot account for the complex interactions that take place inside a whole animal with multiple organs, cells and enzymes which could affect the way a drug molecule moves around the body, is processed or broken down and is eliminated from the body. In addition, the biological mechanisms and pathways we are seeking to modulate are both complex, involving innate and adaptive immune responses and interactions with whole organs and body systems, and highly novel and we want to ensure that the behaviour of these is physiologically relevant and not an artefact arising from cell or tissue culture conditions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimates arrived at based on current expectations (how many animals per study, how many studies of each type per year) and allowing for anticipated changes in demand. For each protocol 1-4, the estimate is 2000 mice over 5 years, which is 400 mice per year per protocol.

For rats, the 1500 figure is composed of 250 rats over 5 years (ie 50 rats per year) for Protocol 1 and 2, and 500 rats over 5 years for Protocols 4 and 5 (ie 100 rats per year per protocol)

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Before performing in vivo studies under this Licence, we will have conducted extensive in vitro research studies to confirm as far as possible that the agents we will use are pharmacologically active against the species specific target and have sufficient potency or affinity to have a biological effect in vivo. This reduces the risk of performing studies with agents that cannot be progressed. Prior to the studies described here, experiments are carried out to ensure that the dosing will be effective, by measuring the amount of treatment in blood after administration. This de-risks again the potential for using new therapeutic agents which are unlikely to achieve active concentrations at the target tissue or organ. Careful consideration is given to the number and size of all groups, and the overall goal is always to use the minimum number consistent with the scientific objectives. As we are testing novel materials it is necessary to include control groups to ensure the interpretation of the data is clear, which reduces the need for follow-up studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The animals we use for these studies are usually standard strains obtained from commercial suppliers which maximises the efficiency of production and animal usage. Occasionally we will use genetically altered animals bred for scientific use and the numbers are carefully monitored to ensure overproduction and wastage is minimised. As described elsewhere in this application, pilot studies will be performed to inform our use of power calculations as well to determine the optimum effect window and kinetics of responses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models described here are mechanistic and are designed to allow us to study particular pathways or systems which are involved in a disease. For example, by using a simple model of cell recruitment into an air-pouch, we can study the movement of inflammatory cells (such as T-cells, monocytes and neutrophils) into the pouch and the mediators and enzymes they release, and look at the effect of blocking those mechanisms. Using this approach enables us to study pathways and pharmacological effects without having to use animal models of arthritis in the first instance. The animal welfare burden in arthritis is greater as the animals can experience pain and discomfort from swollen and inflamed paws, and this licence is not requesting permission for that model. The pouch cannot replace all arthritis studies but does allow us to study the biology and pharmacology of these mechanisms in a lower severity model, reducing the risk of proceeding into a arthritis study with an ineffective new treatment. In a similar way, we can use short/simple (hours-days) mechanistic studies of skin inflammation and itch prior to complex models of immune mediated skin inflammation (days-weeks) to focus our studies. This approach minimises the use of models with a higher welfare impact.

Why can’t you use animals that are less sentient?

These studies are used to provide critical information to project teams regarding the efficacy of our new treatments, and will inform decisions regarding the progress of these treatments into more complex models of disease (which may not fall under the remit of this licence) and eventually into human clinical studies. Using species that are less sentient introduces a significant risk that the information we obtain is not relevant and could lead to wasted animals in the disease models. Terminal only studies would be of limited duration and risk giving information that is compromised as for example blood flow to the skin, liver and other organs may be different under anaesthesia and could affect the measurements, and the presence of anaesthetic could interfere with the mechanisms (or limit our ability to make measurements such as scratch behaviour).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are kept in modern well equipped facilities staffed by experienced and motivated scientific and welfare personnel. Animals are checked at least once daily when not on a study and at least twice daily once dosing and sampling have started. When surgery (under general anaesthetic) is used for implantation of drug delivery devices, peri-operative pain relief (analgesia) will be given as standard.
Hypodermic needles are always discarded after a single injection so that blunted needles (which can cause unnecessary tissue injury and pain) are not used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA Good practice guidelines; AAALAC programme

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a Project Licence holder I am engaged with local and national 3Rs groups and events and am kept informed by my NIO of relevant new information.

82. Integration of DNA replication stress response and genome stability maintenance pathways

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

DNA replication, cell division, Cancer, Genome stability

Animal types	Life stages
Xenopus laevis	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this work is to gain greater understanding into the mechanisms that cells use to respond to DNA replication stress and how these mechanisms work to ensure that DNA synthesis and cell division are regulated to prevent the generation of genome instability which ultimately can lead to carcinogenesis in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important as it will provide further insight into the ways DNA replication stress develops in cells and how this process drives the transformation of a normal cell to a tumour cell in addition to other associated changes in cell morphology. It has now been established that the genome instability observed in most human cancers is driven by the DNA replication stress that occurs as the transformation from normal cell to a cancer cell progresses.

The work supported by this project is likely to identify additional components and pathways involved in to the cellular response to DNA replication stress. In addition to contributing to extending our knowledge of how DNA replication is regulated and although not directly attributable to this project, it is likely that such insights will also prove vital for identifying the key protein factors important for these pathways and in doing so identify new targets that will enable the development of new drugs or therapies to treat a range of human diseases in addition to human cancer.

What outputs do you think you will see at the end of this project?

Outputs from this project are anticipated to be disseminated through the publication of research articles in general interest and specialised scientific journals. In addition to these the results and findings will also be disseminated to the research field via seminars and presentations at scientific meetings. These presentations will mainly be to other scientific researchers with interests in DNA repair, cancer biology and DNA replication at national and international scientific meetings but there is an anticipation that results will also be presented to a lay audience at meetings organised by the various funding charities to provide the volunteers who raise money and donate funds to the charity with details of the work they are supporting.

Who or what will benefit from these outputs, and how?

The work supported by this project is basic biological research so the immediate benefit will be the advancement of scientific knowledge regarding the ways that DNA Replication stress and DNA Damage Response pathways are regulated and how defects in these pathways contribute to the development of cancer. In particular it will provide insights into the regulation, of the DNA replication protein PrimPol by the mitotic kinase PLK1, the mRNA processing protein Cip29, and will lead to studies where the functional significance of phosphorylation and other protein modifications such as Ubiquitylation and Sumoylation for the regulation of DNA replication and cell cycle control will be established. The initial beneficiaries of this knowledge will be other academic researchers working in the fields of cell cycle control, cancer biology and clinical oncologists.

In addition, this work results in the generation of a wide range of antibody, protein and DNA reagents as well as technological and methodological developments in *Xenopus* egg extract production and assays to analyse DNA Replication stress responses. I have made these reagents available to other researchers working in the field and will continue to make reagents generated under this project licence available to the research community. Therefore, in the first instance the main short term benefit will be the provision of reagents, expertise and the extension of knowledge in an important area of biology which will be of interest to a large research community as well as being of interest to researchers in the pharmaceutical and biotech industries.

This advancement in scientific knowledge and the resulting research outputs are unlikely to be translated into advances to treatments that will benefit the public during the duration of the project. However, a greater understanding of the way DNA replication stress response pathways ultimately permit the continued survival of some cancers will provide an important contribution to understanding of how current cancer treatments achieve efficacy as well as identification and development of drugs that will kill cancer cells with greater specificity and this understanding will contribute to improvements in treatments for patients in the longer term.

Also, engagement with the public in publicising and explaining these outputs will also serve to increase public understanding of cancer, its causes and the recent improvements in treatments and prognoses which in turn is likely to have a beneficial effect on the number of people accessing healthcare advice regarding potential cancer symptoms.

How will you look to maximise the outputs of this work?

The impact of this work will be maximised through sharing data with other researchers as well as disseminating the research findings through publication in general/specialist interest international journals. Collaboration has been central to the success of my previous work in this area and such collaboration will ensue that the insight and knowledge generated by this application will continue to be the main route that our expertise in this non-human model system will be successfully exploited to further our understanding of human diseases such as cancer. Several long standing and successful collaborations have been established to bring the key expertise necessary together to maximise the impact of the work conducted and allow translation of the *in vitro* work into effective research using mammalian cells and new collaborations will be established should these be necessary to achieve the aims of the project.

Species and numbers of animals expected to be used

- Xenopus laevis: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project will use egg extracts prepared from the unfertilised eggs of the South African amphibian Xenopus laevis. *Xenopus* are unique as they can be induced to lay eggs all year round and are therefore able to provide material for experiments as required. The eggs are large and contain the large stores of protein and mRNA to support many rounds of cell division with means that large amounts of material can be obtained from relatively few animals.

Typically, what will be done to an animal used in your project?

Laboratory bred male and female frogs are kept in a purpose built aquatic habitat in tanks containing 8- 10 animals each. A water treatment unit conditions and circulates water through the tanks. The environment of the habitat is constantly monitored to ensure optimal, temperature and water quality to keep the animals healthy and in good condition. The day before eggs are required, female frogs are induced to lay eggs by injecting a small quantity of HCG under the skin. Once egg laying is completed (18-36 hours) the animals are returned to the colony.

Male animals provide sperm to be used as a DNA template in DNA synthesis and nuclear formation experiments. Sperm production is also stimulated by injection of HCG. 5-8 days after injection, males are painlessly euthanized before the testes are removed and the sperm prepared for use in experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals display little or no distress during handling and the injection procedure itself. The instances of adverse effects caused by the injection (infection) are extremely rare.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the procedure supporting this project is mild

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

At present it is not possible to reconstitute DNA damage response pathways from purified protein components. Therefore, in order to achieve the project objectives it is necessary to use material obtained from animals.

Which non-animal alternatives did you consider for use in this project?

Various invertebrate models, yeast, fruit fly as well as mammalian tissue culture cells

Why were they not suitable?

It is not possible to prepare cell extracts from invertebrate systems that posess the range of properties shown by egg extracts made from Xenopus eggs. As a result the ability of cell-free extracts from Xenopus to recapitulate cell cycle and DNA damage responses *in vitro* cannot be replicated with the same level of synchrony using eggs from invertebrate species or extracts from mammalian cultured cells. I have also considered other methods of obtaining eggs/sperm from Xenopus that do not involve regulated procedures; However, the quantities of eggs and sperm produced by these techniques are too low to provide sufficient material to achieve the objectives of the work associated with the project

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animals themselves are not used in the experiments directly (animals provide biological material (eggs/sperm) for experimentation) so the number of animals is ultimately determined by the quantity of egg extract required to achieve the project objectives. With regard to female animals, although there can be some variability in the quantity and quality of the eggs laid by individual animals we keep records of the laying performance of each of the tanks in the colony and where available, these historical records along with our extensive past experience means that we can accurately estimate the number of animals required to generate any given volume of egg extract. The number of male animals required has been calculated on the basis of the quantity of sperm required to support experiments which has been estimated on the quantities used for similar work carried out over the past twenty years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The average quantity of eggs and thus volume of egg extract that can be produced from each tank of animals will be estimated. It is therefore possible to estimate the minimum number of procedures that will be necessary to produce sufficient egg extract for each experiment. Therefore planning experiments in advance and calculating the volume of egg extract required we are able to induce egg laying using the minimum number of animals necessary. In addition, identifying instances when previously frozen extract is suitable for use in experiments whenever possible will further reduce the number of animals/procedures required to achieve the projects objectives over the lifetime of the license. Injecting male animals with a small quantity of hCG (protocol 2) maximises the yield of sperm from each animal which reduces the number of animals used over the lifetime of the license. In addition, sperm obtained from male animals is stored frozen in small aliquots and only the minimum quantity of sperm required to support individual experiments is defrosted to keep wastage to a minimum and further reduce the number of animals required to support the experimental work.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of regulated procedures (hormone injection) will be kept to a minimum by planning experiments in advance. The volume of egg extract required will be calculated in advance, and hence the minimum number of procedures required to provide sufficient egg extract to achieve the aims can be estimated. Egg production will also be maximized by ensuring that at least three months elapses before an animal is induced to lay again. Typically an animal may be induced to lay eggs 2-3 times each year. In all cases animals are inspected prior to undergoing the procedure to ensure they are healthy and in good condition. Although freshly made extract is generally preferable for most applications, in some cases previously frozen egg-extract can be used without compromising the experimental objectives.
Therefore the number of procedures required to achieve the objectives of the project will be further reduced by using frozen extract wherever possible. In the event of surplus eggs being laid then all eggs of suitable quality will be used to make extract and any surplus egg extract will be frozen and stored in liquid N_2 for use in subsequent experiments, thus reducing the number of procedures required to fulfil the aims of the project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use adult male and female *Xenopus laevis* to provide the source of biological material (sperm, unfertilised eggs). The production of eggs is induced by a sub-cutaneous injection of human chorionic gonadotropin (HCG). This injection causes minimal stress or pain to the animals. Eggs are laid 14-18 hours after injection. Female animals are returned to the colony after eggs have been laid and are not used again for the production of eggs for a minimum of 3 months to ensure the ovaries have sufficient time to repopulate with mature oocytes. To stimulate sperm production, male animals are also injected with HCG but 5-8 days after injection the males are anesthetized and euthanised prior to removal of the testes.

Why can’t you use animals that are less sentient?

The egg extract that is vital to the success of the work requires the production of high quality unfertilised eggs from the female *Xenopus* so only sexually mature adult female and male animals can be used. *Xenopus* is one of the few amphibians that can be induced to lay eggs in response to exposure to hormone and the characteristics of the eggs (size, type and quantity of biological material obtainable) cannot be replicated using less sentient organisms. On injection of HCG it takes 14-18 hours for egg laying to occur which would not be possible if the animal had been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Although animals do not show significant distress during general handling and when undergoing the regulated procedure, handling is always kept to a minimum. Animals having undergone the procedure are kept in individual tanks which are placed in a dark quiet location overnight while egg laying is taking place. Once egg laying has been completed and the eggs have been harvested the animals remain in their tanks for 24 hours until any residual egg laying has been completed. Animals are then returned to the colony. There is evidence that feeding of animals is associated with a transient rise in the bacterial content of the tank water. As animals having undergone egg laying may be less inclined to eat and be more vulnerable to infection the animals are not fed for 24 hours after having laid eggs, before being returned to the usual feeding regime of the colony. The animals are routinely fed three times a week. Published guidance on the care and husbandry of *Xenopus* (RSPCA 2005) indicates that in the wild *Xenopus laevis* can survive periods of starvation of several months so we do not feel that the animals will be unduly distressed by withholding food for this short period after they have been induced to lay eggs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The animals themselves are not the subject of the experiments proposed in this project. The role of the animals is to provide the biological material (males-sperm, females-eggs) that are used in the experiments. The care and husbandry of the animals will be carried out using the benefit of over 30 years of experience of handling and maintaining these animals successfully to provide the biological material to support laboratory research. This experience will be coupled with reference to published guidance on the care and husbandry of *Xenopus* from organisations such as LASA and the RSPCA as well as published home office guidance on the care and housing of amphibian species.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are part of a worldwide collaborative network of research groups that use *Xenopus laevis* and *Xenopus tropicalis* for laboratory research. This network is active in disseminating information and providing resources regarding improvements in the care and husbandry of *Xenopus* species in a laboratory context. In addition we work with the manufacturers of the Xenoplus aquatic habitat systems to keep up to date with developments and refinements to the equipment used to house amphibians.

83. The Role of Central Sympathetic Control Neurones

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Autonomic control, Cardiovascular control, Physiology, Pharmacology

Animal types	Life stages
Mice	adult, juvenile, aged, embryo, neonate, pregnant
Rats	juvenile, adult, aged, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We and other scientists have identified a family of nerves in the brain that can control the heart and blood vessels. When these nerves are active they increase the blood pressure and heartrate.

Evidence suggests that excessive activity of these nerves could contribute to cardiovascular disease, especially in older people. We do not know what normal function these nerves have though. Scientists have several ideas including the suggestion that they could be the nerves that cause sharp and dangerous increases in heart rate during a sudden shock or fright. The central objectives of this project are to find out what the function of these nerves really is in a normal animal, and how we can modify their activity with drugs to prevent death and disease in people and domestic pets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that

accrue after the project has finished.

Why is it important to undertake this work?

This work is important because, firstly itwill provide new avenues for targeting cardiovascular disease and secondly, it will teach us more about how the cardiovascular system is controlled and allow improvements to computer models of this which may, ultimately, reduce the need for animal experiments.

What outputs do you think you will see at the end of this project?

Information:

We will learn about the native control mechanisms of cardiovascular neurones in the paraventricular nucleus of the hypothalamus (PVN). We will learn what the role of these neurones is in the overall pattern of cardiovascular control.

Publications:

We will publish these data in high quality international journals as we have done with the previous experimental data.

Products:

We do not envisage products resulting from this work, but we have identified candidates (both in terms of specific mechanisms and proteins that may the foundation of novel pharmacological or biological products in the future for control of hypertension or heart disease.

Who or what will benefit from these outputs, and how?

Two clear beneficiaries are Academics seeking to understand how subtle and complex cardiovascular mechanisms operate and Industry who will find useful targets for novel medicines; pharmacological agents and biologics for heart disease and hypertension.

How will you look to maximise the outputs of this work?

Collaboration

Via publication and presentations we seek to engage with other physiologists as well as our medical colleagues. We work particularly closely with the Hospital ITUs physicians who are anxious for novel medicines to control cardiovascular system in crises situations. There are a range of current medications, but in these crisis situations there are always off target effects that need to be navigated.

Dissemination
We hold regular public engagement events to discuss the cardiovascular system. This is with schools, children and adults.

Unsuccess

We plan to publish all data including negative, but together with presentations where we discuss "fails" we hope to prevent wastage of time and animal lives in the future.

Species and numbers of animals expected to be used

- Mice: 300
- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our objectives are to understand the fine cellular and protein level mechanisms of control of the cardiovascular system by the brain. This is fundamental scientific knowledge and will inform future development of medicines that control and protect against cardiovascular diseases in humans and domestic animals. In humans, cardiovascular disease kills approaching 100,000-200,000 people per year working out to be approximately 500 people per day. To study this in detail one needs an analogous mammalian species where the main areas of the brain and the cardiovascular system fundamentally similar. This is the case with most juvenile and adult mammals, not necessarily other animal classes. However, mice and rats have long been studied in fine detail and so we have a vast database of protein and physiological data on their make-up making further scientific advancement realistic. Furthermore, as small and social animals they are easy to keep, look after and work with in comfortable home cages without the stress or discomfort that would be seen in a larger animal, such as a cat, dog or pig.

Typically, what will be done to an animal used in your project?

The primary objectives in this proposal are to investigate mechanisms by challenging animals with either drugs, biologics or stimuli and measure the resulting change in the heart rate and blood pressure etc. Most drug/biologic challenges are by simple injection, but some require the agent to be implanted in the animal requiring a surgical procedure under general anaesthetic. In terms of recording, we have 3 methods; an entirely non-invasive method working on the sample principles as a human arm cuff blood pressure meter (plethysmography), telemetry where transmitters are surgically implanted under the skin, or by arterial cannulation, a technique done entirely under anaesthetic. Each of these methods has strengths and weaknesses. Non-invasive requires no surgery, but can only record for a few seconds at a time (and a limited range of parameters can be measured), cannulation can record for 30 minutes and record all parameters within that time, but the animals are asleep and therefore recorded parameters have to be interpreted with that in mind. Finally telemetry is emerging as the optimal technique for many experiments since the animals can move about and behave normally and data can be collected for a few weeks without any evident discomfort or stress to the animals. Telemetry, however, fails to record some of the parameters that can be recorded with cannulation.

What are the expected impacts and/or adverse effects for the animals during your project?

We are confident that the drugs/biologics will all be harmless, but we will monitor carefully and in the unlikely event that we detected (untreatable) adverse effects we would terminate the experiment.

In terms of some of the surgical preparation, this is always done under general anaesthetic with pain killers. We use the same medicines that would be used for surgery in a veterinary practise, and this is verified by our veterinarian. If analogous surgery was done on a human for medical reason, much of it would be done under a local anaesthetic, but with animals it is important that they sleep through, so that they neither move nor become frightened. It is likely that there is some discomfort when the animals first wake, but this should be mild. We watch carefully and monitor continually as animals wake up to be sure they are not in distress. Typically animals are socialising and grooming (showing normal behaviour), but if that was not the case we would seek veterinary support. If the animals showed distress that could not be quickly rectified by ourselves or the veterinarian, we would put the animal to sleep permanently whether or not this was directly due to the surgery, experiment or anything else.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The official classification we have given for this work is "moderate", this is because there is general anaesthetic use, but the procedures should be otherwise harmless. No animals should be in distress at any stage, but general anaesthetic is not trivial for any animal. Some of our procedures involve "stress" tests; these are calculated to be mild however. We monitor heart rate and blood pressure during these and the level of stress would be equivalent to a sports event or exam, certainly not terror; furthermore it would be for a period of seconds or minutes and not chronic. Brief stress in a healthy animal is thought to be harmless, although in the elderly people or those with heart disease it can be harmful. We do not anticipate any lasting harm to these animals from our stress tests. Chronic stress, even in otherwise healthy animals, from guinea pig to humans will cause physiological damage and we will NOT approach those levels in this work.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project's central purpose is to understand the cellular mechansims by which the brain controls the cardiovascular system. It is a far more complex system than often thought and the only way to do this in the level of detail we propose is to include study of whole animals with a functioning heart and brain.

Which non-animal alternatives did you consider for use in this project?

We considered three primary alternatives to animals here; human studies, cell culture and mathematical models.

Why were they not suitable?

Human studies. In order to test mechanisms we need to do test drugs and procedures which, whilst we believe them to be harmless, could potentially have a low frequency of unexpected negative consequences. In a rodent study, we have the advantage that if this occurs we can humainly terminate the experiment and put the animal to sleep. Clearly with humans we could not do this and so we cannot get anywhere near the level of mechanistic insight we can get using animal studies.

Cell culture. We do indeed use cell culture wherever possible, but whilst we can study some aspects of cardiovascular control we cannot test how specific neurones effect the cardiovascular system from this.

Mathematical models. Again, we use these where possible. We have built models that recapitulate some aspects of the system and these are scientifically interesting but have too many knowledge gaps to allow development of novel medicines or understanding yet. We hope this project will go some way to address this.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We determined the number of animals we would need using extensive analyses of the scientific literature followed by mathematical modelling.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We investigated several different numerical scenarios to devise the optimal number animals to use. Too few would mean the animals were wasted and too many would by definition be a waste. The approach we used was mathematical simulation using modern high performance computers and the
common mathematical programming language Python. In essence this includes using factorial designs such that a number of factors (n) can be assessed without need for n times as many experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As described previously we use mathematical modelling to optimise the number of experiments necessary. One key means we are reducing animal numbers is by constructing in silico models of both central processing neurones, and of the cardiovascular system as a whole. We impute data from the Public data sharing databases where available so we do not need to replicate those experiments, and we share our data in public repositories too. Where at all possible, we share tissue between groups.

We are sometimes able to collect brain tissue (just one example) from animals that are being euthanised anyway and this greatly reduces the number of animals that will practically be euthanised for this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are studying the brain, cardiovascular system interface and it requires and animal to do this.

Where possible, we will use the least invasive method (in our case the tail cuff blood pressure system) and in experiments where more detailed cardiovascular parameters are necessary, we will ensure animals are adequately anesthetised and pain free.

Why can’t you use animals that are less sentient?

Our models need to be analogous to humans domestic pets; mammals in other words with fully developed brains and cardiovascular system such as heart and lungs. Invertebrates have similar neurones, but not similar cardiovascular systems. Non mammals do not have the same control areas of the brain. Neonates and embryos have very different cardiovascular systems.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We acclimatise animals before use with regular human interaction, we monitor the animals ourselves, and have additional help from the animal house together with regular inspections by a full time veterinarian. We use the latest veterinary pain killers, sedatives and anaesthetics where appropriate to improve animal welfare. We also use environmental enrichment in high quality home cages. Before using the non-invasive equipment, animals are acclimatised to this too,
Furthermore, we can improve data quality and thus reduce animal numbers by ensuring we have healthy stress-free animals, therefore, animals are housed comfortably within clean cages and handled regularly by expert staff (so they become used to humans). The animals have spacious cages and fresh air and unlimited clean water. Bedding is changed regularly and their health is monitored by an experienced veterinarian.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the Animals in Science Regulation Unit (ASRU) Guidance and regulatory advice and adhere to the guidance on the operation of the Animals (Scientific Procedures) Act 1986 at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We read the 3Rs scientific literature, follow NC3Rs press releases and materials and attend 3Rs sessions and seminars.

84. Interventions in pregnancy: effects of obesity on maternal and offspring health

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

pregnancy, type 2 diabetes, cardiovascular disease, interventions, programming

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To assess the possible benefits and risks of lifestyle changes and interventions (e.g., taking of medications or exercise) in obese females before and during pregnancy on both the immediate and long-term health of the mother and her offspring.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In western populations such as the UK, 50% of all women of child-bearing age are classified as overweight or obese. The National Institute for Health and Care Excellence (NICE) highlights the negative health risks of this on both the mother and her offspring in the womb and beyond.
One such complication in pregnancy is diabetes. If making changes to the woman's diet

and lifestyle is unsuccessful in improving the condition, metformin (a drug in tablet form) is the next step. Whilst metformin is very successful in treating diabetes in the mother, little is known about its long-term effects on the offspring. Therefore, it is vital to investigate this important gap in our scientific understanding and assess if the benefits of metformin on the mother, outweigh any possible risks to her offspring.

We also aim to identify, assess and understand other types of interventions that could prove beneficial in improving the health of women and their children for example, exercise and the taking of antioxidants. Antioxidants are substances that slow down or prevent damage to cells in the body.

What outputs do you think you will see at the end of this project?

We intend to publish all findings (positive or negative) as research articles which will have been checked by independent scientists in the field. We will also present our findings at scientific meetings in the UK and overseas.

Who or what will benefit from these outputs, and how?

In the short term, it is expected that our published data will provide understanding of the ways in which interventions influence (positively or negatively) the health of the mother and her offspring. These data will inform health professionals (e.g., nurses, doctors, health visitors) about the effects of lifestyle choices and medicines in pregnancy for obese women. Data produced from these outputs will be used within future grants to fund further research into this area. These grants may include those for basic scientific research and/or clinical trials.

In the mid to longer term, these studies will result in collaborations, including clinical research groups and may benefit those such as the pharmaceutical industry. Our basic research will allow a directed approach to assess our findings in human trials which would further knowledge transfer and improve health.

How will you look to maximise the outputs of this work?

We expect to publish in high quality journals and in order to do this our work will be assessed by independent scientists (those not working with our group) to make sure that the science is of excellent quality prior to publication.

Negative data (results that do not provide the expected outcome/result, or in the case of comparing two experimental groups, there are no differences for the measured outcome) usually forms part of all scientific publications. Therefore, negative data will not be dismissed but will be presented at scientific conferences and within scientific papers as is routine.

We will also engage with and disseminate information to other stakeholders including our funding bodies and the public. For example, in the past we have been involved directly with the funders (e.g., British Heart Foundation) by engaging volunteers and donors in events that allow them to observe / carry out the types of experiments we conduct as part of our research. These opportunities are likely to present themselves again in the future.

We will also continue to engage with schoolchildren and the general public through events such as science festivals. We are also very active on Twitter, with over 1200 followers which allows us to continue to disseminate the results of our work to a wider audience.

Species and numbers of animals expected to be used

- Mice: 16,800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have been using mice to generate our model of obesity in pregnancy for approximately 12 years. During this time, we have consistently shown that this model has distinct similarities to many aspects of an obese human pregnancy. For example, the obese mice gain weight between their first and second pregnancies and they show signs of diabetes in pregnancy. We have also shown that similarly to humans, offspring born to obese mothers have a higher risk of disease (e.g., heart disease) in later life.

Mice allow us to study organs and tissues that would be either impossible or unethical in humans. For example, in order to understand what is going on in an organ at the level of the cell, we need to collect organs from the mother and/or offspring for us to perform our laboratory analyses. We also need to study effects of the mothers' diet on her offspring across their life course which are only feasible to animals with short lifespans such as mice.

Life stages required

Female mice before, during and afterpregnancy

- As mice are only pregnant for 21 days this allows us to perform experiments in a feasible time- scale which would be impossible in humans where a pregnancy is much longer at 9 months.

- As our research aims to understand the impact of different environments during pregnancy, it is essential to study females before, during and after their pregnancy.

- *Developing unborn offspring (embryo/fetus) at multiple stages of development (during pregnancy).*

- In order to understand how various maternal environments in pregnancy affect the growth and development of the unborn offspring (fetus) and the placenta (organ that allows the exchange of nutrients and oxygen from the mother to her unborn offspring), it is necessary for us to use tissues from the unborn offspring at different stages of development. Collection of such tissues would be impossible in humans.

Offspring at various ages once they have been separated from their mother.

- We need to use offspring at multiple ages exposed to one of four different pregnancy environments (healthy lean pregnancy, obese pregnancy and lean/obese pregnancy with intervention treatments such as drug treatment or exercise). We aim to study the impact of these different pregnancy environments on the future development of diseases such as type 2 diabetes and heart disease.

- Mouse models are critical for this research as they have a short lifespan (approximately 2 years), which allows us to study these diseases which develop with age. If we were to study the same effects in humans, we would have to follow the mother and child across an entire generation (30- 50 years).

- This mouse model will provide understanding of the consequences of obesity in mouse pregnancy and the risk *vs.* benefit of such strategies to mother and offspring. This information will provide evidence to form a more targeted approach in studying the immediate and longer term impacts of obesity in human pregnancy.

Typically, what will be done to an animal used in your project?

Female mice (who will become mothers) will be weaned onto either a healthy diet or a diet high in fat and sugar and they will remain on these diets for their lifetime. This will generate our two main experimental groups, (1) control females (healthy pregnancy), (2) obese females. Both groups of mice will then be mated for a first pregnancy to ensure that they are fertile and will rear their young successfully. After this first pregnancy, we check that the mice fed the diet high in fat and sugar have gained excess weight and fat mass compared to the lean healthy mice before mating both groups for a second pregnancy. The second pregnancy is known as our experimental pregnancy.

Females who become pregnant for their second time, with or without any interventions (e.g., drug treatments or exercise), will be allocated to one of three possible outcomes.

To study the effects of an obese or healthy pregnancy on the health of the mother and her unborn offspring.

To allow the female to give birth and rear her offspring. Her offspring will then be studied.

To study the direct effects for example of hormones, on the development of disease in the offspring. This outcome requires the surgical procedure, listed below.

Note, the interventions can be implemented either before pregnancy, during pregnancy, during lactation (period where the mother is suckling her young) or a combination of all three.

Measurements in females, before and during pregnancy.

They will have their blood pressure measured using a non-invasive method that is similar to the way humans have their blood pressure taken, except it is done on their tail rather than on the arm. Typically this will be done on 6 occasions and maximally on no more than 8 occasions during the life course of the female.

To measure the degree of obesity, mice will be placed (still conscious) in a tube to have their fat and lean (muscle) mass measured inside an imaging machine such as an echo-MRI. This is like an MRI machine used by humans, but just on a much smaller scale. This is not invasive and usually takes less than 5 minutes. Typically this will be done on 7 occasions and maximally on no more than 10 occasions across the life course of the female.

To assess the heart health of the female and the health of her unborn offspring, we may choose to perform a non-invasive ultrasound scan. To prevent the animal from getting

distressed whilst being handled and held for an awake procedure, we place them under a light anaesthesia (which is inhaled) and would typically last no longer than 2 hours. Mice will be gently awoken after the procedure and monitored closely afterwards. Typically this will be done on 1 occasion and maximally on no more than 3 occasions across the life course of the female.

Mice are usually housed together, but during and after pregnancy our mice are housed alone. We do this so that we can keep a closer eye on the mother (including her daily food intake) and her health during pregnancy. For offspring studies where females are required to litter, we will be able to check on her pups regularly and be certain on who is the mother of the individual pups in the cage.

In human pregnancies, mothers suspected of having diabetes will have a glucose tolerance test where they are given a sugary drink (glucose) and their blood glucose measured at multiple intervals over a 2-to-3-hour period. We will perform the same test in the mice but instead of a sugary drink, glucose will be injected into the peritoneal cavity (lower half of the abdomen) and glucose measured in tail blood at timed intervals over a 2-to-3-hour period. Typically this will be done on 2 occasions and maximally on no more than 4 occasions during the life course of the female.

In order for us to assess the health of the female, we may take small quantities of blood from the tail which would allow us to measure important read outs of health such as blood sugar levels, insulin and cholesterol. Typically this will be done on 3 occasions and maximally on no more than 6 occasions during the life course of the female.

Some pregnant mice will receive an injection of dye (between day 12.5 and day 18.5 of pregnancy, that corresponds to mid to late pregnancy), which will allow us to measure how quickly embryonic cells divide. This injection is delivered quickly into the abdomen. The mother is then left to give birth and we are able to assess the results of the injection of dye in the offspring. This will typically be done only on one occasion and no more than two occasions.

In some pregnant mice a different dye will be injected (between day 12.5 and day 18.5 of pregnancy, that corresponds to mid to late pregnancy) that will allow us to determine if there is poor oxygen delivery to the unborn offspring and their placentas. This injection is delivered quickly into the abdomen and the mice are killed humanely up to 180 minutes later.

For those females that have not been used for point 8, at the end of the study we may perform ultrasound imaging to assess the health of the heart, placenta and fetuses in addition to their response following injection of substances that can speed up or slow down the heart. We will do this under inhaled anaesthesia and once the procedure is finished, the mother and her embryos will be humanely killed whilst still under anaesthetic.

At the chosen end time-point within pregnancy (for those mothers not entering at point 7, 8 and 9), the mother and her embryos will be humanely killed and all tissues will be collected following the confirmation of death and stored for future laboratory analyses. These tissues will be available to our group and collaborators upon request.

Females that are required to litter to allow for the generation of offspring will suckle their pups until weaning (when her pups are 21 days old). After this she may undergo a glucose tolerance test (as described in point 5) prior to her being humanely killed and her tissues collected and stored for laboratory analyses. Her offspring will be housed together

grouped by sex, and fed either a standard (healthy) or obese diet and will undergo procedures listed below, under the heading 'Offspring'.

Surgery in pregnancy

A small number of females will undergo a surgical procedure during pregnancy. This procedure would be performed under general anaesthetic with all the surgical precautions taken pre-, during- and post- surgery. The surgery time is expected to be short (approximately 30 minutes in duration, from sedation to awakening). During surgery, a small incision in the abdomen would be made to expose the uterus containing the fetuses. At this point a very small volume of liquid containing a substance (for example a hormone) will be injected either into the amniotic sac where the fetus is contained or, into the fetal brain. Following injection, the incision would be closed with stitches or staples and the mouse allowed to regain consciousness by removing the anaesthesia. She will receive appropriate pain medication and will be observed by the scientist performing the procedure and by animal technicians. She will then be observed daily to ensure she was in no pain and that the wound was healing as it should. She will be monitored daily to ensure she has a normal birth.

Once recovered these females will be left to litter and bring up their offspring up until weaning (when the pups are 21 days old). At this point the mother may undergo a glucose tolerance test (as described in point 5) prior to her being humanely killed and her tissues collected and stored for laboratory analyses. Her offspring will be housed together grouped by sex and fed either a standard healthy diet or obese diet and will undergo such procedures listed below, under the heading 'Offspring'.

Offspring

A lot of the non-surgical methods used in the 'Measurements in females, before and during pregnancy' section will also be carried out in the offspring as we try to gather an understanding around their heart health and their risk of developing obesity and diabetes.

Assessing fat and lean mass by the method detailed in point 2 above. Typically this will be done on 7 occasions and maximally on no more than 10 occasions across the life course of the animal.

Measuring blood pressure non-invasively on multiple occasions throughout their lifetime by the method detailed in point 1 above. Typically this will be done on 6 occasions and maximally on no more than 8 occasions during the life course of the animal.

Glucose or insulin tolerance tests which require injection of either glucose or insulin by the method detailed in point 5 above. Typically this will be done on 2 occasions and maximally on no more than 4 occasions during the life course ofthe animal.

Blood sampling by the method detailed in point 6 above. Typically this will be done on 3 occasions and maximally on no more than 6 occasions during the life course of the animal.

We have the capability of measuring offspring food intake by weighing food daily within the animal's home cage. We may do this by housing the offspring on their own (single housing) so there is no competition between multiple mice for food. This will provide us with an accurate result on an individual mouse’s drive to eat. Typically this will be done on 3 occasions and maximally on no more than 6 occasions during the life course ofthe animal.

Offspring heart health (using echocardiography) will be assessed using a non-invasive ultrasound scan which will be performed under inhalation anaesthesia (and the mouse will remain anaesthetised throughout the procedure). Typically, the procedure takes no longer than one hour. Animals will be awoken at the end of this procedure. Typically this will be done on 3 occasions and maximally on no more than 6 occasions during the life course of the animal.

Similar to the dams' section, we will also assess offspring heart health in response to a range of drugs that for example, can speed up or slow down the heart rate. Animals will be sedated for the procedure and be killed humanely whilst still under anaesthesia and tissues collected for storage within our lab tissue bank.

To further understand the risk of the offspring developing diabetes, we will perform a procedure called a euglycaemic clamp. In this procedure the offspring will be fasted overnight, and their blood sugar (glucose) levels recorded. Blood glucose levels are measured from a small drop of blood from the mouse's tail. The mouse will then be anaesthetised (and will remain anaesthetised throughout the procedure) and a known quantity of insulin (hormone) will be injected into the abdomen. This will lower the blood glucose levels. Using a cannula inserted into the tail vein, glucose will then be slowly administered to increase and then maintain blood glucose levels at its starting value. After this procedure the mouse will either (a) killed by an overdose of anaesthetic (b) injected with a substance to kill the animal while preserving organ and tissue structure while still under surgical anaesthesia.

Offspring that have not come from point 6 and 7 will be humanely killed at the end of the experiment and their tissues collected and stored for future laboratory analyses for us by our group or collaborators upon request.

A small proportion of surplus offspring (that would otherwise not be used/culled for statistical reasons) and that have only had minimal phenotyping e.g. weighing, body composition or non- invasive blood pressure measurements may be transferred to other collaborative projects for further specialist techniques for which we do not have expertise, i.e. feeding behaviour, autonomous feed preference. This is important to ensure we maintain good 3Rs practice and would avoid the need for more pregnant mice and offspring to be generated.

Any surplus genetically altered mice that have not undergone any regulated procedure will also be made available to other users to maintain good 3Rs practice.

What are the expected impacts and/or adverse effects for the animals during your project?

As the large majority of work is non-invasive there are very few procedures within this license that would be expected to cause any impact or adverse effect.

However one procedure that would be expected to cause adverse effects would be surgery. The surgical procedure will be carried out under anaesthesia and pain will be alleviated through the use of pain relieving medication. We have kept the surgical procedure short to reduce any complications during anaesthesia. Complications surrounding wound healing (where the animal was cut open) are expected to be rare, but where these cases occur we will ensure their pain is adequately controlled using pain relief. In the rare cases where the wound re-opens we will place the animal back under a

short anaesthesia to repair the wound, we will only repair the wound once. If neither of these improve the outcome, the animal would be humanely killed. Post-surgery monitoring will be carried out by the experimenter and animal technicians multiple times per day in the first few days post-surgery and all mice will be provided with soft bedding to provide optimal conditions for quick / uncomplicated healing and housed together where possible.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice

Mild = 98%

Moderate = 2%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Modelling obesity in humans is highly complex as there are a number of physiological alterations that are impossible to model in cell culture systems. A cell culture system involves growing cells in a dish within the laboratory under tightly controlled conditions. The growth of these cells can be monitored and expanded to accommodate the experiment required at the time.

As we are studying long-term health impacts of obesity in pregnancy on the offspring, the short pregnancy (21 days) and lifespan (approximately 2 years) of the mouse model means that we can study disease progression within a short time frame (i.e., for duration of a project). Typically, in humans this could take half a century to study.

Which non-animal alternatives did you consider for use in this project?

Based on findings generated from our previous project license we were able to replace some of our animal work and use cell lines generated from humans and animals to further investigate findings from our animal models in cell culture (where cells are grown in a small dish in the laboratory to increase the number of cells available to do experiments). Cell lines from animal models are still classed as a replacement as they have been immortalised, therefore no further use of animals is required. We will continue to do this as part of this PPL.

Why were they not suitable?

These non-animal alternatives are not suitable for total replacement of animals within our project as we still cannot model pregnancy or the complexity of obesity in a cell culture system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have based the estimated number of mice on the numbers and findings from our previous and current project licenses and our Home Office returns which we return annually.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Multiple users within our research group will coordinate their projects to work on different organ systems while using the same mice. This will not only allows us to gain whole body information on a single mouse, but significantly reduce the number of animals used. This method will also improve data quality as the results from different organ systems can be compared within the same mouse.

To further reduce the numbers of animal used and to replicate what happens clinically whereby only obese women would be offered interventions in pregnancy, we usually only implement intervention strategies in obese females.

We would also utilise where possible banked tissues and cell lines from wild-type and genetically modified animals in the first instance prior to generating any new cohorts.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As we only require the female offspring (from our in-house stock breeders) for our pregnancy experiments, the male offspring will be made available to other users in the facility. Ex-stock breeders will also be made available to the facility for other users. Furthermore, offspring born from the first pregnancy will be offered to other users within the facility or made available for use by members of the lab for example for use in optimisation of molecular analyses.

Being a pregnancy model, we study both the mother (during/after pregnancy) and her offspring (from birth to adulthood) to maximise the measurements and to integrate the outcomes observed for both mother and offspring.

Furthermore, we have an extensive tissue bank of samples that can be utilised prior to generating new animal cohorts. This tissue bank is available to both our group and external collaborators on request.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will only be using mice within this project license. The majority of our methods are non-invasive and these were chosen in order to not only mimic what measurements can be (and are) performed during a human pregnancy but also to minimise any effects on the mice. Some of these methods include the measurement of blood pressure, fat and lean mass, metabolic and heart function as well as assessing placental function and the health of the unborn offspring. All of these measurements cause only very minor or no pain or lasting harm.

Only one of the methods proposed will involve surgery under anaesthesia (sedation). Surgery time is short and will be expected to last approximately 30 minutes. Once awoken the mouse will receive pain relieving medication and constant monitoring by the experimenter and animal technicians. To reduce the procedural and anaesthetic time for the female and her unborn offspring, we have devised a short protocol with a very specific aim. This will ensure that the pregnant female makes a quicker recovery.

Why can’t you use animals that are less sentient?

For a significant number of our protocols we are able to use animals that are less sentient (able to feel things).

Collection of unborn offspring and their tissues.

Culling of pups to standardise litter size to ensure all pups get a good amount of nutrition from the mother.

Death under terminal anaesthesia of pregnant females following non-recovery echocardiography / ultrasound.

Death under terminal anaesthesia of offspring following a euglycaemic clamp.

Death by perfusion fixation under terminal anaesthesia. Perfusion fixation ensures that organs and tissues are preserved. This process starts by pumping a salt-containing liquid through the blood vessels, followed by a liquid fixative (to ensure that tissue structure is maintained). Tissues will then be stored to be used later.

However, for our other work it is not possible to use animals that are less sentient. As we are modelling obesity in pregnancy and aim to assess the long-term health of the offspring, we need to use animals that are sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Based on our previous experience we have been able to refine some of the procedures to minimise harm. Surgery will be performed under aseptic conditions (set of procedures that protect the mouse from infection during surgery), anaesthesia (state of unconsciousness/sleep) and analgesia (pain relief) will be provided immediately, for as long as necessary. There will also be increased monitoring of these animals which will include measurement of body weight and regular checks on wound healing. Any animals exceeding a certain level of weight loss will be humanely killed. Mice will also be provided with soft post-operative bedding, nesting materials, heat pads and mash food where necessary. Pain will be monitored, and pain relief provided in the form of oral medication (e.g., flavoured jelly, paste or milkshake liquid).

Once our experimental animals become pregnant, these females are often housed alone. The reason we do this is to increase the pregnancy monitoring to ensure the health of the dam and her unborn offspring. Single housing also allows us to collect individual data on the dam during pregnancy (e.g., food intake). To create an enriched environment for singly housed animals, enrichment (e.g., tubes, tunnels, houses, nesting materials) will always be provided.

We routinely acclimatise our mice to the blood pressure machine over a period of training. We will continue to do this within this license and for other settings where restraint or handling is required. A similar period of training is used for mice that will be exercised such that we start with lower speeds to allow them to become familiar with the equipment and then gradually increase the running speed over time. There is also a sponge at the back of the treadmill that encourage mice to run, rather than standing stationary. Mice will typically be put on the treadmill at the onset of the dark cycle mice to take into account their nocturnal nature. Mice that refuse to run on multiple occasions will be removed from exercise training.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There is a wealth of resources published on the NC3Rs webpages and this is our first port of call for guidance on best practice, in addition to following and adhering to the ARRIVE guidelines. We will also use and refer to the PREPARE guidelines when planning animal experiments. Further to this, especially for use in surgery, we will refer to guidance from the Laboratory Animal Science Association (LASA), especially LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. A report by the LASA Education, Training and Ethics section. (E Lilley and M. Berdoy eds.).

We also seek advice from our peers especially those who have successfully published similar studies in mice to gain from their experience.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will maintain good contacts with the lead individuals (Named Persons) within our animal facility where we will be informed of any new developments or changes. We also have a 3Rs committee at the establishment and their minutes are available via our institution intranet. Our group will attend termly facility user committee meetings where new information is disseminated.

We will also aim to ensure that people working under this license are subscribed to the 3Rs newsletter from the National Centre for the 3Rs (NC3Rs). In addition to this we will continue to seek knowledge from the NC3Rs webpage (https://nc3rs.org.uk/resource-hubs), and 3Rs tools in-house and external resources such as the Laboratory Animal Science Association (LASA), RSPCA scientific group and Norecopa (https://norecopa.no/databases-guidelines).

In addition to this we are also aware of symposiums, talks, webinars and workshops all discussing the 3Rs. We will endeavour to stay on-top of advancements by attending these events as regularly as possible.

85. Breeding and maintenance of genetically modified and harmful mutant animals

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

breeding, maintenance, GA genetically altered, GAA genetically altered animals, HM harmful mutant

Animal types	Life stages
Mice	adult, pregnant, aged, neonate, juvenile, embryo
Rats	adult, pregnant, aged, juvenile, neonate, embryo
Zebra fish (Danio rerio)	neonate, embryo, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To breed and maintain and supply genetically altered (GA) or harmful mutant (HM) rodents and fish for use in bio-medical research.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically altered and harmful mutant animals are essential for addressing many scientific questions of bio-medical importance including understanding the function of specific genes and the role they play in disease. The work conducted under this licence will enable the breeding of genetically altered and harmful mutant animal for use either in biomedical research studies conducted using tissues taken after the animal has been killed using a schedule 1 technique or in studies conducted under other project licences. This service licence will enable breeding programmes at the establishment to be optimised

and thereby minimise animal usage in line with 3Rs expectation.

What outputs do you think you will see at the end of this project?

Genetically altered and harmful mutant animals suitable for bio-medical research.

Who or what will benefit from these outputs, and how?

The primary benefits of the work conducted under this service licence will be to enable the breeding programmes at the establishment to be optimised to minimise animal usage, in line with the expectations of the 3Rs. The programme of work will benefit scientists undertaking studies performed using tissues obtained after the animal has been killed by a schedule 1 technique, or scientists conducting studies under the authority of PPL with authority to use genetically altered or harmful mutant of the type being bred.

How will you look to maximise the outputs of this work?

A tissue sharing scheme is in-place to ensure the maximum use of the animals bred under this licence.

Species and numbers of animals expected to be used

- Mice: 5000
- Rats: 100
- Zebra fish (Danio rerio): 25000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the most common and least sentient of the mammalian species used in scientific research. The ease with which their genetic make-up can be altered, the wide availability of mouse specific reagents, the extensive range of established disease models and the fact that they share many common physiological processes with humans makes them the species of choice for many bio-medical research projects.

Rats are the species of choice for studies that require an animal that is either physically larger or has a greater ability to learn and problem solve than mice. The genetic manipulation of rats is far more difficult than mice, however several important genetically altered and harmful mutant rat lines exist that are of great value to researchers working on important diseases such as hypertension.

Zebrafish are the most common non-mammalian species used in scientific research and the second most commonly used animal under the Animals Scientific Procedures Act. The ease with which their genetic make-up can be altered and the translucent nature of their bodies, which enables many biological processes to be visualised, make them the species of choice for many basic research projects including studies into joint development and tissue healing.

The animals used under this licence will be adults, as only adult animals are able to breed. The offspring produced may be used at any stage in development, depending upon the scientific need.

Typically, what will be done to an animal used in your project?

Selected genetically altered or harmful mutant animals will be paired up and allowed to breed naturally.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of animals used or generated will suffer no harmful effects. A small proportion (less than 5%) may carry genetic alterations or mutations that could result in the development of disease. However, these will be carefully monitored against assessment criteria that ensure adverse effects are detected at an early stage. Any animal showing adverse effect will be humanely killed to prevent undue suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

sub-threshold 95%, mild 5%.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the outlined work is to generate animals for use in scientific research studies performed on tissues collected after killing. A small proportion of animals may also be transferred to other PPL's for use under other projects.

Which non-animal alternatives did you consider for use in this project?

The use of non-animal alternatives are not applicable to this project.
Why were they not suitable?

There are no non-animal means of generating the complex tissues that compose body systems, such as the blood vascular, renal, immune or nervous system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number is based on usage over the previous five year period.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All requests for breeding under this project must undergo independent ethical review, which requires the applicant to justify the need for the work, the choice of animal species and to provide the statistical methodology used to estimate the number of animals needed to meet the study aim. Animal breeding will comply with the recommendations outlined in the Home Office document 'Efficient breeding of GAA'.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The breeding program will be optimised and carefully monitored to ensure that, as far as possible, only the minimum number of animals required to meet the scientific need are bred.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals carrying genetic alterations or harmful mutations will be paired and bred naturally.

Why can’t you use animals that are less sentient?

All projects using animals generated under this project undergo independent ethical review, which requires the applicant to justify their choice of animal species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The animals used in this project will only experience natural breeding. Animals will be handled using refined methods e.g. tube handling or cupping and will be provided with environmental enrichment in the form of bedding, tubes or hutches and wood sticks for gnawing. All animals will be carefully monitored for signs of impaired wellbeing. Animals

with genetic alterations or mutations known to compromise their wellbeing will be monitored for the associated indicative signs and killed if they either develop these or show any overt signs of suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Breeding programs will be managed in line with guidance documents issued by the NC3Rs, Laboratory Animal Science Association, the Institute of Animal Technology and in compliance with the Home Office document 'Efficient breeding of GAA'.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will continue to meet regularly with our NC3Rs representative and to partake in 3Rs events. I am also a member of the Institute of Animal Technology who provide regular updates on 3Rs matters.

86. Assessing and improving welfare in dairy cattle and calves

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

animal welfare, animal health, preference, disease detection, precision livestock farming

Animal types	Life stages
Cattle	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to improve the health and welfare of cattle by designing cubicles that better meet the needs of cattle and by finding new methods of detecting disease, particularly in calves.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Housing for dairy cows and calves has primarily been designed around the needs of the farmers, in terms of ease of access to animals, ease of cleaning and time-efficiency for staff. However, traditional housing designs do not fully take account of the natural behaviour of the animal. While research has shown that cows prefer to lie in open bedded areas, the majority of dairy farms in the UK use a cubicle system in the lying areas for adult cattle. These cubicles consist of metal frames, that outline a rectangular space for a

single cows to lie in. However, the frame greatly restricts the lying posture of the cows. Cows can only rest on their chests/belly with their legs tucked in and cannot lie flat on their sides. Cubicles are used as they are easy to keep clean compared to open bedded areas, thus reducing the risk of mastitis, which is why the are becoming the norm in the dairy sector. However, cow preference for open lying areas does suggest that it is the restriction to the lying posture that is one of the issues, and work needs to be done to determine whether the design of cubicles can be altered to provide cows with more opportunity to lie in more relaxed postures (and improved welfare). The aim of this part of the project is to determine how the design of cubicles can be improved to better promote cow welfare.

Additionally, we aim to assess the validity and practicality of new methods and monitoring technologies to detect the presence of disease in cows and calves earlier than is currently typical. Disease is a major cause of mortality and poor health in dairy cattle and particularly in calves. Mastitis and lameness are major causes of poor welfare in adult dairy cattle and have major impacts on production and welfare.
Respiratory disease and diarrhoea are particularly prevalent diseases in calves. Calf disease is estimated to cost the UK cattle industry over £60M p.a. and costs £43 per case of pneumonia (NADIS, 2015) and £58 per case of scour (CHAWG, 2014) per affected calf. As well as causing mortality and illness in the young calf, the damage caused by the disease has long-term effects on growth and performance of the animal across its lifetime. Early detection of disease is important, as it allows the individual to be treated before the effects become too damaging, and it prevents the spread of the disease to other animals. This will improve welfare, but will also reduce the use of anti-microbial drugs in farming. Better health in animals will reduce the overall greenhouse gas emissions associated with farming.

What outputs do you think you will see at the end of this project?

At the end of this project, we will have a better understanding of how to construct lying areas for cows that allow them the type of space and bedding material they need to achieve good quality rest and sleep. We will also have new methods of detecting disease in calves. This will involve understanding how behaviour and physiology changes as animals become unwell, and creating methods and technological solutions to detect these changes.

This information will be disseminated to farmers, veterinarians and other stakeholders through webinars, open days and knowledge transfer documents. The findings will also be published in scientific journals and presented at conferences. The findings will also contribute to the development of devices and computer algorithms that can detect disease.

Who or what will benefit from these outputs, and how?

The studies on the design of lying areas for adult cows will produce information on how to best design lying areas that optimise the welfare of cows in a production setting. This information can be used by farmers or farm advisors to promote animal welfare when building new cow housing facilities. The findings can be used by policy makers when writing codes of recommendation for new buildings. If best practice in housing design is applied across the industry, it can be expected to have a positive effect on cow welfare and improve the sustainability of UK dairy farming.

The development of novel methods of disease detection in calves will have benefits for a number of different parties. Firstly, farmers could use these methods to identify individual animals suffering from disease early in the course of the disease. This would allow those

animals to be treated earlier than is the current practice, and before the full adverse effects of the disease are manifested. This would reduce the impact of the disease on animal welfare and reduce the number of costly treatments required. Allowing all calves to grow to their full potential without disease checks will have a positive impact on farm profitability, and reduce overall greenhouse gas emissions at the farm level as slow- growing animals take longer to reach a productive state and are less productive overall. Secondly, early detection and treatment reduces the risk of spreading the infection to other individuals in the group and herd. This has obvious benefits for health and welfare, but there are also societal benefits, as early detection and treatment of disease reduces the need for 'blanket' treatments of groups of calves which contributes to antimicrobial resistance.

We expect that these findings will become available as the studies are completed (from 2024 onwards) and will be disseminated through articles in the agricultural press, presentations at Open Days and shows, and directly to farmers via interaction with farm advisors.

How will you look to maximise the outputs of this work?

The best way to maximise the benefits of this work is to get the information out to the stakeholders who can make the most use of it. As we are working with commercial livestock, farmers are the most important stakeholders to reach. The transfer of any new findings will occur through presentations at Open Days, agricultural shows and by engaging with farm advisors, who deal with farmers on a daily basis. Other stakeholders, such as policy makers and industry bodies will be reached through the production of press releases and the production of research summary documents. The broader scientific community will be reached through publishing in scientific journals.

Species and numbers of animals expected to be used

- Cattle: 750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All of the issues that we wish to investigate are problems that directly affect dairy cows and calves, so the greatest experimental validity is achieved by carrying out the experiments directly on these animals. It will also mean that any findings can be directly used to improve the welfare of these animals.
Currently, no viable alternatives exist for the systems we wish to investigate.

We are using adult cattle to investigate the preferences for lying areas, as the type of lying area under study is only used with adult dairy cattle. We are using calves in the trials assessing methods to detect disease, as the diseases we are studying are of high prevalence in calves and very low prevalence in adult cattle.

Typically, what will be done to an animal used in your project?

In experiments assessing cow preferences for different types of lying area construction,

cows will be housed on their own in a pen for up to 10 days. Other cows will be housed in adjacent pens, with visual and physical contact possible, so that each cow is not entirely isolated.

In experiments assessing methods and technologies to assess disease, blood samples are taken to assess the concentrations of certain chemicals that indicate the presence or absence of disease. Up to 8 blood samples will be taken from each calf over a period of 6 weeks. Additionally, to monitor the health of the calves, the temperature of each calf will be assessed daily by inserting a thermometer into the rectum. Some of the monitoring technology that will be tested is fitted into an eartag which is fixed to the calf using an ear-punch, similar to the current identification eartags that it is mandatory to attach to the ears of calves.

What are the expected impacts and/or adverse effects for the animals during your project?

Cows housed in single pens show some anxiety for a short period (less than one hour) when they are first put into a pen on their own. However, as we always arrange the test pens so that other cows are visible in neighbouring pens, the cows settle down and are observed to eat and lie down in a relaxed manner soon after being moved.

The application of an eartag to a calf results in some initial pain (similar to ear-piercing in humans) but resolves over the next day. An experienced operator applies the tag. The site of the tag is checked for signs of inflammation or infection and treated if necessary.

Taking a blood sample from a calf involves the pin-prick pain of entry of the needle to the vein. However, this is short-lived. Experienced personnel will take the sample to minimise pain.

Taking the temperature of a calf every day using a thermometer inserted into the rectum carries the possibility of irritation to the rectum. However, lubricating gel will be used on the thermometer, and experienced staff will carry out the procedure. We have used this procedure on many calves previously, and no problems of this nature have been seen.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity of:

- Housing adult cattle alone in a pen with access to neighbours for up to 10 days: mild
- Application of eartags using an ear-punch to calves: mild
- Blood sampling of calves: mild
- Daily temperature monitoring using a rectal thermometer: mild All animals on test will experience this expected severity level.

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

All of the issues that we wish to investigate are problems that directly affect dairy cows and calves, so the greatest experimental validity is achieved by carrying out the experiments directly on these animals. Currently, no viable alternatives exist for the systems we wish to investigate. There are no computer models or other model species available, but we will thoroughly investigate potential new ones that arise.

Which non-animal alternatives did you consider for use in this project?

There are currently no non-animal alternatives available for this type of study.

Why were they not suitable?

None available to date.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical advice will be sought from expert statistical consultants in the design of each experiment to get the best design that makes the most of the data collected. Information on the sample sizes used in this application are based on previous experiments that have balanced the need for sufficient animals to achieve reliable results with the need to avoid over-use of animals. In experiments in which we are testing methods to detect disease, the sample sizes are based on the known prevalence of disease in our experimental herd.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The opportunity to reduce the number of animals used in the experiments is taken into consideration in the design of all experiments. Animals will be used as their own controls wherever possible, with base- line measures made to reduce the variation in the data due to differences between groups and individuals (e.g. comparing data from a calf when it is sick and when it is healthy). Cross-over designs will be used so that all animals experience all treatments, rather than having different groups experiencing different treatments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies with a small number of animals will be used to establish methods and screen options such as sensor design. Pilot trials will allow us to establish the best possible

methods before moving to a full experiment with a larger number of animals.

Animals used on all experiments will be sourced from our own farms so that they have had the same rearing and feeding systems throughout life and are of the same genetic stock. This will reduce the 'noise' in the data that is due to previous history and genetics. All animals used to be checked to confirm health, except in the studies that aim to develop methods for detection of disease in calves. In this case, only naturally-occurring cases of disease will be assessed (disease will not be induced).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are assessing the welfare of adult cows and calves, so these are the most appropriate animals to use for these studies. No animal or computer models currently exist, but we will investigate these options if they arise from other work.

We have considered all possible alternatives to the proposed methods, and have concluded that the methods proposed are those that cause the least possible pain, suffering, distress or lasting harm to the animals whilst still giving meaningful results. Having meaningful and reliable results means that the experiment does not have to be repeated.

To understand the preferences of adult cows for lying areas, each cow must be able to express her choice without interference from other animals. This requires that each cow must be housed in a pen on her own to allow her to express her preference for lying areas. Lying is a behaviour that occurs at night, so several nights of data must be captured to give meaningful results.

The fixing of an eartag to calves is necessary because we are testing the robustness and validity of ear- mounted sensors to detect disease. Eartags are used for this type of monitoring as, once the ear has healed, they are less likely to get tangled in equipment compared to collar mounted sensors (which can result in injury) and to be outgrown (which can cause leg lesions) compared to leg-mounted sensors.
The blood sampling of calves is necessary, as we are trying to determine whether sampling saliva is a viable alternative to the analysis of blood in assessing dehydration. Measurements on blood are the gold standard against which we will compare the values found in saliva.

Taking a rectal temperature is necessary as it is the most accurate way of assessing an animal's temperature. The use of an indwelling temperature monitor has been considered, but cannot be used in this case as the animals eventually enter the food chain. Surgery would be required to implant and remove the indwelling sensor, or the animal euthanized early in life. Calves rapidly habituate to the handling required for assessing rectal

temperature.

Why can’t you use animals that are less sentient?

The issues that we are investigating are problems experienced directly by cattle and calves, so the use of these animals at this stage of life is the most direct way of solving the problems. There are no viable alternatives to the use of these life stages or any less sentient species that will respond in similar ways. We are assessing behavioural responses in some studies, which means that the use of terminally anaesthetised animals is not appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Increased monitoring of animals receiving procedures is the main way of minimising welfare harms. Cows housed in single-occupancy pens will be closely monitored for signs of distress. The ears of calves will be closely monitored for a number of days after insertion of the eartags to allow detection of any bruising or inflammation. After blood-sampling has taken place in calves, the wound site will be monitored for bleeding, and the behaviour will be monitored to ensure that normal behaviour such as feeding and resting is not disrupted.

Using staff who are well trained in the procedures is also important. Staff who have been trained to carry out the procedures will do them competently, quickly and effectively, thus minimising harm to the animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will keep up to date with updates to Home Office requirements and to 3Rs advice on their websites. New developments in the field of cattle welfare can be gathered from scientific publications and conference abstracts.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information on advances in the 3Rs in this field are communicated through our institute's AWERB. Information on advances in methodologies are often communicated through scientific publications and at conferences, and we will stay informed about new developments via these channels.

87. Circadian rhythms in health and disease of the musculoskeletal system

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Osteoarthritis, body clock, exercise, therapy, ageing

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how daily rest and activity patterns regulate skeletal tissue functions and protect us from age-related diseases. We also aim to investigate whether we can utilize our intrinsic body clock mechanisms to enhance tissue repair and improve treatment options for skeletal conditions, such as osteoarthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Osteoarthritis is common and debilitating, affecting 60% of people over the age of 65, with currently no cure and no disease modifying drugs. Numbers of people suffering from OA

will rise with increased longevity in the population and the disease represents a significant economic burden on the health service and is a major cause of decreased quality of life amongst the ageing population. There are currently no effective treatments for OA and joint replacement and analgesia are the only options for suffers of OA. Therefore, new understanding of how cartilage tissue is maintained on a daily basis and how this process goes wrong with ageing is urgently needed.

Body clocks are 24 hourly (circadian) rhythms driving key aspects of our physiology and behaviour, including the sleep/wake cycle. Recent research has demonstrated an essential role of the intrinsic clock timing mechanisms for normal function and structural integrity of the articular cartilage and other connective tissues. The program of work proposed here will help us understand how connective tissues such as those in the articular cartilage in our joints are maintained by our body clocks and daily rest/activity cycles, and why loss of this temporal control mechanism contributes to the development of osteoarthritis and other age-related diseases. The new knowledge gained in this project will help us understand why we develop this disease when we get older, and how we may be able to utilise the body clock mechanism to optimize treatment timings or design novel therapeutic approaches.

What outputs do you think you will see at the end of this project?

The research outputs of this project will include:

In depth understanding of how connective tissues in our skeletal system are formed and maintained on a daily basis, despite the routines of wear and tear associated with loading and activity. It is currently unknown whether and how exercise can reset our body clocks in the skeletal system. Proving our hypothesis in vivo in mice will allow us to identify a novel disease modifying intervention (timed daily exercise) for age-related skeletal diseases, such as osteoarthritis. These non-invasive approaches are likely to bring significant clinical benefits to patients experiencing osteoarthritic pain. This information will open new research avenues in the field of connective tissue research, arthritis, exercise biology and sports medicine.

A mouse model of osteoarthritis (OA) where clock genes of interest are selectively deleted in the cartilage of adult mice.

Data from our mouse model showing how body clocks influence the onset and progression of OA, both spontaneously and following surgical destabilisation of the knee joint. These will include imaging data and joint 'damage scores' to demonstrate whether OA develops more quickly and with greater severity in our model compared to controls, data on joint mobility and data on the levels of molecules that are associated with pathways that promote or inhibit the onset and development of OA.

Insights into the mechanisms by which body clocks have protective effects in joint tissues and how our drug candidates harness these mechanisms in the treatment of OA.

We will publish our findings in open access peer-reviewed journals making them available to the OA research community.

We will present our findings in the form of posters and oral presentations at conferences. The project will support our development of a disease-modifying treatment for OA.

Who or what will benefit from these outputs, and how?

These outputs have the potential to benefit patients with OA - a very common and debilitating joint disease that affects millions of people worldwide - by improving our understanding of the disease process and, ultimately, by supporting the development of new disease modifying treatment and interventions.

The outputs will also be of value to scientists who are conducting basic and clinical research in OA by providing new insights into the regulation of disease-associated mechanisms. This research will also shed new light on exercise biology and sports medicine.

We will also engage with media outlets (including newspapers, radio and television networks) to publicise our major findings and maximize impact of this work.

How will you look to maximise the outputs of this work?

We will maximise the outputs by disseminating the outcomes of our work through conferences, seminars and publications (of both successful and unsuccessful approaches). We will also engage with OA patients and their clinicians to ensure that our work to develop disease-modifying drugs or interventions (e.g. timed exercise) for OA is aligned with their priorities and needs. We will also collaborate with other researchers by making our knock-out mouse models available to other researchers.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will utilise mice as a model of human osteoarthritis. We will also conduct treadmill exercises using young adult mice to investigate effects of exercise training on their skeletal circadian rhythms.

Use of a mouse model will allow us to carry out genetic modification to generate cartilage-specific gene knockouts in order to specifically explore our protein of interest in the knee joint during the development of OA. The generation of the gene knockout will require a breeding programme, which will use pregnant mice, embryos and all life stages from birth to adult mice.

Cartilage-specific gene knockout will be stimulated in young adult mice at the point when they have a mature musculoskeletal system. We will use these knockout mice to explore the spontaneous development of OA over a timeframe of up to 18 months.

We will also use the DMM (destabilisation of the medial meniscus) model of knee OA, where surgical destabilisation of the knee joint causes OA to develop over a few months. This model is used by many researchers in the OA field and is well accepted as providing

informative data on disease-associated pathways and the effects of therapeutic interventions.

Typically, what will be done to an animal used in your project?

The generation of genetically modified mice will involve natural mating of animals. The mice will be kept in standard conditions for up to 15 months. Some mice will be kept for up to 18 months without joint destabilisation surgery and then humanely killed so that joint tissues can be examined for molecular and cellular changes.

Mice with their clock molecules genetically engineered to carry either a light-emitting molecule or a deletion will undergo graded endurance training using a multi-user motorised treadmill, until running continuously for up to 60-mins per day, up to 5 days a week for up to 4 weeks. Each mouse will only go through one regimen of exercise. Animals will be acclimatised to both the environmental conditions (such as the mechanical noise of the motor) and to treadmill running which will gradually increase to the designed duration and speed. On completion of the exercise regime, mice will be killed for tissue collection and downstream analysis of circadian rhythms.

To induce cartilage-specific gene knockout, mice will be treated with tamoxifen. This will be administered either orally or by injection. To induce OA, mice will undergo a precise surgical procedure (under anaesthetic) to destabilise the knee joint. Animals will be humanely killed at a series of endpoints after surgery (up to a maximum of 20-weeks) so that joint tissues can be examined for molecular and cellular changes.

Some mice will be treated by a series of injections (up to a maximum of 1x/week, max 12 injections) with our drug candidates to improve disease outcomes.

As well as the endpoint examinations of knee joint tissues, the development of OA might also be examined using non-invasive imaging methods, such as x-ray and MRI (no more than once per month, max. 12 months), and by observation of the animals' mobility (a maximum of once per week).

Control mice, e.g. without gene knockout, will be included for comparison in all elements of the project.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected as a result of the breeding of genetically modified mice.

Adverse reactions are not anticipated for the treadmill running regimes we plan to use. Habituation to treadmill training may induce mild physiological and psychological stress. If an animal refuses to run during the habituation steps, it will be removed from the study. Short-term treatment with Tamoxifen can result in some weight loss; these effects will be short-lived.

Following joint destabilisation surgery, mice might experience some inflammation, discomfort and ultimately arthritis in their joint - i.e. a swollen joint and possibly limping. Our previous work in the DMM model has shown that, although we can see changes in the joint tissues at the endpoints of experiments, mice show very little sign of discomfort.

Injection with our drug candidates is not expected to have any adverse effects, based on our previous work.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding programme is a mild procedure. No animals are expected to experience adverse effects. The treadmill exercise is a mild procedure. No animals are expected to experience adverse effects.
The effects of tamoxifen treatment may be mild or moderate; this will be minimised by optimising the dose and route of delivery. Most animals will experience some effect.

The effects of DMM surgery is moderate. All or most animals will be affected.

The spontaneous development of OA in our gene deletion mice may be mild or moderate. We do not yet know the extent to which OA will develop in these mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying the complex biological process by which the articular cartilage is maintained through daily wear and tear, and subsequently can become degraded in osteoarthritis. The onset and progression of OA in humans is very variable. We consider that this is due to differences in intrinsic protective pathways within the joint. We have identified circadian timing mechanism in the cartilage as a critical regulator to inhibit OA-associated processes.

We are now at the stage of directly determining whether circadian rhythm disruption are pathogenic factors in the aetiology of OA and for these studies, there is no alternative but the in vivo model. Defining the molecular mechanisms involved and how they influence joint structure and function will improve our understanding of OA and support our development of new disease-modifying drugs. We make extensive use of cell culture models to study individual aspects of the process, but the holistic and complex process of connective tissue functions, including the aspects of the complex series of events leading to cartilage degradation associated with osteoarthritis cannot be studied in vitro.

The use of a mouse model is essential to achieve our aim. Mice have a musculoskeletal system that is similar to humans and are well established as informative models of OA. Mice are also the ideal species for genetic modification. The generation of a cartilage-specific gene knockout for our proteins of interest in young adult mice will allow us to specifically define the effects of clock genes within the knee joint. Previous studies have

already shown protective effects of circadian rhythms in mice and we are now uniquely placed to conduct the in vivo studies necessary to prove the causal link between chondrocyte circadian disruption and OA disease phenotypes and unravel the underlying mechanisms.

Mice mature much more rapidly than humans, so we will be able to look at the age-associated development of OA in our model over a relatively short timeframe (up to 18 months). In addition, surgical destabilisation of the knee joint in mice causes rapid onset of OA and is a very well accepted model of post-traumatic OA in humans. In these mouse models we will be able to use non-invasive methods to assess changes in joint mobility and structure during the study timeframes. At the study endpoints we will also be able to quantify joint damage and determine the expression of genes and proteins implicated in OA. In the joint destabilisation model we will be able to gather data for very early time points (from 6 hours after surgery) through to a maximum of 20 weeks. Evaluation of precisely defined time points, from the point of onset and throughout the progression of OA, could not be achieved using human tissues.

Before in vivo studies, we will test potential therapies in cell culture models to check that they have the expected effects in improving circadian rhythms and modulating the expression and activity of the clock related chondro-protective pathways.

Which non-animal alternatives did you consider for use in this project?

We have considered using clinical knee tissue samples from people with late-stage, symptomatic OA that are collected during joint replacement surgery, or early stage OA. We have already used these to explore how our protein of interest influences the expression of other proteins known to be associated with cartilage damage and how our drug candidate acts to suppress cartilage breakdown. We have also considered the use of cell culture models of cartilage, which we have used previously to generate mechanistic data.

Why were they not suitable?

The proposed work requires a model system that provides an accurate representation of the whole knee joint and where we can carry out analyses at precisely defined time points that represent OA onset through to late-stage disease. Human clinical samples are not suitable because they would not allow us to carry out genetic manipulation. Furthermore, there are no good diagnostic markers for early OA, and patients are seen by clinical teams at variable times following joint injuries, so it is impossible to identify patients at specific stages of the disease. Cell culture models could provide the option of genetic manipulation to knockout the protein encoding our gene of interest. However, OA is a disease of the whole joint and disease progression depends on the mechanical loading of the joint, which can only be achieved in a live animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated that up to 5000 mice will be involved in our breeding programme that will generate the genetically modified mice to be used for clock gene reporters and cartilage-specific knockout of our genes of interest. This is based on: (1) the number of experiments we plan to use these mice for, and
(2) the conservative assumption that each litter of mice we breed will include one mouse with the correct genotype.

We will use up to 500 mice for our studies on treadmill exercise. This is based on various timing and frequency of exercise protocols.

We will use up to 1000 mice for our studies on the spontaneous development of OA. In addition, we estimate that up to 400 mice will be used in the DMM model of OA. This is based on: (1) the different experimental time points we will use (in order to explore the effects of our protein of interest throughout the early stages of OA development), and (2) previous work by ourselves and collaborators using the DMM model, which suggests that each experimental group will need to include 10-12 mice in order to generate informative data. Among these mice for spontaneous or induced OA studies, we have estimated that up to 200 will be treated with Tamoxifen to stimulate cartilage-specific gene knockout. This is based on genetic targeting of 2 different clock genes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the outcomes of work in our own and collaborators labs and taken the advice of a statistician to reduce the number of mice being used in each experimental group. We will continually review the outcomes of experiments and use our data to optimise animal numbers as the project progresses.

By using both male and female mice in the spontaneous OA and DMM-induced OA studies we will reduce the numbers of genetically modified mice that we need to breed. Furthermore, generating data in both male and female animals is important with regard to the translation of our findings towards human clinical studies, where OA is common in both women and men.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continually review the outcomes of experiments and use our data to optimise animal numbers as the project progresses. We will also draw on our established local expertise for tamoxifen induction to ensure minimal animals are needed for the generation of cartilage-specific gene knockout.

We will follow the PREPARE guidelines (Smith et al 2017) to ensure the quality, reproducibility and translatability of our animal experiments.

To ensure efficient breeding, we will minimise the number of animals kept "on the shelf" and will breed, as far as possible, on demand. We will also have regular reviews of the colony performance. We have already optimised genotyping protocols.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use genetically modified mouse models to allow selective deletion of clock genes in the cartilage of young adult mice. This model will be used to explore the effects of the gene deletion on the onset and progression of knee osteoarthritis (OA). We will determine whether OA develops spontaneously in the knockout mice over time (up to 18 months); in this case we anticipate that any OA-like symptoms will be mild and slowly progressing. In genetically engineered mouse lines where there is an absence of any spontaneous OA phenotypes, we will initiate OA by surgical destabilisation of the knee joint in the DMM (destabilisation of the medial meniscus) mouse model. This is a very well characterised model, which we have used previously. We have observed that whilst mice develop OA- like damage to their cartilage, they exhibit little or no evidence of discomfort/pain over the timeframe of our proposed experiments.

Healthy mice enjoy running and it is an enriched experience for them to do so. Healthy wild type mice under standard animal house conditions will ‘run’ for 8-15 km per day in a running wheel. Indeed, we will use wheel running to confirm intact behavioural circadian rhythms in young adult mice with cartilage tissue-specific deletion of clock genes. However, voluntary running (e.g. through running wheel) is not suitable training apparatus for the specific aim in this project as previous work has shown that running wheels produce a heterogeneous response in their level of running. In addition, mice will not normally run at daytime. As such, treadmill is the methodology of choice because it is the only regimen that simultaneously allows for precise control of time of exercise, its intensity and volume.

Why can’t you use animals that are less sentient?

OA is a complex disease that involves the whole joint and is influenced by factors including joint mechanics as well as cellular and molecular processes. In order to explore the onset and development of human OA we need to use a live animal model with a mature musculoskeletal system that is similar to an adult human. The adult mouse fulfils this requirement. In addition, there are well-established methods for genetic modification and for surgical induction of OA in mice - both of which are essential for the proposed project. For the treadmill exercise study, again we need adult mice that have a mature musculoskeletal system that is similar to an adult human.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Potential refinements include habituation for treadmill, increased monitoring, post-operative care and pain management.

The major welfare cost to the clock gene knockout mice in this study is the development of OA-like symptoms. Since the purpose of this project is to study OA in the mouse knee

joint, this welfare cost cannot be changed. However, any apparent pain associated with the onset of OA will be controlled by the use of appropriate analgesics as advised by the NVS with animals monitored to ensure adequate dosing.

With regards to the Tamoxifen induction of cartilage-specific gene knockout in our mouse model, we will continue to optimise the least harmful way of administering Tamoxifen in terms of the route, dosage, duration and intervals, whilst still ensuring effective knockout (determined by genotyping). Tamoxifen treatment can cause some weight loss but these are typically transient.

With regards to the DMM surgical model of OA, we will continually monitor our procedures for pre- and post-operative care to ensure that these are optimised. For example, using sterile techniques to prevent infection at surgical sites and making adjustments to food, bedding and enrichment and using postoperative analgesics if required. In addition, we will carry out pilot studies and order our experiments so that the data we gather can be used to refine the numbers of animals being used at each stage, i.e. to ensure that all experiments are informative, but without using more animals than necessary. As well as collecting data on joint damage and gene expression profiles at the end of each experiment, we will use non-invasive methods (such as imaging and observation of animals' mobility) during the course of each experiment so as to maximise the information we obtain, but without any additional welfare costs to the mice.

With regards to the treadmill exercise experiments, experience from a local colleague shows that adverse reactions are not anticipated for the running regimes we plan to use. Habituation to treadmill training may induce mild physiological and psychological stress. To mitigate this, animals will be acclimatised to both the environmental conditions and to treadmill running. Animals will be monitored for adverse signs such as fatigue and indications of injury, which if they occur the exercise will be halted.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use published documents recommended by NC3Rs to ensure that we are using the most refined approaches in all our experiments.

We will closely follow the best and refined practice on GA breeding, Aseptic surgery, Prepare guidelines, Pilot studies, Systematic review, Enrichment, Social housing, Tube handling and 3Rs assessment, as listed on the NC3Rs website.

With regards to DMM model of OA, we will regularly review the scientific literature for work by other researchers in the field to identify opportunities for refinement. In terms of treadmill exercise, we will closely review the scientific literature for similar work from other groups to refine our protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are registered with NC3Rs and subscribe to their monthly newsletters, which will keep us informed regarding advances in the 3Rs. We also have access to an NC3Rs Regional Programme Manager. We will utilise the NC3Rs Experimental Design Assistant as well as seeking guidance from our local NVS and NACWO to inform the implementation of any advances that can be applied to our project.

88. Efficacy of anticoccidials and antiprotozoals against protozoal diseases in farm animals and farmed birds.

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Coccidia, Eimeria, Cryptosporidium, Anticoccidials, Antiprotozoals

Animal types	Life stages
Cattle	juvenile, adult, pregnant, neonate
Sheep	adult, juvenile, neonate, pregnant
Goats	adult, juvenile, neonate, pregnant
Pigs	juvenile, adult, pregnant, neonate
Domestic fowl (Gallus gallus domesticus)	juvenile, adult, neonate
Domestic poultry	juvenile, adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To propagate protozoa, particularly coccidian and to test anticoccidials and antiprotozoals for efficacy against coccidiosis in the target species. The target species will be infected either naturally or artificially then treated (may treat or commence treatment prior to infection). Following on from this we will examine parasite excretion levels in faeces and e.g. perform post-mortem assessment of intestinal lesions in order to confirm the efficacy for a selected anticoccidial and/or antiprotozoal.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that

accrue after the project has finished.

Why is it important to undertake this work?

To assess the efficacy of novel and varying dose rates of anticoccidial and antiprotozoal therapeutic agents on coccidiosis in a range of target animals. Coccidiosis is a ubiquitous disease and results in the loss of €2.3billion worldwide in poultry (mainly Eimeria) and $120million worldwide in other livestock species (Eimeria and Cryptosporidium). There are also many other important protozoal diseases of livestock that cause economic losses. These include histomoniasis, Spironucleus and Trichomonas. This work will help to contribute towards better understanding and control of animal diseases and may lead to novel veterinary medicines reaching the market to combat coccidiosis and other protozoal disease of animals (such as cryptosporidiosis, Babesia and giardiosis).

What outputs do you think you will see at the end of this project?

Contribution to the development of new anticoccidial and other antiprotozoal treatments with the possibility of scientific papers being produced. The result of the projects will be scientific reports that will help progress the understanding and treatment of protozoal infections within farm animals, with many contributing to regulatory submissions.

Who or what will benefit from these outputs, and how?

The direct benefits will be a series of study reports, normally one for each of the studies conducted. These provide the information that the client needs to support, for example, their claims and/or applications for veterinary medicine or food additive claims.

Indirect benefits will be the contribution towards helping to control protozoal diseases in animals which is a significant cause of suffering to animals and economic cost to the community. There is a constant need to combat the development of drug resistance by parasites, which may be brought about by adapting management techniques and existing products or by novel approaches. Compounds that act in novel ways have to be developed, tested for efficacy and brought to market. Existing products need to be evaluated against current field strains to ensure that they remain effective.

Financial income for the company enabling further contract research studies.

How will you look to maximise the outputs of this work?

We will work with global companies, institutes and charities to disseminate the study findings, publish research papers, attend relevant conferences and we also play an active role in creating guidelines in this area of research.

Species and numbers of animals expected to be used

- Cattle: 300
- Sheep: 200
- Goats: 50
- Pigs: 150
- Domestic fowl (Gallus gallus domesticus): 4000
- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Many of our studies are conducted in the target species for authorisation or support of, for example, a veterinary medicine and such testing is required by the regulatory authorities. There is a policy of checking whether non-animal alternatives are possible, for example by regular visits to the NC3Rs website (http://www.nc3rs.org.uk) and attending relevant conferences. Where there is a validated in vitro model then the client would be informed and the in-vivo work refused.

Typically, what will be done to an animal used in your project?

They may be infected either for passaging, dose determination purposes or for artificial infection prior to or following or during the administration of a treatment. Artificial infection may be done via oral gavage, exposure in the environment or insertion in the cloaca.

Treatment may be administered orally in feed, water or using a gavage. Subcutaneous, intramuscular or intravenous injection may be used, also a subcutaneous slow release device may be used. The treatment may also be applied topically to the skin in the form of a spray or pour-on.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are expected to tolerate the administration procedures with a maximum of transient discomfort.

Often there is a requirement to use a recently isolated field strain whose pathogenicity is characterised during the initial passage(s).

There is an expectation that clinical disease will develop and bloody/mucoid diarrhoea is expected in infected individuals.

Where species are mixed there is an attempt to get the combination and levels in the strain into proportions to show the required production and pathology impact without unnecessary clinical disease.

In order to mitigate the risk of clinical disease (diarrhoea, significant morbidity and mortality in some cases), the strain to be used in a study is normally tested in a small pilot first.

Extra checks are put in place throughout each 24 hour period at key times after infection (in both pilots and main studies) to coincide with expected timing of clinical signs in order to make sure that animals can be euthanased if necessary before exceeding the moderate severity limit. The intervals between checks are determined on a case by case basis and are normally at a minimum of one hour.

Typically animals infected with coccidia show a peak of clinical signs for 3 – 4 days in each cycle. Thereafter subsequent cycles (in studies such as floor pen studies that

continue past the first infection cycle) are normally less severe as the animals are older and more immune.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

25% mild and 75% moderate severity (see full breakdown in protocols). The maximum expected severity is moderate with any animals that reach this threshold being treated or euthanased as appropriate before they reach the severe threshold.

Animal types	Est. numbers (mild)	Est. numbers (moderate)	Life stages
Cattle	75	225	Neonate, Juvenile,Adult, Pregnant
Sheep	50	150	Neonate, Juvenile,Adult, Pregnant
Goats	12	38	Neonate, Juvenile,Adult, Pregnant
Pigs	37	113	Neonate, Juvenile,Adult, Pregnant
Birds	2000	6000	Neonate, Juvenile, Adult

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Anticoccidial and antiprotozoal veterinary medicines, biologicals, feeds and feed additives must be trialled in the target species for initial safety/tolerance and efficacy before taking forwards to regulatory submission or the market. Unless there is a viable alternative such as an established and validated tissue model available, the target animal will need to be used in these studies.

Which non-animal alternatives did you consider for use in this project?
N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use a combination of tools to estimate the numbers of animals needed. This normally includes the NC3Rs Experimental Design Assistant, VICH and WAAVP guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used.

Peer-reviewed journals and advice from external peers together with in-house experience and historical data over a number of years is used to ensure that animal numbers are adequate.

We are fully committed to reduction, nonetheless the exact numbers of animals required will vary with the particular project needs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have many years of experience of working with coccidial and protozoal infections, passaging and treatment regimes. This ensures the minimum number of animals are being used for any particular study. Due to our experience we have optimised our processes which enables us to maintain high welfare standards whilst delivering studies that meet requirements. We utilise resources such as the NC3Rs Experimental Design Assistant, VICH and WAAVP guidelines as well as consulting guidelines set by regulatory bodies and other relevant literature.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies are used to establish an appropriate infection level prior to the start of a main study. This ensures a consistent and safe infection level resulting in meaningful and valid results without compromising on animal welfare and safety.
Wherever possible the pilot study will be conducted in the same proposed breed or strain of animal as the main study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm

to the animals.

The animals used are the target species for the veterinary medicines or other product being studied. Any infection models will have welfare at the centre of their design.

In addition, animals on these studies will have a heightened level of observations immediately after and, where necessary, in the days and nights following administration of any substance, particularly around anticipated peaks of clinical signs associated with a particular infection.

If clinical signs are approaching or have breached the severity limits in place, then the Establishment Licence Holder, Project Licence Holder, NACWO(s), NVS and, where appropriate, a member of the Animals in Science Regulation Inspection Unit will be consulted to decide the course of action. This could involve immediate alleviating of suffering via euthanasia, or treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering.

Why can't you use animals that are less sentient?

We have to use these animals as hosts due to the research being directly related to treatment and/or prevention of infection in these species.

However we regularly refine existing and/or validate animal models consistent with 3Rs initiatives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
We minimise suffering by examining each study plan to identify opportunities to reduce handling by, for example, using experienced and knowledgeable staff, habituating animals to procedures where necessary, meeting or exceeding codes of practice and current guidance or literature suggestions for enrichment.

The animals used are the target species for the anticoccidial or antiprotozoal product on trial. Any models will have welfare at the centre of their design. In addition, animals on these studies will have a heightened level of observations immediately after and in the days following administration of any substance. RRL's standard level of monitoring is a minimum of twice daily. Frequency of observations are increased on an as needed basis based on animal observations and behaviour. For example, observation frequency would increase to hourly, overnight monitoring following the appearance of clinical signs associated with coccidia infection. Observations would normally be general health observations but these are supplemented with clinical observations by our NVS (or similar), monitoring oftemperature and other parameters as necessary.

If a treatment is to be administered over the course of a number of days, such as in feed or water, then we would aim to administer at the same time daily to allow the animal to become accustomed to the dosing regimen. We may also associate dosing and administration with feeding times as positive reinforcement for the animal

If it is believed an animal is approaching and likely to breach the predetermined severity category then we have a well-established process. This includes seeking veterinary advice from our NVS or another veterinary surgeon, discussions with the NACWOs, PELh, PPLh, PILh and Study Investigator. This group of people decide the best next steps in terms of animal welfare. This could be either, immediate alleviating of suffering if irreversible clinical

signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, and increased monitoring if the animal is unlikely to breach the severity limit by the conclusion of the study if appropriate.

If an animal breaches the predetermined severity category for the study then immediate action is taken. This often includes rapid discussions with the NVS, PELh, PPLh and PILh alongside the study investigator. We would also, if possible, contact an ASRU inspector. The course of action could be immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, maintaining and closely monitoring the animal if the scientific need is justified and the end of the study is within a short time frame, if agreed by an ASRU inspector. All decisions are taken on a study by study basis and will differ with treatments and species.

We will also continually review our procedures and refine as much as possible with guidance from, for example, VICH, WAAVP, EMA, and other relevant organisations and published literature.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

World Association for the Advancement of Veterinary Parasitology (WAAVP) and VICH guidelines for best practice. These guidelines are now seen by most regulatory authorities as the standard by which parasite-related protocols are written, and consider numbers of parasites required for study purposes.

Suitable literature will be used to stay up to date with husbandry practices to ensure that initiatives for e.g. enrichment can be assessed and incorporated as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly reference the NC3Rs website, published literature, attend relevant conferences and employees are members of The Royal Society of Biology and other relevant organisations.

89. Amphibian egg extracts as tools for understanding genome stability

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, cell division, genome stability, mutations, DNA replication

Animal types	Life stages
Xenopus laevis	adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Genetic instability is a characteristic of a large proportion of cancers and occurs most often when the DNA in a cell is being copied (replicated), before the cell divides. The aim of the research programme is to understand the pathways used by normal cells to prevent defects in the copying process, or failing that to induce cell death without further division.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding of the basic biology that underpins genetic stability is important for the development of drugs to treat diseases such as cancer where this becomes defective. Several of the pathways that the lab has played a role in elucidating have been targeted by anti-cancer drugs that are being trialled in the clinic.

What outputs do you think you will see at the end of this project?

We will have a better understanding at the molecular and biochemical level of the pathways used by cells to prevent genetic instability and will have a better understanding of what happens when these pathways are blocked or inhibited. This in turn may lead to new ideas about how genetic instability could be targeted in diseases such as cancer. The results will be presented in a number of publications.

Who or what will benefit from these outputs, and how?

Beneficiaries will be other scientists working in related disciplines and biotechnology and pharmaceutical companies interested in developing new therapies for diseases such as cancer.

How will you look to maximise the outputs of this work?

We will continue collaborations with scientists around the world as appropriate. Where new compounds with potential clinical use become available we will examine their effect on pathways relevant to our work and will make the results freely available. If we discover new potential drug targets we will engage with other researchers or biotechnology and pharmaceutical companies to explore the feasibility of developing a drug discovery campaign.

Species and numbers of animals expected to be used

- Xenopus laevis: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cell-free extracts of Xenopus eggs provide the only currently available system for supporting cell cycle progress in vitro. They therefore offer a unique opportunity to investigate genome stability pathways at a biochemical level.

Typically, what will be done to an animal used in your project?

Females will be injected with a hormone that naturally induces egg laying; they then lay eggs over the next day. Females are then rested for 4 months before being used again for egg-laying.

What are the expected impacts and/or adverse effects for the animals during your project?

Frogs experience transient discomfort as they are being injected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cell-free extracts of Xenopus eggs provide the only currently available system for supporting cell cycle progress in vitro. They therefore offer a unique opportunity to investigate genome stability pathways at a biochemical level.

Which non-animal alternatives did you consider for use in this project?

The lab uses and continues to use a number of non-animal alternatives, including mammalian tissue culture cells and recombinant proteins.

Why were they not suitable?

Whilst mammalian tissue culture cells and recombinant proteins are very useful and have provided much valuable information, they ultimately cannot substitute for the unique combination of attributes provided by egg extract: a physiological system where genome stability pathways can be analysed and manipulated biochemically.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We know approximately the volume of egg extract that we will require each year to perform our planned experiments. From our knowledge of the average amount of useable extract obtained from each female, we calculate the total number ofanimals required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have reduced the number of animals required in several ways: i) freezing extract so that none goes to waste; ii) minimising the amount of extract required in each experiment; iii) maximising the number of eggs produced by each female; and iv) improving the quality and quantity of extract by continual refinements to the extract-making protocol.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As soon as possible during the experimental phases of the project we will move our discoveries from the Xenopus system to other non-animal systems such as mammalian tissue culture cells and recombinant proteins, either by undertaking the work ourselves or by collaborations with experts in the relevant systems.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use cell-free extracts of Xenopus eggs which faithfully recreate the nuclear events of the cell division cycle in vitro. In order to induce egg-laying, captive frogs must be injected with hormones, which causes only transient discomfort. We have investigated in some detail the possibility of adding hormones to the water the frogs live in, but this yields small and unreproducible numbers of laid eggs; despite trying a large range of different conditions for doing this, we have not been able to significantly increase yield or reproducibility using this method.

Why can’t you use animals that are less sentient?

Adult females are required to lay eggs. No comparable system has been developed from less sentient animals (a comparable extract from Drosophila eggs has a large number of technical drawbacks compared to the Xenopus system).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will ensure that the housing and husbandry is of the highest quality, as the health and wellbeing of the frogs has a very large influence on the quality of eggs produced. We will continue to improve extract procedures to maximise the usefulness of the extracts and to minimise the number of unusable low- quality eggs that are laid.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the most up-to-date protocols published in the scientific literature relating to animal husbandry, egg production and extract preparation.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to communicate with other Xenopus researchers to learn of new technical developments and refinements in the field.

90. Diet Induced Obesity model in rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Obesity, Metabolic, Diabetes, Cholesterol

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This is a licence in which the programme of work is designed to produce prepared rodents and/or use of rodents to conduct basic early stage research. The rodents form the basis of several different animal models of diseases such as such as type 2 diabetes, high blood pressure, high cholesterol and other diet induced circulatory problems. Essentially animals are fed a high fat diet or high fat/high sugar diet for a number of weeks. As a result, they become obese, and usually have high blood sugar, and develop impaired sugar tolerance. These animals are then used to study the adverse clinical and genetic effects of obesity and type 2 diabetes and to test drug candidates that are expected to affect these conditions in humans. This is a demand-led service supported by a scientifically justified need. We will never exceed the moderate severity limit. The scientific background for each individual use is specific to each researcher but broadly addresses scientific and clinical needs in the following areas of research: obesity and metabolic related disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The benefits of the service program are therefore to provide facility for the scientific community to complete these programs of work where resources may otherwise have been limited. The availability of appropriate facility and expertise then ensures the procedures will be performed to a consistently high standard allowing greater reproducibility and ensuring the highest standards of rodent care.

What outputs do you think you will see at the end of this project?

As a result of conditioning rodents to become obese through the alteration of diet, clients can conduct basic early stage research. The rodents form the basis of several different animal models of diseases such as such as type 2 diabetes, high blood pressure, high cholesterol and other diet induced circulatory problems.

Who or what will benefit from these outputs, and how?

As this is a service licence the client will benefit upon receipt of the obese model as this will facilitate their area of research.

Therefore, this project will contribute to the achievement of scientific benefit on clients' own PPLs e.g. wider scientific community and patients.

How will you look to maximise the outputs of this work?

As this is a service licence, the work will be led by customer demand and will be managed centrally to ensure the 3R's are observed under this licence before shipping to the customer licence.

Species and numbers of animals expected to be used

- Mice: 7000
- Rats: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice and rats are good models for basic research into obesity and develop similar obesity related complications to humans. Multiple studies have been conducted in rodents to demonstrate the translational effectiveness of these animals in biomedical research.

Typically, what will be done to an animal used in your project?

Essentially animals are fed a high fat diet or high fat/high sugar diet for a number of weeks. As a result, they become obese, and usually have high blood sugar, and develop impaired sugar tolerance. These animals are then used to study the adverse clinical and genetic effects of obesity and diseases such as type 2 diabetes and enable the researcher to test drug candidates that are expected to affect these conditions in humans.

During a typical procedure a small piece of ear tissue may be obtained to allow for genetic analysis, blood samples (No more than 10% of estimated circulating blood volume within a 24hr period or >15% of estimated circulating blood volume in 28days), administration of diets of altered composition and/or medicated feed and /or drinking water to modulate/induce obesity or other obesity related diseases (e.g. atherosclerosis) , and potentially administration of glucose or insulin via injection for glucose/insulin tolerance testing.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals will develop diabetes. These animals will be closely monitored for signs such as excessive urination or water consumption compared to control animals and appropriate husbandry procedures will be employed to ensure adequate dry bedding and water is available to minimise likelihood of welfare impact from cage environment.

Blood samples will be taken from superficial blood vessels with no adverse effect expected.

Injections carry a risk of local inflammatory lesions, but this will be reduced or eliminated through keeping the administration to the minimum volume compatible with the scientific objectives.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals will become obese and may develop moderate clinical signs associated with obesity, such as type 2 diabetes.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are essential for research into human and animal diseases, as behavioural models and full system responses cannot be replicated using non-animal methods. Our Establishment will make consideration to the use of alternatives for every study and if unable to replace the use of live animals, will identify the most appropriate reduction strategies for the research work.

Which non-animal alternatives did you consider for use in this project?

There are no alternatives to using live animals for this area of research.

Why were they not suitable?

Full system responses cannot be replicated using non-animal methods.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This licence is a service licence and therefore numbers estimated are driven from historical customer demand for the service.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Consideration to identifying the most appropriate ways to reduce the numbers of animals used for their research work will be discussed with every new client project enquiry and ask them to confirm that they have received statistical advice on their experimental design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our AWERB will assess the project proposal internally for all new DIO clients/protocols. Recommendation will be made to reduce the number of animals used to the minimum required to safely deliver a valid result, use of pilot studies to define the optimum schedules for induction/treatment will be considered.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Wild type and genetically altered rats and mice will be used in this project.

This project is of a moderate severity and will involve feeding animals a higher fat/calorific diet to bring on the onset of obesity. There are no other less stressful methods to produce a reliable obese model mimicking human obesity related complications.

Why can’t you use animals that are less sentient?

A mammal is needed to compare to human anatomy therefore rodents are used as the least sentient mammal used in research

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All studies will have ethical and welfare review before starting and this will ensure minimal costs to the animal will occur. All clients will need to ensure statistical analysis has been completed to ensure the minimum number of animals are used in order to meet the scientific outcome.

For diabetic animals there will be increased monitoring of animals that develop polyuria and polydipsia
– twice weekly bedding changes and water bottle refilling, and the use of body condition scores will aid welfare assessment and humane endpoints.

We will minimise tail handling and encourage the use of non-tail handling techniques for routine husbandry procedures, such as cupping.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R's Experimental design and reporting.

NC3R's Guidelines for the Design and Statistical Analysis of Experiments Using Laboratory Animals,
Michael F. W. Festing and Douglas G.Altman

The ARRIVE guidelines 2.0

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All studies will have ethical review and each client will be asked to justify the ethical use of animals. This project supplies animals that become obese for further research.

I attend industry conferences and ensure all learning on the 3R's are applied to my project where possible.

91. Microbial and immune drivers of infection in chronic lung disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Asthma, Chronic obstructive pulmonary disease, Immunology, Microbiome, Respiratory infection

Animal types	Life stages
Mice	adult, aged, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The Aims of this project are:

To understand the role played by the lung microbiome ('resident' bacteria that are present in the normal lungs) in controlling how the body's immune system responds to harmful viruses, bacteria or fungi.

To determine how changes that occur in the lung microbiome of patients with the conditions asthma and COPD (chronic obstructive pulmonary disease, a smoking related disorder) predisposes these individuals to infections by harmful viruses, bacteria or fungi.

To study whether we could administer specific bacteria normally present in the microbiome of healthy people into the airways of patients with asthma and COPD to alter their microbiome and boost their immune system's response to harmful viruses, bacteria or fungi.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic lung diseases including asthma and chronic obstructive pulmonary disease (COPD) are major causes of death worldwide. Patients with these conditions are prone to infections by harmful viruses, bacteria and fungi that lead to acute symptom flare-ups ('exacerbations'), devastating episodes with a 1 in 4 mortality rate. We urgently need to improve our understanding of why some patients are more susceptible to infections. We could use this understanding to develop new ways of treating the condition with the aim of improving quality of life and outcomes for patients.

Recent studies have revealed that the lungs are colonised by millions of resident 'commensal' bacteria ('microbiome') which may help to protect against infections triggered by other more harmful bacteria. Asthma and COPD patients show outgrowth of certain commensals within their microbiome. We do not know whether this outgrowth is just a consequence of the disease or if, by upsetting the immune system, specific commensals actually contribute to increased susceptibility to infection by harmful viruses, bacteria or fungi.

This projects asks the following questions:

Do commensals in the lung have a general protective role in preventing infections by harmful viruses, bacteria or fungi?

Do specific changes in the microbiome that occur in asthma or COPD reduce the immune system's ability to fight infection by harmful viruses, bacteria or fungi?

Could we administer commensals from healthy people into patients with asthma or COPD to improve their immune system's ability to fight off infection?

We will take a two-pronged approach to answer these questions. Firstly, we will use human samples to study if asthmatic or COPD patients with frequent severe infections have outgrowth of certain commensal bacteria within their microbiome. We will then conduct experiments in mouse models that are not ethically or technically possible in humans to deplete or manipulate the lung microbiome by introducing commensals that are found to be increased in patients with asthma and COPD. We will study how these commensals directly affect the immune system's ability to fight off harmful viruses, bacteria or fungi.

It is anticipated that this work will identify important commensals that can directly upset or enhance the immune system. This would then lead to development of new therapies where healthy commensals could be introduced into the lungs of patients to boost their immune response when exposed to harmful bacteria, viruses or fungi. In summary, this research will provide new scientific insight into an area of huge clinical importance and facilitate development of exciting new therapies to reduce the burden of disease caused by asthma and COPD.

What outputs do you think you will see at the end of this project?

Existing respiratory microbiome studies have generated lists of commensals present in asthma and COPD with no clear understanding about how these changes contribute to symptoms or susceptibility to harmful infections. The current proposal will address this major gap in our understanding by providing new insight into how the respiratory tract microbiome interacts with the immune system to control protection against infection and how these processes are disturbed in people with asthma or COPD. This will lead to a number of tangible outputs, as detailed below:

Fundamental new knowledge on the critical microbial regulators of host defense to respiratory infection and how these factors are altered in chronic lung disease. The role of the microbiome at other body sites (e.g. the gut) is well established but very little is known about if and how the lung microbiome regulates protection or susceptibility to harmful infections and the key members of the microbiome involved are unknown. This project will provide detailed insight into this area for the first time.

New therapies for treating patients. Through our fundamental work, we aim to identify important commensals that can directly upset or enhance the immune system. This would then lead to development of new therapies where healthy commensal bacteria or bacterial products could be introduced into the lungs of patients with asthma or COPD to boost their immune response when exposed to harmful viruses, bacteria or fungi.

Research Publications. New knowledge and techniques developed in this project will be published in peer-reviewed scientific journals with early deposition on 'preprint' servers (e.g. BioRxiV) to ensure rapid dissemination to the wider community.

Data sharing. Certain aspects of the work planned will include 'sequencing' technologies where large datasets of genes, proteins or commensal bacteria are generated from lung tissue samples collected within experiments. These data will be deposited on public repositories to allow other researchers to access the data and use it in their own studies, thereby maximising the potential wider benefits of the results generated.

Future potential to reduce animal usage. Many animal disease models show large degrees of variation when attempts are made to replicate them in different animal facilities. The reasons for this are unknown but one theory is that animals in different facilities may have variations in their microbiome. Through understanding how different commensal bacterial groups affect the immune system, we may be able to yield insight that will better control variation between facilities and therefore produce more consistent models to reduce animal usage long-term.

Who or what will benefit from these outputs, and how?

This project will provide a major scientific advance that will be of relevance to a range of disciplines within the UK and internationally. We envisage benefits arising from several areas that are all achievable within the period of this PPL and will also extend long-term.

Benefit to other respiratory researchers. There is growing interest in the airway microbiome in respiratory disease. Although our proposal focusses on the microbiome in the context of asthma and COPD, respiratory tract microbiome changes occur in many chronic lung conditions (e.g. cystic fibrosis, idiopathic pulmonary fibrosis etc.) and our findings will be of broad interest to researchers in these areas. Short term benefits (<5 years) include research publications, training of new staff, new research collaborations, conference presentations and development of new experimental protocols. Longer term benefits (>5 years) include establishing a framework for future studies where causality can

be examined using the models we develop, potential new Intellectual Property (IP) opportunities including new drug candidates and further grant funding based on successful track record.

Benefit to Immunologists: Outside of the respiratory field, this proposal will also examine fundamental questions regarding how commensal bacteria can shape the immune system and how disturbances in microbiota composition affect the immune system's response to infection generally. This insight will have wide implications for basic immunologists interested in this area. Short term benefits (<5 years) include research publications, training of new staff, new research collaborations, conference presentations and development of new experimental protocols. Longer term benefits (>5 years) include establishing a framework for future studies where causation can be examined using the models we develop, potential new IP opportunities including new drug opportunities and further grant funding based on successful track record.

Benefit to animal researchers and suppliers: Our research may provide crucial insight into why certain animal models cannot be reproduced by independent groups. In some cases, this could be dictated by differences in the respiratory microbiome composition of animals used to replicate studies (presence or absence of certain commensals). This will have broad benefit to researchers working in academic and industrial animal facilities and additionally for commercial animal suppliers (who may use the information to standardise the microbiome of their mouse lines). Short-term benefits (<5 years) include publications in journals specialising in laboratory animal science, presentations at conferences with a similar focus and refinement of existing models to better control for lung microbiome variability. Longer term benefits (> 5 years) relate to new insight that will allow researchers in the future to better control these variables and development of better commercially available mouse lines through standardisation of microbiota.

Benefit to patients: Asthma and COPD are major causes of mortality worldwide with very few effective therapies. Our research will gain better understanding of the mechanisms that underlie increased infection susceptibility in affected patients and drive development of new effective therapies for these devastating conditions. This work will not only identify new therapeutic targets but provide new models to demonstrate 'proof of concept' before therapies can be moved into clinical trials. Short- term benefits (<5 years) include better definition of patient sub-groups that gain benefit from existing therapies, better awareness of these conditions through public engagement of findings we generate and acceleration of the drug discovery pipeline. Long-term benefits include development of new 'probiotic' therapies or anti-bacterial/anti-viral/anti-fungal agents that can be incorporated into clinical practice.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work through the following routes:
Public engagement: We will communicate the findings of this research to the general public in a format that is easily understandable to justify importance and disseminate key findings. This will occur through a range of platforms including social media, press releases, newsletters and participation in Science Festivals.

Presentation at conferences: We will disseminate our findings with other respiratory, immunology and animal model researchers through presentation of data at national and international conferences.

Scientific publications: We will publish our protocols and results within research papers in scientific journals (as open access manuscripts with early deposition on preprint servers) and through other platforms including online data repositories.

Communication with patient groups.We will liaise with relevant patient groups as a two-way process to discuss key findings generated during this project and use their input to guide future research directions and results dissemination. We have strong links to the British Lung Foundation and Asthma UK and will organise 'Meet the Research Team' sessions for patients and employees of these organisations to effectively disseminate our findings within UK and international patient communities.

Translation of findings into human experimental studies: As clinical academics we are well positioned to rapidly translate our mechanistic findings into clinical trials of promising therapies. We have a number of established clinical and industrial collaborations providing strong support to the feasibility of this goal.

Species and numbers of animals expected to be used

- Mice: 7600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project largely uses adult mice (since both asthma and COPD affect adult subjects) with some experiments using 'aged' mice (as COPD is a disease that frequently affects elderly individuals). The decision to use a mouse model was made after careful consideration based on the requirement that we seek to definitively understand complex mechanisms underlying how the microbiome acts to control the immune system. A mouse model was essential as it is not possible to recreate the complexities of lung bacterial communities in cells cultured in the laboratory and it is also currently not ethically or technically possible to deplete or manipulate the airway microbiome in human subjects. Using the mouse model therefore provides an experimental system where we can manipulate the human microbiome in a controlled way that is relevant to human disease.

Mice are closely related to humans in terms of similarity of genetics and immune system function so that experiments done can be directly related to human disease. Mouse models also have the advantage of having readily available reagents (antibodies) that can be used to block specific substances that are produced by the immune system in response to the microbiome. We also have a long track record of carrying out experiments in mice and we have already set up many of the models we plan to use in this project.

Typically, what will be done to an animal used in your project?

A typical experiment would involve mice receiving a light inhaled anaesthetic to allow intranasal (through the nose into the lungs) administration of antibiotics. This would occur daily for five days to deplete the existing lung microbiome. Using a similar method, we would then intranasally administer commensal bacteria (of the type seen in the lungs of asthmatic or COPD patients) for three days to mimic the microbiome of these conditions.

This would be followed by intranasal administration of a virus, bacteria or fungus that causes disease in humans (e.g rhinovirus, Streptococcus pneumoniae or Aspergillus Fumigatus). Animals are visually monitored every day during this experimental protocol and also weighed twice per week to ensure the infection is not causing weight loss which is a sign of ill health. Animals would typically be humanely killed at early (8, 24 hours after infection) and later timepoints (4 and 7 days after infection) and we would take a range of samples to study the immune response to the infection in detail.

In some experiments, we will administer substances into the lungs of mice to induce changes consistent with asthma. This would typically involve mice again receiving a light inhaled anaesthetic to allow intranasal administration of house dust mite (a substance that induces an allergic reaction in the lungs that mimics asthma). This would occur three times per week for a total of three weeks. Following this, mice will again receive intranasal administration of commensal bacteria for three days followed by administration of a virus, bacteria or fungus. Animals are visually monitored every day during this experimental protocol and also weighed twice per week to ensure the infection is not causing weight loss which is a sign of ill health. Animals would again be humanely killed at early (e.g. 24 hours) and late (e.g. 4 days) timepoints and we would take a range of samples to study the immune response.

In other experiments, we will similarly administer substances into the lungs of mice to induce changes consistent with COPD. This would typically involve mice receiving a light inhaled anaesthetic to allow intranasal administration of a single dose of elastase (an substance that induces lung changes similar to COPD). Ten days later (when COPD changes become established), mice will again receive intranasal administration of commensal bacteria for three days followed by administration of a virus, bacteria or fungus. Animals are visually monitored every day during this experimental protocol and also weighed twice per week to ensure the infection is not causing weight loss which is a sign of ill health. Animals would again be humanely killed at early (e.g. 24 hours) and late (e.g. 4 days) timepoints and we would take a range of samples to study the immune response.

In some of the above described experiments, we will also measure how these manipulations affect the 'function' of the lungs. This will typically (~90% of experiments where lung function is required) be done using a technique called 'whole body plethysmography' where mice are placed in small individual chambers for around 50 minutes which are connected to sensors that can measure the breathing rate and depth. We typically administer a aerosol 'bronchoconstrictor' (substance that briefly and mildly challenges the breathing) into the chamber to see how the breathing rate and depth responds. Mice are closely monitored for any signs of distress throughout this process.
In some experiments involving the above described models, we will also use mice that have been bred to specifically lack or over-express certain genes that encode immune substances in the lungs. By examining how this affects immune responses (in comparison to mice with normal levels of the gene), we can determine whether the gene plays an important role in dictating the immune response.

What are the expected impacts and/or adverse effects for the animals during your project?

Intranasal administration of viruses, bacteria or fungi into mice may induce varying degrees of 'inflammation' (caused by white blood cells flooding into the lungs to fight infection). This inflammation can lead to clinical signs. We are interested in evaluating this inflammatory response to understand how the presence of specific commensal bacteria

may affect this. Depending on the type of viral, bacterial or fungal infection and/or dose some animals will occasionally develop mild to moderate symptoms, consisting of reduced activity, hunched posture and tachypnoea (breathing rate faster than normally expected). These effects would generally commence around 48 hours after infection and may persist until the end of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 75% of mice are likely to experience moderate levels of severity. The remaining 25% of mice are likely to experience mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The decision to use a mouse model was made after careful consideration in comparison to other alternative approaches. The overall goal of this project is to definitively understand the mechanisms underlying how the lung microbiome interacts with the immune system to regulate protection against infections in health and promote susceptibility to infections in patients with disease (asthma or COPD). To do this, we needed an experimental system that: (i) allowed us to deplete or manipulate the airway microbiome to understand if it plays a causal role in the immune system's response and (ii) allowed us to block substances produced by the immune system that may be under control by the microbiome.

A mouse model is the only realistic option that would allow us to carry out these types of studies in a controlled manner that is still relevant to human disease and it is therefore essential that we use animal models to achieve our aims. Similar types of studies have been carried out in mouse models within the gut microbiome field and have yielded unique insights that has led to the development of effective new drugs for use in clinical management of intestinal diseases (e.g. for Clostridium difficile infections).

Which non-animal alternatives did you consider for use in this project?

We considered the following alternatives for use in the project:

Use of human lung cells cultured in a test tube in the lab

Use of studies directly in human patients.

Why were they not suitable?

Use of human lung cells cultured in a test tube is an extremely simplistic model that does not accurately recreate the make-up of bacterial communities within the lungs. The immune system is also extremely complex and involves a number of other cells apart from lung cells including a range of different white blood cells that have diverse roles. It is impossible to recreate this complexity in an artificial lung cell culture model and therefore these models are extremely limited for understanding these relationships.

Use of studies directly in human patients is currently unfeasible as it is not possible to deplete the human airway microbiome in the same way we can in mice. We also cannot currently administer bacteria into the lungs of patients without extensive safety testing and ethical approval. Finally, we would not be ethically permitted to block many substances produced by the immune system that may be under control by the microbiome in humans.

Overall, the mouse was the best model to enable us to manipulate the airway microbiome in a predictable way that is still highly relevant to human disease to gain functional insight into how commensal bacteria interact with the immune system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This work is supported by research grants where detailed proposal of numbers required to test our hypotheses have been calculated. Estimated numbers are based on experimental/control groups required in the proposed experiments. The numbers have been generated on the anticipation that initial timecourse experiments will be used to define optimal single timepoints to be used in more focussed subsequent studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?
We consulted the 'Prepare' and 'Arrive' guidelines and used the NC3Rs Experimental Design Assistant Tool to ensure that all studies are carefully designed and implemented in line with recognised standards and that all sources of bias are considered and minimised. For testing of novel therapies (e.g. administration of commensal bacteria), a larger control group and smaller test groups will be used which can provide sufficient power whilst reducing animal numbers. For dose finding experiments, we use small numbers of animals. Initially, a timecourse experiment is usually conducted. Subsequent experiments are then carried out at a single timepoint where the greatest effect/change was observed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All animal numbers and costings for this proposal were calculated in consultation with the Animal Facility Manager, according to the 3Rs. The number of animals per group will be reviewed regularly throughout the project to determine if protocol variability would allow a reduction in numbers while still providing meaningful results. For testing of novel therapies (e.g. administration of commensal bacteria), a larger control group and smaller test groups

will be used which can provide sufficient power whilst reducing animal numbers. For dose finding experiments, we use small numbers of animals in pilot studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are adopting fully optimised and validated mouse models of viral, bacterial or fungal infection that mimic the key features of human lung disease +/- respiratory infection. Mouse experimental infection models used in this project have been used widely in respiratory research for many years and therefore we can be confident that the methods used cause minimal pain, suffering and distress whilst providing meaningful results that are closely relevant to understanding of human disease.

Why can’t you use animals that are less sentient?

The mouse is the most appropriate animal for understanding host-microbial interactions for a number of reasons. It is an organism that is closely related to humans with structurally and functionally related genes and close similarities in many aspects of how the immune system acts. Relevant resources to block or boost certain substances (e.g antibodies) released by the immune system are also widely available for use in mice. This allows us to carry out functional experiments to manipulate components of the immune system to directly understand whether they play a causal role in disease. These types of approaches are less readily available in other animals. Use of this species for these experiments also offers the benefit of a vast amount of existing literature ensuring that protocols are refined and animal welfare can be better ensured than other species where the same level of understanding is not available. Use of less sentient animals would not be suitable for this project as we require a model which mimics the response of the human immune system to infection and a system where we can reliably block specific immune mediators that we believe to be important. The mouse is by far the best model to achieve this.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will always make sure that, by surveying the scientific literature, studies are not unnecessarily repeated. Appropriate negative and positive controls for a given treatment are essential to avoid unnecessary repetition of experiments, but where pilot experiments demonstrate that a control is redundant, study designs will be refined accordingly in future studies.

We will also keep up to date with latest advances/optimisations of experimental animal models of COPD and asthma through reading the literature and conference attendance to ensure that the most refined models are being adopted. As an example, we ourselves have previously refined a 4 week dosing protocol to induce COPD down to a single dose.

Such optimised approaches can reduce the number of anaesthesia administrations required per animal.

Animal suffering will be minimised by regular checking of animals for relevant symptoms that constitute the end point of the experiment.

In some experiments, we will carry out lung function measurements. We will use unrestrained whole body plethysmography (our normal approach) which is a mild procedure that does not require anaesthesia and allow mice to be utilised for further analyses subsequent to lung function measurement. Only where differences between study groups are deemed significant will we progress to invasive assessment on anaesthetised mice. This approach constitutes both a reduction and a refinement in the use of terminal procedures in line with the 3Rs directive. Good, sympathetic animal handling techniques will be used throughout to minimize discomfort.

The use of germ-free mice, where appropriate, will help reduce animal usage as there is less variation between mice in an experimental group, in comparison to antibiotic treated mice. Thus it is often possible to use fewer mice per experimental group and therefore fewer types of experiment are required to demonstrate that the microbiota is causing a particular outcome in the animal, thus reducing the total number of animals required to confirm or refute the research hypothesis

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will be designed in accordance to the NC3Rs PREPARE and ARRIVE guidelines. The models described have been optimised over a number of years by us and others in the field and represent the most refined approaches recognised currently. We will continue to consult publications, guidelines and attend relevant conferences to keep updated and will refine our methods where needed to ensure we keep up to date with the field standards.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will proactively seek to stay informed about advances in 3Rs in order to implement these during the duration of this project. All personal licence holders working under this licence will attend the ‘Guide to the 3Rs & Responsible Animal Research’ course run locally. This course will serve as an introduction to the concept of 3Rs and provide a solid foundation in principles related to implementation of 3Rs, animal welfare and standards for good practice. We will regularly liaise with our dedicated 3Rs programme manager who oversees educational activities related to the application of the 3Rs principles to animal research across the University. We will participate in Animal Welfare and Ethical Review Body (AWERB) meetings locally to ensure we remain up to date with local developments. We will additionally attend internal 3Rs training courses and seminars including in vivo statistics courses with an emphasis of 3Rs. We will also attend training days and seminars run by external organisations such as the NC3Rs and the Fund for the Replacement of Animals in Medical Experiments (FRAME).

Finally, we are planning to start a monthly 3Rs journal club which will focus on a paper selected from the NC3Rs F1000 Research Gateway and all postgraduate students within the wider department will be invited to attend and participate. This will allow us to collectively maintain awareness of new developments in 3Rs methods.

92. Neural mechanism of pain and itch in the spinal cord

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pain, Itch, Electrophysiology, Projection neurons, Primary afferents

Animal types	Life stages
Mice	pregnant, adult, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The spinal cord plays an important role in carrying and modifying sensory information perceived as pain or itch, but we still know little about how this information is processed. The aim of this project is to identify populations of nerve cells in the spinal cord and show how these are organised into circuits that underlie these sensations under normal conditions and in disease states.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pain and itch are considered to be transmitted by similar pathways. However, there is some evidence that these two sensations are processed by different mechanisms. In fact, pain treatment has no effect on the treatment of itch. We will investigate acute pain and

itch mechanisms in the spinal cord and compare how those signals are discriminated and conveyed to the brain. We will also investigate long- lasting (chronic) pain and itch mechanisms which are more relevant to diseases that need clinical treatment.

What outputs do you think you will see at the end of this project?

Pain and itch are unpleasant sensations caused by various diseases. They reduce the quality of life and represent a significant economic and societal burden. However, the treatments for these conditions, especially itch, are limited because the mechanisms by which pain signals are transmitted within the nervous system are still largely unknown. A better understanding of these pathways will allow the development of new therapies that are more effective, more selective and have fewer undesirable side- effects. Outputs will include publications in peer-reviewed open access journals.

Who or what will benefit from these outputs, and how?

This study will provide fundamental understanding of the circuits for pain and itch in the spinal cord. Although this will not result directly in development of new treatments in the short term, the improved knowledge provided by this project should lead in the longer term to development of new forms of treatment for chronic pain and itch, and will therefore eventually be beneficial for patients.

How will you look to maximise the outputs of this work?

We will continue to collaborate with other groups working on spinal cord mechanisms of pain and itch. We will disseminate our knowledge through peer-reviewed open access scientific publications, review articles and book chapters, as well as regular presentation of the data at scientific meetings.

Species and numbers of animals expected to be used

- Mice: 10,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice because of the availability of genetically-modified animals that allow specific types of nerve cell to be identified and have their functions altered. An additional advantage is that models for pain and itch have already been established in this species. Experiments will generally be performed in young adult animals, but in some cases injections have to be given to juvenile or neonatal animals, for example to allow targeting of different populations of nerve cells.

Typically, what will be done to an animal used in your project?

Some animals will undergo a chronic pain model, involving either chemotherapy treatment or nerve injury.

Chemotherapy treatment neuropathic pain model: We will inject drugs that are used for chemotherapy in cancer patients, such as paclitaxel. These will be administered up to a maximum of four times over a ten day period. This will lead to a persistent pain state, similar to that seen in patients treated with these drugs, in which there is increased sensitivity to mechanical stimulation and to changes in temperature.

Nerve injury neuropathic pain model: We will perform surgery on nerves in the hindlimb that convey skin sensation resulting in a long-term change that mimics neuropathic pain in patients. Again, this will result in increased sensitivity to mechanical stimulation and to changes in temperature.

In both of these models, acute pain thresholds will be tested by using normally non-painful mechanical and thermal stimuli from which the animal can readily escape. These sets of behavioural tests will typically be performed on three occasions for each animal. We will also observe any spontaneous behaviours, including licking, flinching and wiping of the skin. Animals will be on procedure for no more than 8 weeks after induction of the neuropathic state.

Some of the animals will undergo a chronic itch model. We will topically apply irritants on 5 days a week for a maximum of 3 weeks. This will result in a persistent increase in itch on the affected skin region. We will assess spontaneous itch by observing behaviour such as scratching and biting. We will assess evoked itch by recording scratching or biting behaviour induced by normally non-painful mechanical stimulation or by application to the skin of chemicals that cause itch. Animals will survive for no more than 8 weeks after induction of the chronic itch condition.

Some of the animals will receive injections into the spinal cord or the brain of chemicals or non-toxic viruses. These will allow specific nerve cells to be labelled with fluorescent markers or to have their activity manipulated. In most cases, these injections will be performed on normal animals, but in some cases (estimated 25%) they will be carried out on animals that also undergo either a chronic pain or itch model.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that receive injections into the spinal cord or brain will receive post-operative pain-killers, and should show no more than mild discomfort following the operation. There will be transient post- operative weight loss, but they will rapidly recover and should show no other ill effects.

Neuropathic pain models will show relatively mild signs of pain that include increased sensitivity to mechanical and thermal stimuli, and these effects may be permanent. The animals' ability to move around their cages is not reduced after these procedures, and they eat and drink normally.

The chronic itch model will cause chronic itch conditions such as scratching, which will last for the duration of the experiment. Again, the animals' ability to move around their cages will not be affected, and they will eat and drink normally.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals in this study (~70%) will experience only mild severity. The remaining animals (~30%) will experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sensory mechanisms, including pain and itch, are complex and involve the interaction of multiple types of nerve cells. In the spinal cord, there are various types of cell and their roles are still poorly understood. Although experiments with cultured cells can be used to investigate the function of individual cell types, studies designed to examine the organisation and function of nerve circuits in the spinal cord, together with changes in these circuits that underlie chronic pain states, can only be performed on animals. This is because animals provide the only source of spinal cord tissue in which the complex organisation of these circuits is retained and remains functional.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives would include human spinal cord tissue obtained post mortem or cultured cells.

Why were they not suitable?

It would not be possible to obtain human spinal cord tissue that was sufficiently well preserved for detailed anatomical studies or that retained live neurons and functioning circuits. It is impossible to carry out studies of this type on cultured cells, since these do not have the complex organisation of the intact spinal cord, and therefore do not allow investigation of how nerve circuits in the spinal cord contribute to pain and itch.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will determine the numbers of animals based on estimated sample size calculated and our previous experiences. When necessary, we will consult statisticians.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Advice was taken from a local statistician and from online tools for performing power calculations. We will also use the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding of genetically modified mice will involve keeping animals that have two copies of the mutation whenever possible. This will reduce the numbers that need to be generated to obtain sufficient mice of appropriate genetic types.

For behavioural experiments, we will perform pilot experiments that will allow us to estimate the minimum number of mice to be tested to produce statistically significant results. For experiments involving recording of nerve cell activity we will record from several different nerve cells in a single spinal cord, and test multiple stimuli on each cell, in order to reduce the number of experiments required. Where possible, we will use gene-altered mice to label specific population of spinal cord cells, thus avoiding the need to use brain injections in order to reveal these cells.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use nerve injury and chemotherapy models to investigate chronic pain, and a model that resembles eczema to investigate chronic itch. These models are all well-established and widely used in pain and itch research, and they have all been refined during the course of previous studies by many laboratories to model clinical conditions. None of these models will cause any significant alteration to the behaviour of the animal, apart from increased scratching and biting of the skin in the itch model. All animals will be monitored regularly using monitoring sheets.

Why can't you use animals that are less sentient?

Mice are the lowest animals, in terms of evolution, on which these experiments could be conducted. They are the only possible species that could be used for these studies, due to the availability of genetically modified lines, which allow targeting of different nerve cell populations. The majority of experiments will be performed on adult animals because there are changes in the structure and function of the spinal cord during development. Many of the experiments will be performed on tissue taken from animals that were terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All the animals will be humanely killed at the end of the experiments. All surgical operations will be performed under general anaesthesia. Any clinical problems will be dealt with in consultation with the NVS. There are strict pre-determined ‘humane endpoints’ in place, based on clinical signs, at which animals are promptly and humanely killed to ensure that no animals suffer unnecessarily.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will abide by published guidelines (NC3Rs) as well as local guidelines, to ensure best working practice. We will also adhere to the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere).

93. Investigating the impact of different management approaches on laboratory animal welfare using objective measures of affective state

Project duration 5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

refinement, affective state, animal welfare, behaviour, husbandry

Animal types	Life stages
Mice	adult, juvenile
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To improve the objective assessment of affective state in non-human species and apply these methods to better understand the welfare implications of different housing and husbandry procedures for laboratory rodents.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Animals housed in captivity are restricted in terms of expressing natural behaviours and this can lead to poor welfare. Provision of food and water is essential for survival but housing and husbandry procedures impact of the animals' wellbeing and affective state. It is unlikely that any human-managed environment can fully replicate the animal's natural state and deciding on optimal housing and husbandry methods within practical constraints

has largely been based on a human perspective of the animals' experience and are not based on objective assessment of the animals' affective experience.

The majority of current research relies on indirect measures such as overt changes in behaviour or stress-related physiology. We have developed more reliable and unbiased methods to assess affective state in laboratory rodents and now seek to apply these to reduce the cumulative suffering in laboratory rodents which arise from different housing and husbandry methods and refine simple procedures. Our methods are highly specialised and not easily used by other researchers and so a second component of this project is to use our objective readout of affective state to provide a ground truth against which to assess whether there are indicators of a change in affective state e.g. ultrasonic vocalisation, which are easier to record and more widely applicable.

What outputs do you think you will see at the end of this project?

The primary outcome from this project will be data, based on affective state measurements e.g. by assessing the animals performance in behavioural tasks that quantify either decision-making (judgement bias tasks) or learning and memory (affective bias test and reward learning assay), to indicate the changes to the housing and husbandry systems of laboratory rodent required to bring about improvements in animal welfare.

We will also undertake studies to further develop behavioural tasks and measures which can be used to objectively quantify affective state in rodents with the aim to improve their ease of use and hence wider applications.

Who or what will benefit from these outputs, and how?

Within its 5 year time scale, the project is expected to generate empirical data identifying changes to housing and husbandry systems used for laboratory rodents required to bring about improved welfare. In so doing, the study will provide the scientific evidence needed to support changes in policy which benefit animal welfare. The study findings will be relevant to all research institutions managing laboratory rodents including academia, industry and breeding establishments.

The data generated from the studies developing improved methods to objectively assess affective state could offer the potential for larger scale assessments of different housing and husbandry methods enabling other research groups to undertake their own assessment of their animal management and procedures. These methods will benefit both welfare researchers and scientists interested in emotional behaviour and the development of novel treatments for human mood disorders. With the validation work we have planned in this project, these methods could also replace less refined approaches.

In the longer-term, the outcomes of this work will be to generate the empirical data required to support changes in policy.

How will you look to maximise the outputs of this work?

Our aim is to always publish all the results from our studies. We utilise pre-registration and support open science using pre-print servers to disseminate completed studies as soon as possible.

The methods we have developed and specialist expertise in translational rodent models for psychiatry research also means we have built an excellent network of collaborators in

both academia and industry. Importantly, we are currently supported by funding from the NC3Rs which supports researchers in dissemination through specialist publications and their own website provides a platform for researchers to access the latest 3Rs developments. Our excellent networks across academia and industry will also support disseminating our findings and maximising the impacts for arising outputs.

Species and numbers of animals expected to be used

- Mice: 1200
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our objectives are specifically related to the welfare of laboratory rats and mice, the most commonly used laboratory species, and therefore we need to use both these species to achieve our objectives. There are species specific differences in the optimal management approaches for mice versus rats and hence we will need to use both species. The choice of species for the specific study will be determined by the experimental objective and some studies may involve comparisons between mice and rats.

As our objectives relate to the impacts of housing and husbandry on animal's lifetime experience it is important that we can replicate the experience of laboratory rodents at different stages of the life course. Most studies will focus on young adults which are the age range used most widely but we also want to understand the longer term impacts on animals and so some studies will work with juvenile animals through to a maximum of 15 months old.

Typically, what will be done to an animal used in your project?

Animals may be exposed to different housing or husbandry methods e.g. group versus individual housing, different types of environmental enrichment or handling procedures. We then use behavioural measures from specially designed reward-based tasks to directly compare the affective state consequences of different management methods.

The studies aim to enhance animal welfare and so will utilise current standard husbandry methods and compare these with approaches designed to induce more positive affective states. For some studies, this may include housing and handling of animals using methods which are hypothesised to be less refined but we need to be able to show this using our objective methods. Although we will manipulate the cage environment, animals will always be provided with nesting material as a minimum. Some animals may be housed individually for periods of up to 6 months.

In studies where we are testing the validity of a method to quantify affective state, animals may undergo acute or chronic manipulations designed to induce relatively more positive or negative affective states using either pharmacological or psychosocial manipulations. The pharmacological manipulations will use refined dosing methods with most treatments administered using drinking water or in palatable solutions which are self-administered by

the animal. For some treatments we may need to administer by injection with a brief period of restraint (mice only) or using our refined method (rats). Animals may receive repeated treatments, by the most refined route for the pharmacokinetics of the drug, up to once daily and for periods of up to 3 months. Psychosocial manipulations may include acute or chronic exposure to individual housing, altered housing density and exposure to different animals of the same species for periods up to 3 months.

A typical experiment will last ~6 months and will include pre-training of animals in the behavioural task which may include food or water restriction to motivate behaviour. Animals undergo a period of housing and/or handing manipulation and then are re-tested in the behavioural tests before they are killed and tissue and blood samples (max of 4 tail bleeds) collected for post mortem analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals used in these studies will not show any clinical signs or experience procedures which involve more than a transient period of acute pain or distress. The majority of animals will experience housing and husbandry conditions which will be similar to those used under standard laboratory conditions.
Animals may experience increased levels of inter-individual aggression, long term negative affective states and/or short-term stress from the pharmacological and psychosocial manipulations. For some studies animals will require food or water restriction to motivate their engagement with the rewards available in the behavioural task. Restriction will cause mild hunger, but animals will maintain growth and restriction is only used when animals are doing the behavioural tasks and they are returned to ad libitum the rest of time they are in the protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice = mild, 100% Rats = mild, 100%

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our primary interest is in the welfare outcomes of different husbandry systems management methods and this can only be achieved using intact living animals of the relevant species which will benefit from the outcomes. We are also studying complex, higher order behaviours which are only expressed in the more complex mammalian

species and cannot be modelled in lower species. To achieve the aims of our project we need to be able to undertake direct manipulations of the animals housing and husbandry experience and then quantify the arising affective states.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives are not suitable for this project.

Why were they not suitable?

There are no non-animals alternatives which could be used in this project as the scientific objectives are species specific and involve assessing the affective state, which only exists in higher living organisms like mammals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on our current research funding and the specific objectives defined in those research grants. We have also included some animals based on our projected research income and projects which are currently in development or under review with funding bodies. The studies are expected to evaluate ~ 3 variations in housing in conventional versus IVC caging (NC3Rs grant) and 6 studies looking at variations in husbandry and handling techniques using a group size of 12-16 cages. The sample size is determined from data generated during previous work. Evaluation of novel measures of affective state will use group sizes of 16-24 cages based on our pilot data and will investigate ~2 different behavioural assays and 4 studies focusing on home cage recording monitoring of behaviour and ultrasonic vocalisations.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have undertaken meta-analyses of the behavioural methods to provide a reliable estimate of effect size and then used this to design our experiments. Where required, we integrate both the behavioural work and ex vivo studies to maximise the data we can obtained from any one animal and enhance the interpretation of the behavioural studies. For relatively simple studies we can utilise the NC3Rs EDA but where we require more complex designs, we work with local experts in experiment design or our industrial partners who have dedicated statistical support within their organisations.

Depending on the specific objective where possible, we utilise within-subject study designs. This reduces the total numbers of animals as each animal can act as its own control and generate multiple data points with reduced variability. Although this does mean animals may be on protocol for longer or receive more interventions, combined with our refinements, these should not lead to any significant increase in cumulative suffering but can dramatically reduce animal numbers.

When we are working with chronic manipulations, within-subject designs are not appropriate and for these studies we reduce the numbers of animals by limiting the use of placebo controls and utilise historical data wherever possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We collaborate with computational neuroscientists to maximise the outputs from our behavioural data.

The same animal may be used across a number of behavioural tasks so we can look at individual phenotypes and understand how changes in affective state affect the wider behavioural profile of the animals. This avoids the need to use separate cohorts for each behavioural test and also reduces variability and overall numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of studies will compare current housing and husbandry methods with approaches designed to be more refined (~70%). Our current focus is on housing of male mice and the extent to which inter-cage aggression leads to poor welfare versus individual housing and how the affective state of animals in group versus individual housing is affected when they are housed in conventional versus individually ventilated cages. We are also interested in the impacts of temperature and whether mice are in a relatively more positive affective state when housed at higher temperatures and how this interacts with group versus individual housing. Our rat studies focus on the welfare benefits of caging which can increase available space particularly enabling more vertical behaviours and whether play pens and human simulated play can generate more positive affective states. This will mean that some animals may be exposed to management methods which are hypothesised to be more stressful and/or less optimal e.g. different types and levels of environmental enrichment, different handling methods with or without habituation, but we need these comparisons to provide the objective scientific data to show welfare benefits and impact on policy.

For studies designed to develop better methods to objectively quantify affective state, some animals will experience short term or long term negative affective states generated using mild interventions. These are necessary to validate the methods and it is important to be able to compare with established literature and to determine if the readouts are generalisable or only sensitive to a specific type of manipulation. To be of widespread applicability, these readouts need to be reliable and sensitive across different types of manipulation and so it is important that we compare different models. The affective state manipulations we propose using are expected to induce affective state changes similar to

those animals might experience within the normal routines of animal management e.g. stress associated with short periods of restraint for health checks.

Why can't you use animals that are less sentient?

The scientific objectives of the project are specific to rats and mice and cannot be undertaken in a less sentient species and require an awake behaving animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals undergo a minimum of one week's habituation to handling which is combined with rewards to enhance the animal's positive association with human interactions. Non-aversive handling methods are used, and animals are housed in enriched cages unless the specific scientific objective requires a different approach i.e. when comparing the welfare implications of different handling methods.

Substance administration will use refined methods with animals trained to take drugs from a syringe in a palatable solution or using modified restraint method which we have shown reduces stress responses by ~50%. Only where the pharmacology of the treatment does not permit one of these refined routes would an animal be treated using a less refined method.

Inductions of a negative affective state will use the least aversive method and duration which can generate the behavioural response we require or is necessary to re-produce the housing or husbandry condition.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have been leaders in the field of refinements for cognitive and affective neuroscience and utilise our objective methods to quantify emotional state in rodents and disseminate our findings through publications and presentations.

I attend regular CPD events including those run by the NC3Rs and assess and implement refinements which are compatible with our research objective. I attend meetings such as LASA and subject specific conferences. I also utlise the NC3Rs resources to follow the latest guidance on procedures including methods to recognise and manage suffering.

Studies are designed and reported in line with both the ARRIVE and PREPARE guidelines and all data are made freely available following publication.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I attend the annual 3Rs symposium held across the local University network and regularly attend webinars and workshops hosted by the NC3Rs. I attend and contribute to national and international conferences in my field enabling me to keep up with the latest developments and also disseminate outcomes and refinements from our own research programmes. The institution also benefits from an NC3Rs regional manager with whom we have established an excellent working relationship and regular meet to discuss regional matters relevant to our research and the 3Rs.The development of refined methods has been a core objective for my research and is being implemented in this application.

94. Mononuclear phagocyte function in inflammation and cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

immunity, mononuclear phagocytes, cancer, inflammation

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The goal of this project is to understand how white blood cells called mononuclear phagocytes participate in the control of cancer and the response of patients to drugs that are designed to activate white blood cells to kill cancer cells. We will also study the roles of these cells in the unwanted side effects of these drugs, which can often result in patients suffering from inflammatory diseases such as inflammatory bowel disease (colitis) and arthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Improved understanding of the genetic basis underlying mononuclear phagocyte regulation of immunity in the context of cancer and immunotherapy which may lead to the development of new improved therapeutic approaches.

What outputs do you think you will see at the end of this project?

The goal of this project is to understand how macrophages (MF) and dendritic cells (DC), which develop from white blood cells called mononuclear phagocytes, help provide protective immunity against cancer cells and immunotherapy. Specifically, we want to understand how we can target these cells to improve anti-cancer immunotherapy and reduce unwanted side effects. Given the tissue specific nature of the tumour microenvironment, it is important to address these questions in a range of tumour models to assess common and unique aspects of MF and DC function in cancer immunotherapy.

Who or what will benefit from these outputs, and how?

Improved understanding of the genetic basis underlying MF and DC regulation of immunity in the context of inflammation, infection and cancer which may lead to the development of new approaches to vaccination or immunotherapy.

How will you look to maximise the outputs of this work?

This project will involve several national and international collaborations. Results of the research and methodological developments will be disseminated at national and international conferences and in peer reviewed publications in the scientific press.

Species and numbers of animals expected to be used

- Mice: 24100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Use of laboratory mice provides a unique way to test and analyse tumour growth and immune responses a) in realistic in vivo conditions, b) in models in which genetic conservations bring knowledge relevant for the human immune system, c) in a genetically controlled system. Mouse experiments have and continue to contribute to the development and testing of new anti-cancer treatments, vaccines and immunotherapies in patients and improving human health.

Typically, what will be done to an animal used in your project?

We intend to understand how different types of mononuclear phagocyte populations affect tumour development and responses to immunotherapy, including adverse autoimmune events associated with therapy such as arthritis and colitis. We will use laboratory mice, including genetically modified strains bearing modified gene loci relevant to mononuclear phagocyte function. Mice will typically be injected with different tumour cells or inflammatory stimuli to model tumour growth in different organs for example the mammary gland, pancreas or peritoneal cavity and we will measure the effects of specific genes in the immune response to specific antigens expressed by the tumour cells. Typically we will measure effects by imaging immune cell behaviour in tissues of using flow cytometry and imaging.

What are the expected impacts and/or adverse effects for the animals during your project?

Immunisation:

Animals may experience slight discomfort associated with inflammation similar to mild, self-resolving infections or vaccination in humans that resolves in several days.

Irradiation:

May cause damage to gut epithelium resulting in malabsorption and weight loss, and allow overgrowth of microorganisms resulting in enteritis. Leukopenia may cause bone marrow depression resulting in increased susceptibility to infections, platelet deficiency may increase risk of haemorrhages and anaemia. These are only likely to occur in the rare instance that reconstitution with donor cells fails.

Tumour growth:

Strong immune responses against soft tissue tumours may show signs of ulceration, which may be suppurating or exudative. In rare cases, tumour growth may result in systemic adverse effects associated with inflammation or weight loss.

Tumour growth in the peritoneal cavity or pancreas may result in a marked abdominal distension produced by peritoneal ascitic fluid. Intra-venous injection of tumour cells can cause dyspnoea due to lung metastasis.

Spontaneous tumour growth in the mammary gland, lung, epidermis and pancreas is usually well tolerated. Excessive tumour growth may lead to general signs of distress or pain; sensitivity to handling, pilo-erection or persistent hunched posture, other clinical signs suggestive of excessive tumour burden include weight loss, impaired mobility.

Surgery:

After surgery, wound breakdown may be observed. Colitis:
Animals may exhibit weight loss and diarrhoea, weight should remain in the region of 85-95 % of initial weight before spontaneous full recovery (from around 5-7 days).

Arthritis:

Mice will show swelling and reddening of one or more paws and reduced mobility. In very rare cases (<1%) ulceration may occur. Severity normally reaches a maximum at around 10-14 days after onset and spontaneously resolves between 21-28 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?
The majority of protocols involve acute inflammation that resolves in several days and are of mild severity (70 %). Tumour growth experiments, colitis and antibody-induced arthritis will be considered moderate (30 %) due to their longer duration (typically <30 days).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse models enable genetically controlled experiments that can lead to the establishment of causal relationships, thus permitting more conclusive experiments to probe the functions of specific genes in the immune system. The high level of conservation between genes, cell types and signalling pathways means that findings acquired in the mouse model are generally highly relevant for our understanding of the human immune system and relevant diseases, including infectious diseases, autoimmune diseases and cancer.

Which non-animal alternatives did you consider for use in this project?

Besides our use of in vivo animal experimentation, our lab has developed a numbers of primary cell culture methods for the analysis of specific cell interactions in vitro and the development of alternative methods for the production of genetically modified MF and DC using stem cell cultures (iPSC). These approaches are used in parallel to help reduce our involvement in animal experimentation within the frame of our scientific objectives. For example, some target genes may be screened in vitro first for their effects on MF or DC activation in order to limit the number of GM mouse strains that would be evaluated in vivo.

Why were they not suitable?

The development of adaptive immunity is a complex process involving the interactions of different cell types such as MF, DC, T and B lymphocytes, and the activation of multiple signalling pathways. These interactions occur in specific tissue microenvironments created within the highly organised areas of lymphoid organs. In addition, immune responses are tightly controlled by modulation of HSCs in the bone marrow providing MF and DC progenitors that migrate from the blood to peripheral tissues and lymphoid organs. As a result, it is impossible to model all these interactions by in vitro studies only.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Extensive experience with the models proposed has shown that 6-8 animals per group is usually sufficient to obtain statistically robust data. Some procedures are expected to be of moderate severity (protocols 7-9) and intervention to minimise potential suffering will be required. Thus, group size needs to account for this and remaining animals sufficient to

provide statistical significance. Statistical advice is on hand at the within SIMS at KCL to optimise approaches where necessary.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Multi-parametric analysis will be performed on tissues harvested post-mortem in all experiments to maximise the information obtained and reduce the number of mice used and more generally the number of experiments required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When appropriate, surplus tissues will be conserved for the establishment of reference samples and to minimise the need to new experiments.

Efficient GM colony management will prevent unnecessary breeding and minimise offspring with undesirable genotypes. Littermates genotyped as heterozygous or WT will be used as appropriate age and sex matched controls. This allows optimal use of mouse numbers generated and is best scientific practice for the study of genetic alterations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocols have been optimised to induce mostly sub-clinical, non-lethal and self-limiting inflammation in C57BL/6, that will be used in this project. These models trigger transient acute local inflammation, which may possibly result in slight, but reversible, discomfort and possibly weight loss.

Models of tumour growth (protocols 5, 7) are required to assess the development of protective immunity against tumour-associated antigens. These studies will aid the rational development of protective anti-tumoural immunotherapies, leading to the activation of CD8+ T cells capable of limiting tumour growth.

Microbial challenge experiments (protocol 3) will utilise non-lethal microbial stimuli in C57BL/6 mice, these protocols are designed to induce a transient acute inflammation that may involve the onset of transient “flu-like” symptoms and mild discomfort, including slight but reversible weight loss.

Why can’t you use animals that are less sentient?

The vast majority of experiments will be performed with C57BL6 mice because this is the strain of choice for genetically modified mice. Adult mice will be used with a fully mature immune system to reflect the relevant clinical contexts.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all procedures, an integrated daily monitoring will be performed. When necessary, analgesia and/or temperature control will be used to alleviate pain, discomfort or distress, due to acute inflammation. Mice will be killed if they show any persistent adverse effects after 24 hours, or weight loss of >20%.

For tumour growth experiments, humane endpoints will be applied rigorously according to established guidelines for experimental tumour growth. Tumour size will be monitored and animals killed at fixed, pre-defined time points before they reach clinical signs (protocols 5, 7).

In microbial challenge experiments (protocol 3), animals that fail to overcome infection will be killed by a schedule 1 method.

To ensure the rigorous implementation of humane endpoints, all experiments will be performed by specifically-trained scientists, holders of personal licenses and expert in the implementations of these models.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Smith AJ, et al. (2018) PREPARE: guidelines for planning animal research and testing. Lab Animal 52(2):135-141.

Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156.

Workman et al. Guidelines for the welfare and use of animals in cancer research. British Journal of Cancer (2010) 102, 1555 – 1577.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to the NC3Rs monthly updates on the latest science and technology to replace animal studies, providing information new research approaches that may avoid the need for in vivo models. NC3Rs resources also help support best experimental design to ensure robust and reproducible methods and outcomes, as well as guidance on the latest knowledge to improve laboratory animal welfare.

95. Fish developmental biology and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

development, stem cells, tissue homeostasis, congenital disease, ageing

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, neonate, juvenile, adult
Medaka (Oryzias latipes)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the cellular, genetic and molecular mechanisms of development and stem cell function. We also want to develop fish models for human congenital conditions in order to understand better the basis for these conditions and to allow screening for candidate drug targets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are two main reasons to do this work. The first is simply to understand a basic aspect of developmental biology - how a complex, multicellular organism is formed, and maintained. The second derives from the fact that these same processes occur in all

organisms, including humans, and so knowledge of these mechanisms underpins our ability to understand and diagnose, as well as perhaps to treat, human congenital disease (e.g. Hirschsprung's disease and other neurocristopathies), but also human ageing, since these stem cells are the source of new cells for tissue maintenance.

What outputs do you think you will see at the end of this project?

Our work will result in outputs through the appropriate channels of conference presentation and publication (20+ and 10+ respectively), wherever possible in high impact and/or open access journals; in addition, we anticipate generating models of human congenital disease (e.g. multiple (2-5) humanised mutants for *sox10*, expected to allow modeling of SOX10-dependent neurocristopathies). These outputs will be freely accessible to other researchers, clinicians and industry. These end users will be able to utilise them in developing their own research and biomedical applications.

Who or what will benefit from these outputs, and how?

In general, the short-term (1-5 yrs) benefits will be to our and other academic, clinical and biomedical industry researchers, by providing increased understanding of the molecular genetic mechanisms of normal neural crest cell development, and thus of what goes wrong (e.g. better genotype-phenotype correlation) in the context of congenital diseases of the neural crest (neurocristopathies), particularly Hirschsprung's disease (prevalence 1:5000) and Waardenburg syndromes 1-4 (all of lower incidence). In the medium/long-term (5-15 yrs) we anticipate our findings and approaches may influence perception, diagnosis and perhaps even treatment of these diseases.

How will you look to maximise the outputs of this work?

We will disseminate our knowledge through publication and presentation at conferences and in institutional seminars: We have an excellent track record of publication (e.g. 1 book (editor), 5 Book Chapters, 25 journal articles/commentaries published during period of previous license) and visibility (our work has been cited >15500 times, including >4450 since 2016 (Google Scholar, accessed 10/11/2021)). In addition, we regularly present our findings at major international, national and local conferences and through institutional seminars (e.g. I have given 63 (10 during period of previous license, despite the massive impact of COVID) invited conference presentations, plus a further 17 (3) meeting talks as selected abstracts, 113 (20) poster presentations, and 82 (15) invited institutional seminars). Through contacts established over the years we have been able to build a broad and expanding network of national and international collaborators; currently active collaborations expected to continue into the current license period include those with researchers in Bristol, Exeter, London and Surrey, plus the USA, Russia, Japan and France, but we will also be open to developing new collaborations wherever they will maximise our outputs. We will establish collaborations with other researchers by sharing knowledge, experience and reagents. We will also look for opportunities to work closely with clinicians and industry optimizing the chance of translational impact. Publication of unsuccessful approaches is a new opportunity and one we will be open to exploring if/when appropriate.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 33800
- Medaka (Oryzias latipes): 3250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

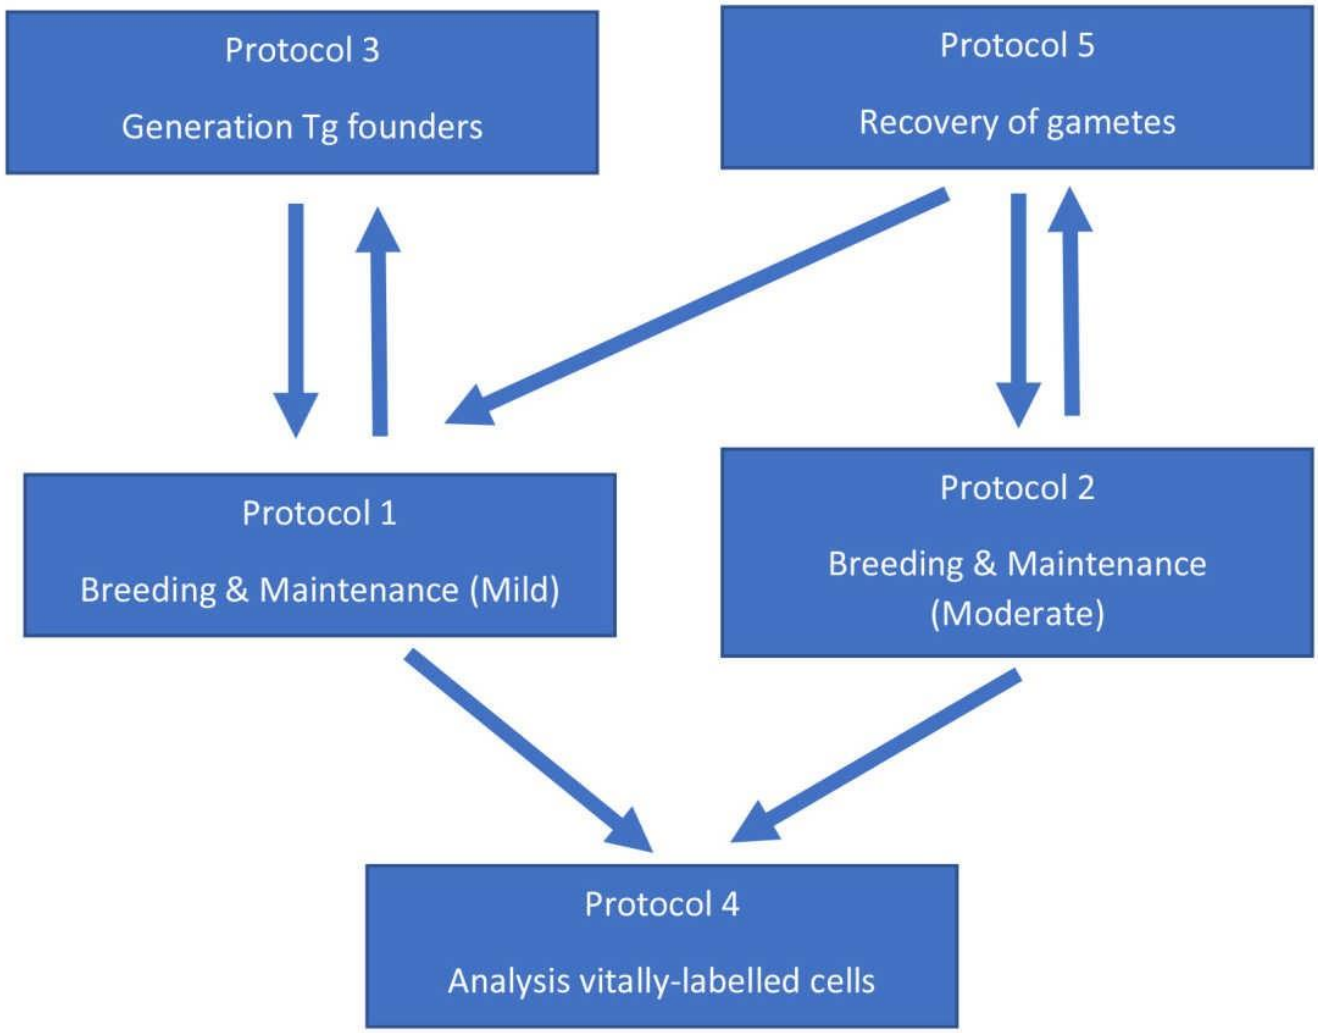
Explain why you are using these types of animals and your choice of life stages.

We use fish model systems since these are the least sentient of the vertebrate model systems, but also because they provide significant experimental advantages. Zebrafish and medaka are the two best- studied fish model systems, and thus have an abundance of resources facilitating their experimental investigation. The animals develop externally and are optically clear (often allowing for observation of development with no intervention needed); we therefore make most of our observations without any need for surgery or other intervention giving discomfort to the protected animal. Our work largely focuses on embryonic and early larval stages prior to free-feeding, both to minimise the suffering, and to maximise the productivity, since these stages are both appropriate for most of our studies and easiest to work with experimentally. For the pigment pattern work we have to use the juvenile-adult stages since these are when the well-studied adult pigment pattern is being formed, but again observations can be made on intact living animals. For the humanised *sox10* mutant studies it is conceivable that phenotypes will not be detectable until post-free-feeding stages, so we expect to monitor these where scientifically justified.

Typically, what will be done to an animal used in your project?

An animal used in this Project will typically undergo or have previously undergone genetic modification. This is important, for example, for generating fluorescent reporter transgenic lines essential for monitoring the cell behaviour and function, and also for introducing mutations in genes known or expected to influence development. This is an important part of our research in understanding the molecular and cellular mechanisms underpinning development and associated human disease.
Usually fish generated will simply be used to breed embryos for analysis prior to free-feeding. In some cases these embryos will need to be raised to larval or later stages, but usually then will either be fixed for analysis or imaged live under Protocol 4.

Fig. 1 Flow diagram showing transfer between protocols



What are the expected impacts and/or adverse effects for the animals during your project?

Animals used in this Project are expected to experience minimal pain and suffering as a result of our manipulations. However, in certain cases when a genetically altered animal is created to mimic a human disease condition, it is possible that fish might experience some clinical symptoms. This can generally be avoided by maintaining our genetically altered lines in healthy heterozygous forms.

Occasionally, our experimental manipulations can also produce side effects. We will make sure that any individual showing signs of non-transient discomfort is killed immediately by Schedule 1 methods.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (>90%) of animals used in this Project will experience pain or distress that is no greater than mild. We anticipate that a maximum of <10% of animals used in this Project will experience a moderate severity. Any such individual presenting any signs of pain or distress that is not rapidly curable will be killed under Schedule 1.

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As the main goal of our research is the understanding of the cellular and molecular mechanisms required for stem cell development in the vertebrate embryo, alternatives not using animals at all are not yet available. The originality and strength of our study is the ability to follow development in vivo, using imaging of fluorescent transgenic zebrafish, ensuring that the cellular environment is an authentic one. In vivo studies are the only way to identify the cellular behaviour underpinning developmental defects. Moreover, our in vivo studies allow the examination of the cell behavioural changes resulting from genetic lesions, allowing us to perform small molecule drug screening to identify compounds that could ameliorate the symptoms, offering mechanistic insight and, perhaps, opportunities for novel drug development.

Which non-animal alternatives did you consider for use in this project?

We have been actively exploring mathematical modelling, and have used it extensively in our work on both developmental gene function and pigment pattern formation. In the latter case, we have now published models that mimic the patterning process rather well, and can be used to focus future experimental studies, including those proposed in this project. We have also considered cell culture models.

Why were they not suitable?

The complex environment of the embryo, with multiple cell-types and with cells moving locations in a reproducible way, makes cell culture models (including complex *in vitro* models which do not mimic the complex *in vivo* environment and, as summarised on the NC3Rs website, are an improvement on 2D cell culture, but have significant reproducibility issues) inadequate. However, this is a rapidly changing area, so we will continue to monitor the literature for suitable models that we can use.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimation of fish usage is non-trivial, since multiple confounding factors make simple calculations impossible, and instead force reliance on previous experience within the wider fish researcher community. The key point is that the overwhelming majority of our animal usage is in generating or maintaining genetically altered (GA) lines. In the first case, stochastic effects are important in affecting i) how many founder fish actually have germ-line integration of the transgene, and then transmit to the next generation, as well as ii) the extent to which positional effects alter the behaviour of the transgene from that intended. In both cases, a further stochastic effect that is of major significance is that of the unpredictability of sex ratios. Furthermore, for almost all work, the key issue is a regular supply of good quality embryos for experimental study; this necessitates maintaining larger than minimal numbers of fish so that individuals are not usually used more than once per week. Over-usage would be problematic from a welfare point of view since it could well result in stress. We note that the harmless nature of the GA in the majority of the lines when kept as hemizygotes or heterozygotes goes a long way to reducing to a minimum the suffering caused. The numbers requested in this license for each protocol have been estimated in accordance with these principles.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Key to reducing the numbers being used is that almost all (approximately 90%) manipulations and observations will be performed on zebrafish embryos or early larvae at stages prior to the stage when they are capable of independent feeding, and hence on stages that are outside of the Animal (Scientific Procedures) Act. However, in the remaining cases (approximately 10%) it will be necessary to rear experimentally manipulated fish after they become protected by the Act. Where possible our emphasis will be on assessing effects as early as possible, so that older, larval and adult stages will be only used where completely necessary, and we will take statistical advice to ensure the numbers used are appropriate.

We will take advantage of the optical clarity of fish larvae to allow the use of new microscopic methods to image developing stem cells and congenital disease models. The aim of much of our work is to use transgenes that do not disrupt normal processes to report on those processes as they happen. So, although the animals are transgenic and therefore fall under the Act, they will not suffer in any way compared to nonGA fish. Creating stable transgenic lines is, by itself, a way to reduce the number of animals used. The establishment of healthy viable adults carrying a transgene allows us to reduce the number of embryos studied compared to the quantity we would have to use in a transient transgenic system (i.e. where embryo is injected with transgene, creating a transgenic chimaera), because the transgenic line will be expected to be homogenously expressed within the appropriate cell-types.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of our animal usage will result from generation and maintenance of mutant and transgenic stocks. We will use the latest transgenesis techniques so as to ensure that the minimum numbers of founder fish are generated, and will take advantage of developments

in inducible gene expression (e.g. CreERT2) to ensure that transgenes are expressed wherever possible only when needed.

We have already used, and will continue to develop, mathematical modelling approaches to limit our experimental work, by guiding us as to the mechanisms that need to be investigated experimentally.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish and medaka as model systems during this Project. Fish are the least sentient of the vertebrate models suitable for genetic research. The Project will use the latest in vivo technologies used by other researchers in the field to minimise any animal suffering, such as well-established gene editing and imaging techniques which allow manipulation of specific genes in selected cell-types and/or during selected time periods, so as to try to avoid systemic or pleiotropic effects. Our methods will allow us to generate transgenic lines reporting the expression in specific cell types of relevant genes, and animals with mutations in genes required for development. We also plan to use imaging techniques to monitor stem cell behaviour and function and assays to investigate the developmental effects of these genetic manipulations.

Why can’t you use animals that are less sentient?

We chose the fish as our vertebrate animal model because these are the least sentient of the major vertebrate models, and because the embryos develop outside the mother (allowing collection without affecting adult mothers) and are optically clear (allowing for observation of development with no intervention needed). We make the vast majority of our observations on embryos/early larvae prior to free-feeding and hence minimise the use of later stages. Live observations of later stages are performed only when scientifically necessary, and by non-invasive methods. We therefore make our observations without any need for surgery or other intervention giving discomfort to the protected animal. We anticipate that the majority of our procedures will not exceed mild severity limit and will not generate pain or distress (a maximum of 10% of animals are expected to exceed that limit, and no animal will experience a severity above moderate). Any individual presenting any signs of pain or distress that is not rapidly resolved will be killed under Schedule 1.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all our studies we will address effects as early as possible and we will use anaesthetics whenever appropriate. Non-invasive methods will be used throughout. As stated in Protocol 1, the majority of lines carrying mutations will be kept as healthy heterozygotes and are expected to only show phenotypes when homozygous. Therefore, this will reduce

any potential suffering of animals. Any individual presenting signs of non-transient distress or pain will be culled under Schedule 1.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will monitor the published literature to ensure experiments are conducted in the most refined way. We will use pilot studies to refine protocols being developed/modified in the lab. We will refine our use of specific anaesthetics as their advantages and disadvantages are understood. Where revised methodology has become available, we will endeavour to update our protocols accordingly.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I regularly interact with our NC3Rs Regional Programme Manager and attend meetings/events organised by the NC3Rs.

96. Mechanisms promoting cancer progression

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Immune system, Metabolism, Blood vessel development, Microbiome

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
