Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to identify and understand the factors that cause cancer to develop, progress and spread in mice. We will develop and assess new treatments targeting mechanisms driving cancer progression. We will develop novel diagnostic tools to aid identifying key cancer stages.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Breast cancer is the most common cancer in the UK. Colorectal cancer is the third most common cancer in the UK. Unfortunately, these cancers are equally associated with high death rates. For example, only 53% of patient with colorectal cancer survive for more than 10 years.
Early detection of cancers mean patients are more likely to respond to treatment and remain cancer free for a longer period. Previous studies have shown us that different

mechanisms and cell types support cancer cell growths and development.

It is important that we continue to identify these mechanisms and gain better understanding of the range of cell types that drive the development of cancer tumours. This in turn will provide information that will help develop new treatments to target such cells and mechanisms.

What outputs do you think you will see at the end of this project?

Using mice bearing human cancer xenografts and syngeneic mouse tumour models we will have gained the following aspects at the end of this project:

Identification of novel genetic changes in cancer cells that impact on treatments and any resistance to such treatments.

Improved knowledge of how different aspects of the immune system and other cells impact on cancer development and response to treatments

Improved knowledge of cellular responses to low oxygen and nutrient levels.

Use this knowledge to develop new cancer treatments

This information will be shared with the scientific community through publications and conferences.

Who or what will benefit from these outputs, and how?

Patients with solid tumour cancers like breast and colorectal cancers, clinicians and academic researchers will benefit from the outputs of this project.

Ultimately, the results of this research will enable improved diagnostics of patients and also improved outcome following provision to provide more appropriate therapy and increasing current drug efficacy against cancer. This is due to this project enabling us to have a better understanding of the mechanisms and involvement of cell types that add to profile of an ‘aggressive cancer type,’ thus drive cancer progression and resistance to current therapies.

How will you look to maximise the outputs of this work?

This information will be shared with the scientific community through meetings, publications (including unsuccessful approaches involving animals) and conferences. In addition, we hold in vivo meeting regularly and invite collaborators from similar scientific backgrounds to attend and exchange knowledge and experiences. These improve the outputs of our projects.

Species and numbers of animals expected to be used

- Mice: 4200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using mice to model the complex processes in human cancer progression and generate clinically relevant information. The majority of these processes do not occur in non-mammalian species.

Mice need to be at the age that they can bred and produce healthy offspring. Successful growth of cancer and tolerance to therapy is dependent on the use of young adult mice. Juveniles, neonates and pregnant females are used in cases where early deletion of a gene is required, based on the expression profile of that gene.

Typically, what will be done to an animal used in your project?

Genetically altered mice may be bred and given an injection of a gene inducing or deleting agent to modify its genetic status. The administration of these drugs will be typically daily for one week.

Mice may be injected directly with tumour cells or recieve an injection of substances or non-tumour cell types to initiate cancer development. The injection will be given at either the site at which the tumour is normally found or systemically via the tail vein.

Mice may be given a substance or non-proliferating cells to modify the process which is being studied. Administration may be as a single or combination of treatments. Imaging may take place to identify changes that occur at key disease stages.

Typically, samples will be collected at key disease stages to develop biomarkers or therapeutic antibodies and to assess change in the cancer.

What are the expected impacts and/or adverse effects for the animals during your project?

Some mice will undergo tumour implantation under the skin, and these visually observed tumours will grow to a permitted maximum size. Presence of visual tumours near endpoint size may cause some mild to moderate discomfort, such as animals fail to gain weight or have slow weight loss, or have mild diarrhoea. As animals with internal tumour burdens approach endpoint stage, they may experience breathing difficulties if the cancer cells form growths in the lungs or swollen abdomens observed following growth in liver, or gut. Some of the external tumours may naturally ulcerate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold (68%), Mild (18%) and moderate (14%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse tumour models, in combination with imaging, will allow us to study closely the cellular mechanisms of cancer and the effectiveness of the new diagnostics and therapies. These can be translated to the clinical setting. The animal models of cancer also most closely fit the complex processes and interactions between cell types that occur in human cancer. Some of these processes involving immune cells and other cell types do not occur in non-mammalian species and therefore cannot be studied in lower organisms.

Which non-animal alternatives did you consider for use in this project?

Access to material and results from patients with cancer in the clinic and previous animal experiments are available and will reduce the number of animal experiments required. Collectively, this material and data can be interrogated in a series of computer modelling to aid finding new links to processes and mechanisms driving cancer progression.

We can model certain basic processes in the laboratory setting. Cell culture will be used throughout this project to provide key information on gene function and mechanisms of cell adaptation to specific stresses in culture. We can model basic outcomes following exposure to new therapies (such as reduce growth rates, cause cell death, and block specific blood vessel development stages).

Why were they not suitable?

At present, the use of non-animal methods does not allow us to answer all of our scientific questions. Non-animal models cannot fully recapitulate the 3D nature of the cancer tissue and the many different cell types interacting with each other, the fluctuations in blood delivery of oxygen and nutrients and how these collectively influence response to therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous studies have shown what number of animals are required for each study, appropriate to the cancer type, and conditions investigated with appropriate numbers of animals and controls in the experimental design. Data on the numbers of animals required for breeding and maintaining a productive colony is also available from our archive of mouse database.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We regularly cross-reference our experimental design, where appropriate with online tools such as the NC3Rs Experimental Design Assistant. We also use statistical design models to aid confirmation of appropriate numbers of animals to be used.

Computer modelling of non-animal model data, previous animal experimental data and information from pilot animal studies also aids the selection of appropriate targets and experimental design for maximum output information at the end of the experiment but using the least number of animals. An example of this is incorporating imaging points into our design. Use of imaging increases the output from each animal, creating a better picture of the changes that occur at key cancer progression stages without the need to kill animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Well planned, efficient breeding calculations are carried out to ensure that only those animals needed for colony maintenance and experimental studies are produced. A mouse database gives us the most recent data to enable these calculations to be carried out.

The use of imaging techniques allows for more information to be gathered from each individual animal.

Harvesting of extra tissues and appropriate sample collections at the end of the experiment and banking them allows for future use and negates the need for animals in these cases.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice lacking a functional aspect of the immune system will be used to investigate which part of the immune system influences cancer progression. Such immuno-deficient animals enable us to grow human cancer cell lines that would normally be rejected by an active immune system.
We will use mice with or without a genetic change because we can directly study the mechanisms involved in specific processes in cancer progression, for instance blood vessel development or metabolism changes. Use of genetic modifications enables targeting specific key pathways/mechanisms that is impossible to replace by an alternative method, e.g. due to current lack of appropriate specific inhibitors and avoids animals being subjected to multiple administration of substances.

Animals used for breeding will only undergo methods that are natural and suitable to maintain the genetic status of the strain.

Pilot studies are always conducted using the fewest number of animals to establish the novel growth cancer profile, novel substances used to target cancer progression, and confirm appropriate imaging plan to map changes during tumour progression.

Imaging provides an important insight to cancer progression, enabling us to visualise actual tumour burden and real time changes inside the tumours without dependency on changes in animal health and behaviour.

Why can't you use animals that are less sentient?

The experiments proposed are being conducted in the least sentient possible animal system.

The adult mouse model is relevant to our studies because they enable us to address our studies into processes that promote cancer progression, for example they have a functional active immune system at this stage. The mouse model is most widely used and accepted animal system for these types of studies. In addition, the information provide at this animal stage and tumour models translates into the clinical setting.

Tumour bearing animals and exposure to substances are being conducted in animals that are at an appropriate age, for instance where the immune system is active and initiation of tumour models, blood vessel development is well established.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experimental designs are based on previous recorded and pilot experimental observations and outcomes. This ensures appropriate use of procedures and routes to minimise welfare costs for animals. We provide appropriate pain management following any procedures.

We regularly monitor animals for changes in their health, for example measure their weight change and their behaviour.

Observations during experiments are documented to allow control measures such as increased monitoring or treatments to avoid and reduce further harm to the animals. We always conduct pilot studies to check that measures and experimental designs will minimise welfare costs for animals when necessary for novel substances/cell types.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The design of experimental procedure will be interrogated against best practices guidance in order to ensure the most refined methodology is used, such as: local AWERB guidelines, those outlined on NC3Rs (e.g. ARRIVE guidelines), Guidance on Animal Testing and Research from the Home Office, LASA and RSPCA guidelines, PREPARE guidelines and published guidelines on tumour models.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review publications (including those relating to the 3Rs) and attend conferences, discuss with other experienced groups, Named Animal Welfare Officer, hold

in vivo meetings to ensure that we constantly implement advances in techniques and non-animal alternatives. We also check experimental needs and designs with information on websites, such as Home office, the NC3Rs, LASA and RSPCAs.

97. The Neuroscience of circadian rhythms in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Circadian rhythms, Neurophysiology, Physiology, Chronotherapy, ageing

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how our brain generates and keeps daily timing in our physiology and behaviour, such as our sleep-wake cycle, mealtime, and peak concentration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our daily or circadian body clock is one of the most important timing systems in our body, ensuring that the activity throughout our nervous system and body is appropriately aligned with our physiology and behaviour across the day and at night. These demands include, for example, what time we sleep and wake up, our peak ability to process information, the best time to eat, and optimisation of brain toxin clearance. Disruption of these daily

rhythms can lead to severe health consequences, including premature ageing, increased risk of cancer and cardiovascular diseases, eating and mental health disorders.

In mammals, the master circadian clock is found in a brain region called the suprachiasmatic nucleus (SCN). Although the SCN is the master clock, circadian clocks are also found in many areas of the brain and body, which provide circadian timing at a tissue-specific level. For example, brain clocks aligning the activity of specific brain areas with the time-of-day at which these brain regions must be at peak performance, and heart muscle clocks increasing heart muscle tone during wakefulness and not during sleep. These extra-SCN circadian clocks form our extended circadian system (synonymous to our cardiovascular system, for example), and signal to one another through poorly understood mechanisms.

The overarching aim of the project is to understand how the SCN generates and coordinates circadian timing in the nervous system to organise bodily functions that are crucial to daily life, and how the different clock systems in the brain interact to maintain timing coordination in the circadian system across the day and at night. In doing so, we hope to unravel how and when disturbances and misalignment in the circadian clock network lead to ill-health and poor welfare, and how old-age and diseases, such as dementia, act to disrupt circadian timing in the body, leading to exacerbation of disease condition and further welfare degradation. Our ultimate goal is to use this new knowledge to help to generate appropriate pharmaceutical and non-pharmaceutical therapies to combat circadian rhythm disruption at the level of the body, when individuals in our societies are faced with modern life challenges, such as perpetual shift-work, travelling across time-zones and/or poor-health. Knowledge generated by this work programme, will also contribute in the long run towards our understanding of Chronomedicine, thus at what time-of-day should some medications be taken and for how long, and lighting conditions that patients in hospitals should be maintained under for rapid recovery. Indeed, this knowledge may also be used to improve the welfare of farm animals and animals used in research.

What outputs do you think you will see at the end of this project?

The immediate direct output will be from publication in high-profile international journals. My work has an excellent track record of producing such publications, and the intended programme of work under this PPL is a continuation of my research published in these high-profile Journals (such as Science, PNAS, PLoS Comp. Biol., J. Neurosci, eLife, etc, please see above).

Specifically from this programme of work, we expect to provide detailed information on how the novel “analogue” mode of electrical communication in the circadian system collaborates with its “digital” counterparts to generate and signal circadian rhythms in the body. This work will provide very rich and interrelated datasets at the molecular, cellular, brain circuit-wide, physiological and behavioural levels during health and youth. We will also determine how these multi-scale information are affected during ill-health and old age. This project will not be producing new animal models, but in the future we will be looking to cross our existing lines (such as our Per1-Venus reporter line) with other disease models (such as Alzheimer’s disease models) to provide useful tools and data for circadian biologists and other neuroscientists interested in contributing to our understanding of how clock rhythms are compromised during ill-health. We will seek further amendments to our PPL when the need to expand this to disease models emerges.

Who or what will benefit from these outputs, and how?

In the short term, the data generated by this work will initially be used by my group to shape our future research direction and interests. This work investigates some fundamental neuronal and glial signalling processes in the brain, and as such our publications (peer-reviewed journals and conference presentation) will influence researchers in the circadian and in the wider neuroscience communities. It is realistic to expect that this work will uncover new fundamental principles in circadian neuroscience and brain cell signalling pathways, exposing new avenues and possibilities for novel drug targets, while igniting testable hypotheses for drug repositioning. So, in the mid-to-long term, the pharma industries could therefore benefit from these findings. This work will generate rich in vitro and in vivo datasets which are likely to provide substantial opportunities for further computational analysis and modelling. The applicant has good relationships with a number of theoretical neuroscientists and mathematicians (in local, national and international institutions) and is committed to making data and mathematical codes freely available beyond the life of this project to any parties that can make further use of it. This in the long run may progress to the development of new research methods and technologies to facilitate work and data interpretation in the circadian field and neuroscience, which will ultimately lead to reduction and refinement of work with animals.

Part of our work program is dedicated to communicating our findings and understanding to the general public and patient's groupings, using these interactions to learn more about the human perspectives of circadian disruptions. The aim in the short-mid-to-long term is to impact and empower the patients by improving their understanding of the link between circadian disruption and mental disorders, for example, and how small changes in everyday routines and improved health management can make a big difference to their quality of life. This could have a good social impact leading to improved lifestyle choices on daily habits (e.g. feeding, bedtime), which in the long run could lead to improved healthcare policies.

How will you look to maximise the outputs of this work?

We have an excellent track record in collaborating with mathematicians and computational neuroscientists. Once we have published the data, all mathematical codes and analytical tools will be made freely available to the scientific communities.

We will continue to publish our work in peer-reviewed journals, and where possible involving press- releasing our work to maximise visibility.

We will continue with public engagement and disseminate our work at conferences.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult mice. The overall aim of the project is to understand how the brain

generates circadian rhythms in our physiology and behaviour. Mice will be used as the broad anatomy and physiology of this species is well understood and provide the best compromise in terms of correlating with human biology whilst exhibiting the lowest level of sentience. The mouse is also the animal model of choice for circadian biology research across the world. Therefore, we will be able to compare our results with the large body of literature available. In addition, many research and analytical tools have been developed for the mouse, making the data obtained more interpretable, reproducible, and refined.

Our aim is to understand how the brain organises circadian rhythms during youth and ageing. So, we need to use animals of different ages.

Typically, what will be done to an animal used in your project?

Typically, an animal will be born in the breeding room where it will be maintained until tissue collection. Some animals, however, will be placed in an altered light-dark cycle (circadian light/dark regimes) before tissue collection. During the altered light-dark cycle, a mouse will appropriately go through one or several light changes to prepare its circadian system before tissue collection. These light-dark cycles could be an advance of 12 hours and/or placed in constant darkness or received a pulse of light at a given time-of-day, for example, and may last from 4 days to 20 weeks, depending on the nature of the experiments. Training the circadian system in these various light/dark condition(s) is important as we study the effects of the light/dark cycle on our daily rhythm and how this affects sleep timing.

Sometimes, we will also measure the wheel-running activity of the mouse in a running wheel (as we would with our pet hamster at home) so that we have an understanding of the light/dark effects on behaviour. For collecting brain tissue from the mouse, typically, the mouse will be placed under non- recovery anaesthesia and then be killed by cervical dislocation.

What are the expected impacts and/or adverse effects for the animals during your project?

As these are all very mild procedures, we are not expecting adverse effects on the animals for most of the work we do. However, when we measure circadian rhythm using a running wheel, we would unavoidably have to singly-house the animal. Social isolation can be stressful, but the benefit is we will be continuously monitoring their circadian rhythm and sleeping patterns. We will therefore be able to monitor signs of distress. We will provide the animals with good environmental enrichment as much as possible to reduce stress. Fortunately, running wheels also reduce stress during social isolation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All our procedures are considered mild.

A small proportion of animals (< 1%) may be singly housed for up to 20 weeks. Of those, < 1% may experience some long-term mild harm.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying how circadian rhythms are generated and signalled in the brain and body of mammals and how these signals “break down” during environmental perturbation and disease with the view to relate and translate the findings to understanding the human circadian system. Due to the complexity of the nervous system and the intricate interactions of the circadian system in mammals very little information is available. As such, the only route to advancing our learning is through essential animal research work in an appropriate species. In addition, as incredibly advanced as our modern technologies are, they are not sophisticated enough for us to interrogate them on cell and circuit functionality as they exist in the whole organisms. Indeed, non-protected animals, such as worms and drosophila, do not possess brains that are complex enough to investigate our aims and will provide inappropriate information.

Which non-animal alternatives did you consider for use in this project?

We have considered using computational and mathematical modelling and non-protected species such the worms and flies.

Why were they not suitable?

However, as incredibly advanced as our modern technologies are, they are not sophisticated enough for us to interrogate them on cell and circuit functionality as they exist only in whole organisms. Non- protected species, such as worms and drosophila, do not possess brains that are complex enough to investigate our aims and will provide inappropriate information.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

We have estimated the number of animals required based on pilot studies and our published data. We have extensive experience in using these models and scientific methods to extract and analyse the data, and can therefore accurately estimate the number of animals we will need per group to obtain statistically valid results. As we generate more results, we will continue to assess group sizes to see whether the number of animals can be further reduced from those currently proposed. We will also use the latest statistical methods for data analysis to reduce sample size. We are also using mathematical modelling to make appropriate predictions that can be tested in future work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have made use of all local support including our statistician and other resources such as the NC3Rs Experimental Design Assistant and the ARRIVE guidelines. We have also made use of our long-term collaboration with mathematical modellers to identify some of the meaningful targets to focus our investigation. We have also sought advice from collaborators at other research facilities when designing experiments. We are also using animals that are engineered (transgenic) to provide the most accurate results possible, thereby reducing statistical variance in our results. We are also using animal species that are models of choice in the circadian research field, thereby allowing us to refine our methods and optimally interpret our results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our use of long-term cell culture systems will reduce the number of experiments that need to use live animals. We conduct pilot experiments where necessary to ensure that our experimental systems are optimised before conducting full studies. Where possible we will carry out studies in a step-wise manner to minimise the number of animals used. These are appropriately advised by our mathematical models. Our collaborators work on different parts of the brain and body. So, we will share tissues with them to reduce the total number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using adult mice that contain genetic markers in their brain circadian clock cells. In these models, we will be able to monitor and manipulate circadian activity ex vivo after placing the animals in appropriate light-dark conditions. The animals will be placed from 4 days to up to 20 weeks in these light-dark conditions. We will then perform imaging and record electrical activity from their brain ex vivo.

Why can’t you use animals that are less sentient?

Our aim is to understand how the mammalian brain generate and perceive circadian time to organise physiology and behaviour across the day-night cycle. For most of the project, it is important that the animals possess a certain level of sentience, so that they can appropriately perceive the light-dark cycle to generate the complexities in the brain and physiological responses that are comparable to humans, rather than a basic reflex reaction.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At all stages of the project, we will conduct welfare assessments on the animals to evaluate the impact of procedures. We will accordingly review our procedures to determine whether aversive procedures can be minimised without adversely affecting scientific outcomes. We will also seek advice from the named people and other scientists working in the field.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will keep up to date with relevant scientific articles and attend seminars and conferences. We will also keep up to date with published guidelines by the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs) and Laboratory Animal Science Associations (LASA).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date by reading scientific articles and attending conferences. We will also liaise frequently with the named veterinary surgeon, named animal care and welfare officer, and our named National Centre for the Replacement, Reduction and Refinement on the use of animals in research (NC3Rs) support for expert advice and best practice. In addition, we have signed up for the newsletters by the National Centre for the NC3Rs, and we will regularly consult their website and attend webinars to keep our knowledge in this area up to date.

98. Epigenetic inheritance and the control of developmental and physiological processes

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

genes, gene regulation, developmental disorders, genetics, epigenetics

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged
Zebra fish	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand the function and regulation of genes that are important for animal body function and development throughout the life-course.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our study has important implications for the health and well being of the individual and their offspring. Epigenetics refers to a range of factors that regulate the activity of genes, a controlled process that is important for ensuring that genes are expressed properly in the right cells at the right time.

When epigenetic processes do not work properly, cells behave abnormally leading to diseases such as growth abnormalities, disorders of the nervous system, metabolic diseases such as obesity and diabetes and cancer *. For example, Angelman syndrome,

an imprinting disorder leading to severe intellectual disability affects 1 in 12,000-1 in 20,000 people worldwide, and Prader-Willi syndrome, another imprinting disorder linked to intellectual disability, compulsive eating and obesity affects 1 in 10,000-1 in 25,000 people worldwide.
Epigenetic marks are set early in development and altered over time. While much can be learned about epigenetics from studying cells in a dish, information about the ways epigenetic changes are regulated can only be understood by investigating the whole body throughout its life.

* https://www.nature.com/scitable/content/epigenetic-diseases-and-their-causes-and-symptoms-37397/

What outputs do you think you will see at the end of this project?

We will generate new knowledge, to be shared with others, which will lead to the discovery of important factors that change gene expression without altering the genetic code in the form of DNA, this field is known as epigenetics. Specifically, processes in the contexts of the nervous system, growth and development and lifestyle-related diseases, for the benefit of humanity.

We will also understand fundamental processes associated with health and wellbeing in parents and the effect on offspring when these are perturbed genetically or environmentally. This has the potential to lead, in the long term, to new ways to detect diseases, predict their development and identify new ways to design medications for treatment.

Our findings will be published in scientific journals which are accessible to all, and our data will be placed in publicly available online resources. These published data will support future funding applications and has the potential to take the scientific discoveries to the clinic and the medical field.

Who or what will benefit from these outputs, and how?

During the 5 year course of the licence:

Our research in epigenetics will have an impact on our understanding of genetic diseases by identifying regions of the DNA where abnormal changes might lead to developmental and life-style related disorders, and cancer.

Our research on nutrition, before and after birth, will help understand more about why babies can be born with an abnormal weight. Additionally, our findings will look at the long-term impact nutrition has on their health and wellbeing over the lifecourse. This work will also have an impact on our understanding the benefits of breastfeeding for babies and mothers.

Our research on epigenetic processes being passed from parent to offspring, will help us understand whether and how environmental changes influence our DNA. We will investigate the extent of these environmental influences and how or if they can be inherited from parent to offspring and even to the next generations.

How will you look to maximise the outputs of this work?

Our research is highly collaborative and we will actively seek to contribute our expertise, technology and materials, positive and negative data to others and are often sought out by colleagues who wish to collaborate with us. We have a good track record in this, as evident from the publications that we co- author with others.

We will continue to establish and participate in national and international scientific organisations to maximise the impact of our research and add value altogether. We will continue to present our work prior to publication at conferences, seminars and lectures.

We actively collaborate with scientific companies to screen for the best tools to be used in the research community and weregularly report successful and unsuccessful results.

We are obliged by our funding agencies to publish our studies only in peer-reviewed open access journals.

Species and numbers of animals expected to be used

- Mice: 25,550
- Zebra fish (Danio rerio): 11,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and zebrafish are used to investigate aspects of our studies. An extensive catalogue of genes already exists for these organisms and they are widely used across the scientific community which allows for accurate comparisons between data. Also, well-established procedures already exist that are not harmful for the animals which can be used to mutate the genes or change their regulation. Many of the genes found in mice and zebrafish are found in humans too.

We study developmental processes therefore it is necessary to study all life stages.

Typically, what will be done to an animal used in your project?

For the vast majority of our work animals will be mated and material collected, post mortem (after death), at various life stages.

To study embryonic development, female mice will typically be injected into the abdomen, with a hormone to stimulate egg production, this is done twice in an animal's life and eggs are collected post mortem.

To assess metabolic processes animals may receive an altered diet, and substances such as glucose or insulin, will typically be administered once into the abdomen, followed by blood sampling of one drop, using a blood sugar monitor similar to that used by diabetics. Up to 6 blood samples will be taken from the tail vein over 4 hours. Typically, a mouse will experience each of these above procedures.

Some animals will undergo 1, 2 or sometimes 3 behavioural tests typically to test motor skills, anxiety and spatial navigation.
To evaluate mouse milk the mothers will be separated from the pups for up to 4 hours to allow milk to accumulate in the mammary glands. After this 4-hour period of separation, mothers will be anaesthetised and will have an injection of hormone to stimulate milk production. The nipple will be gently squeezed to release the milk. Mothers will then recover on a heated pad, and then returned to the pups that will remain in the nest undisturbed in a heated cabinet.

To study neurogenesis in zebrafish, animals will typically be singly housed, undergo behavioural tests, may have blood taken, and tissue sampling under anaesthesia such as fin clip. The fin clip is the collection of the very tip of the tail fin under brief anaesthesia. The fin tail grows back shortly afterwards. Taking a fin clip does not interfere with swimming.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of animals will undergo well-established procedures and will experience no adverse effects.

When new mouse lines are created or new crosses are bred we do not know the effects these will have on the offspring. Occasionally, these new lines may generate offspring with delayed developmental growth and the offspring may be born with a lower birth weight compared to their wild-type litter mates. Sometimes these mice with a lower birth weight regain a normal weight during adulthood.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: Sub-threshold - up to 60% Mild - up to 30% Moderate - up to 10%

Zebrafish: Sub-threshold - up to 60% Mild - up to 25% Moderate - up to 15%

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are performing experiments to assess the health of the whole organism. Our observations include multiple body systems and organs working together in a living animal, and multiple generations which we explore as part of our objectives. Such experiments

cannot be performed in a dish which usually only allows studying simple systems and very few cell types. Epigenetic states in a dish are very different to their natural state in the living animal, and currently are unable to recapitulate the physiological status.

We are studying mechanisms and pathways in a developing organism in embryonic and adult stages, therefore, we need to look at different time points throughout development. As cells in a dish are exact copies of each other this means that changes occurring in developing cells cannot be seen.

Which non-animal alternatives did you consider for use in this project?

We use non-animal alternatives as much as possible before moving on to animal models. Such alternatives include cells in a dish experiments, which allow us to answer simple questions without a live animal. We perform initial experiments in cells to test some of our hypotheses and choose the best candidate genes and pathways to focus on before moving on to animal experiments. This way, we can reduce the total number of animals we use.

In addition, we use cells to mimic as much as possible developmental processes in dishes. Such technologies make it possible to study early developmental processes, such as embryonic development.

To reduce animal work, we use publicly available sources and re-analyse existing data wherever possible with computer-based work and analysis.

Why were they not suitable?

Very often, the non-animal alternatives are not suitable. We cannot conduct experiments that address the health of an entire organism in the dish, which lacks the complexity and the interactions occurring in a physiological context.

Epigenetic states differ very significantly between cells in a dish and a living organism and to be able to conduct experiments that produce reliable and relevant data, we must use animal models.

When studying maternal-offspring interactions, there are no alternative non-animal methods that are sophisticated enough to address behavioural, hormonal, epigenetic and physiological questions which are very important aspects of our research programme.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

We have estimated the numbers based on our work over the past 30 years. Key members of our team have enough knowledge and experience for their research field. We estimated the numbers depending on their projects using robust statistical analysis software on data generated from initial experiments using a small number of animals or cells in a dish (pilot studies) or from past experiments to allow us to determine our sample size.

Our research requires the use of large numbers of animals. The nature of our work focuses on the differences inherited from the mother and father. In order to see such differences, we need to follow the transmission from the mother and father in separate breeding pairs, which doubles our animal numbers for every experiment.

Additionally, in many settings of breeding pairs, we only need to study either males or females, for example when studying mammary gland biology, which means we only use 50% of the animals that are born.

Moreover, many experiments only focus on a certain mutation which is only carried by 25% of the animals that are born. For these cases when many animals that are born will not be used in such experiments, we have a sophisticated communication platform within the lab, to ensure maximal usage by other researchers, for example for breeding, pilot experiments, tissue collection.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use online tools such as NC3Rs EDA https://www.nc3rs.org.uk/experimental-design-assistant-eda and PREPARE guidelines https://norecopa.no/PREPARE, and NC3Rs website https://nc3rs.org.uk/3rs- advice-project-licence-applicants-reduction . Additionally, we consult collaborators or experts when we need to design new experiments in which we need to acquire additional expertise.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

efficient breeding

We work closely with animal technicians in the facility, who will advise us if breeding pairs are not producing any litters or producing fewer litters. Furthermore, all breeding information is recorded in our online colony management system, where we record all animals and their procedures. Therefore we will notice immediately if breeders have problems.

sharing of animals, tissue samples, and cell lines

We communicate regularly to share animals, tissue samples, and cell lines. We use shared files to summarise and share the information of stock tissue samples and cell lines. All animal information has been recorded in colony management system, therefore animal users can easily check which animals are available.

We share animals, tissues and cell lines with our collaborators worldwide. This means that others do not need to generate new mutants or samples, minimising animal numbers.

preservation of mouse strains

We freeze sperm or preimplantation embryos from mouse strains that are not planning to use at least for a couple of years. We have deposited some lines into The European Mouse Mutant Archive which are made available to the scientific community.

pilot studies

Where possible we conduct initial studies on cells in a dish or with a small number of animals to determine whether experiments are then required in larger numbers. Occasionally our scientific questions can be answered by laboratory based experiments alone.

We optimise protocols with small-scale experiments with wild-type samples before conducting experiments using mutants.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We work on mice as it is a well-established system to genetically manipulate this organism as well as to maintain controlled breeding. It is also possible to carry out phenotypic analysis of mice. Due to the genetically homozygous background of laboratory mice, genetic background effects do not affect analysis and make it easier to interpret results with fewer animals being required. The mouse genome has been well studied and characterised, therefore protocols for embryo and reproductive manipulations are well-established and safe for the mouse.

Many of our new mouse lines have been generated using CRISPR technology, which can generate multiple mutations using a single targeted event. This therefore requires the use of less mice and speeds up the generation of new mouse models. Mutations can then be selected for and an extensive breeding scheme can be avoided.

We also work on zebrafish which share a high degree of genetic and tissue similarities to mammals. As zebrafish lay as many as 200-300 eggs per mating, fewer animals are required per breeding programme. The eggs are laid outside the body therefore offspring can be studied whilst avoiding harm to the mother.

Why can’t you use animals that are less sentient?
Our research aims to assess mammalian gene function therefore the mouse is the best model for our work. Due to the lack of imprinting in species such as the zebrafish, we cannot use alternative species for most of our research. Our studies aim to look at the function of imprinted genes throughout development so immature life stages cannot be studied alone.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use well established protocols and will carry out pilot studies before starting procedures. Procedures will be discussed with experienced collaborators to minimise welfare costs for the animals. Any animal that has been through a procedure will

continuously be monitored at regular intervals examples include observing changes in locomotion (zebrafish), signs of gasping at the surface of water (zebrafish), sitting at the bottom of the tank (zebrafish), scoring sheets during procedural changes, weighing (mice), heat mats (mice) and providing post operative bedding (mice). When appropriate, pain management such as the use of medicated palatable substances for voluntary treatment, e.g. flavoured jelly, paste or milk shake liquid will be given to mice or appropriate pain-relief drugs will be dissolved in the water for zebrafish.

Mice are typically group housed with enrichments such as chew blocks, tunnels, mouse houses and nesting material. Zebrafish are typically group tanked and provided with enrichment if needed. We are always open to new suggestions by the NACWO for enrichments, such as running wheels etc.

If possible, for any new mouse lines, inducible constructs will be used so that mice only display a phenotype (visible physical characteristics such as behaviour or growth and appearance) once the deletion is induced. We will refine the humane end point for new mouse lines and will seek advice from the Vet and the Home Office Inspector if needed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our lab has been conducting embryological work over the last 30 years, therefore we have published protocols which ensure experiments are conducted in the most refined way. For any new procedures we will review published protocols from experienced collaborators before conducting any experiments.

We use ARRIVE guidelines to ensure our experiments are performed in the most refined way, and for the responsible reporting of results. This includes a thorough study design, sample size, inclusion and exclusion criteria, randomisation, blinding (where possible), outcome measures and state of the art statistical methods.

We use PREPARE guidelines which includes three areas that determine the quality of the preparation of animal studies:

Formulation of the study (literature, ethics, design etc)

Discussions between us and the animal facility (objectives, time-scale, facility evaluation, training and health assessment)

Methods (test substances, quarantine and monitoring, housing and husbandry, procedures and humane end point)

Specifically, for zebrafish we will ensure that our experiments are conducted in the most refined way, according to NC3Rs https://nc3rs.org.uk/zebrafish-welfare and enrichment provided if needed such as artificial plants as recommended by the Zebrafish Husbandry Association https://zhaonline.org/.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly discuss with the Named Persons at our institution on the best practices and new approaches in the 3Rs, including using the NC3Rs website pages https://nc3rs.org.uk/resource-hubs. We have subscribed to the NC3Rs e-newsletter to

receive information on the latest 3Rs developments as well as information on NC3Rs events and workshops, which we can attend. We consider the latest practical guidance from Laboratory Animal Science Association (LASA), and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). Additionally, we use external resources such as Jackson labs database https://resources.jax.org/. Lastly, we will maintain contact with our local NC3Rs Regional Programme Manager for advice on implementing advances in the 3Rs.

99. Stem cell regenerative medicine for neurodegeneration

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Stem cells, Therapy, Neurodegeneration, Behaviour, Neuropathology

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to validate a novel pharmaceutical advance, a stem cell derived secretome, as a treatment for multiple neurodegenerative conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Dementia is a growing world-wide problem with recent data indicating that the prevalence of dementia will double in Europe and triple worldwide by 2050. Currently an estimated 1 million people are living with dementia in the UK alone. Dementia is an umbrella term describing a gradual and progressive loss of cognitive abilities cause by disease.

Alzheimer's is by far the most common form of dementia, while all common forms of dementia display specific brain changes in specialised brain areas. Other conditions, such a motor neurone disease and Parkinson's disease are also defined by similar changes in specific brain regions. This suggests an overlap in the molecular pathways that give rise to these conditions, and thereby suggest that potential therapeutics may also exploit these similarities. The specific brain changes that define these conditions all feature the aberrant accumulation of aggregates of proteins in the brain.

Currently Only 4 drugs, offering symptomatic relief, are licensed for the treatment of dementia (although none target the underlying pathology). Although treatments undergoing current clinical trials aim to reduce the predominant pathological feature of each of the different types of dementia, none of these targets all pathologies. Currently, no phase 3 trial has met its primary goals. Therefore, there is an urgent unmet clinical need to develop therapeutics that target all pathologies and halt/reverse clinical symptoms.

What outputs do you think you will see at the end of this project?

The programme of work is designed to determine the efficacy of a novel therapeutic approach to neurodegenerative disease related pathology and clinical symptoms. The expected benefits are two- fold: validation of the therapeutic potential for stem cell generated secretomes and a clear understanding of the link between pathology and clinical symptoms. Outputs generated will consist of a substantial body of published work detailing brain changes co-incident with behavioural deficits and responses to therapeutic treatment. This will provide a valuable resource that will aid research into treatment of Alzheimer’s disease and other neurodegenerative conditions.

Who or what will benefit from these outputs, and how?

The impacts of these outputs will help in the in the early stages of translational research into different neurodegenerative conditions, initial results will be reported after the first year of the project. Longer term benefits will be realised through translation of the key findings into disease modifying treatments. These treatments will specifically benefit patients with dementia, motor neurone disease and Parkinson's disease.

How will you look to maximise the outputs of this work?

Impact of outputs will be maximised through publication of results in open access scientific journals and through dissemination at international conferences. In order to maximise this, outputs will also be presented in lay terms to non-scientific audiences through articles in The Conversation, dissemination at Cafe Scientifique events and through Webinars. The project is a collaborative effort involving behavioural scientists, bioinformaticians and molecular biologists. Through their respective networks information and outputs will be disseminated.

Species and numbers of animals expected to be used

- Mice: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Four mouse models have been selected that model Alzheimer's disease (AD), Parkinson's disease (PD), Frontotemporal dementia (FTDP) and motor neurone disease (MND). These present with only a single brain pathology representative of the disease they are modelling. All models have well characterised temporal appearance of cognitive and/or motor and pathological phenotypes and will be investigated at an age coincident with already established pathology and behavioural deficits, this will be either adolescent or adult stage dependent on the model. Primary and secondary endpoints will be behavioural (mobility and/or cognition) and pathological (brain pathology). The choice of life stage has been determined by the known onset of pathology and behavioural changes.

Typically, what will be done to an animal used in your project?

Following acclimatisation and habituation, each animal will undergo behavioural testing of mobility and/or cognition for a few days to capture their baseline abilities. After this each animal will be treated either with a placebo or a test compound that we believe will slow the animals behavioural decline and remove the hallmarks of the disease from their brains. The vehicle or test compound will be injected into the tail vein of each animal to maximise successful delivery of compound. Blood samples will be taken after 2 weeks and a further 2 weeks later the animals will undergo behavioural testing again to determine the effect. Following this, animals will receive another tail vein injection of either vehicle or test compound to mitigate against systemic clearance of test compounds, and again blood samples will be taken after 2 weeks. After a further 2 weeks the animal will undergo further behavioural testing. Once the behavioural testing is complete the animals will be humanely killed, and their brains collected for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that as the animals age over the duration of the project (around 10 weeks in total) that there will be a gradual worsening of the animals' cognitive abilities and for some of the models a worsening of their motor co-ordination. The impact of the worsening cognitive abilities will be mild, while the impact of gradual motor deficits will not advance enough to cause distress. The behavioural test they will perform will not have any adverse effects. As with any systemic administration, there is the possibility of irritation around the injection site which may impact briefly.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

The likely/expected severity of procedural harms is moderate in all animals. It is expected that there will be momentary stress induced by the tail vein injection. For the behavioural analysis, there will likely be mild severity due to unfamiliarity of behavioral apparatus, this will be short term as the animals become habituated to the apparatus, this would be expected in 100% of the animals. Procedural harms are associated with the phenotype of all the animals. Cognitive deficits will be mild and sub-threshold of moderate severity, 50% of all animals will fall into this category, those that display motor deficits will experience moderate severity, 75% of animals will experience this. Of those animals which present with a motor phenotype there is the possibility that a number may present with an

accelerated phenotype which could be classed as severe. While this is unlikely it could present in 15% of the animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The tissue affected by Alzheimer's disease and other neurodegenerative conditions cannot be donated by living human beings, while post-mortem tissue is not suitable for the physiological assays involved. Non-animal alternatives are not developed enough for us to use as an alternative.

At the cellular and systems level, most of the proteins found in mouse brain share similar functions to the proteins found in the human brain. This means that the major intracellular signalling pathways are highly conserved from mouse to man, and the higher functions of the brain, specific to mammals, dependent on regulation of such proteins are also conserved. This, combined with the relatively short lifespan of the mouse, along with the tools available for genetic manipulation (such as the introduction of mutations that give rise to the pathologies evident in the brains of individuals with different neurodegenerative conditions), make it the most appropriate model of the complex neurological systems to be studied that also recapitulates the cognitive and behavioural symptoms that present with these conditions.

Which non-animal alternatives did you consider for use in this project?

A number of non-animal alternatives were considered for this project, including:

- Immortalised cell lines
- Inducible pluripotent stem cells
- Human post mortem tissue

Why were they not suitable?

The nearest substitute we have to animals is immortalised cell lines, however, while cell lines are a valuable model for many functional and biochemical assays, they do not develop axons and synapses and so are not morphologically representative of specialised cells such as neurones. In addition, no such immortal cell lines currently exist that replicate the intracellular accumulation of proteins similar to those that occur in the brains of individuals with different neurodegenerative conditions. Similarly with inducible pluripotent stems cells, these can be isolated from individuals with specific conditions and so can reflect a specific disease state, however they also do not form the complex morphological networks with other cell types found in the brain.

The tissue affected by individuals with Alzheimer's disease or any of the neurodegenerative conditions cannot be donated by living human beings, while post-

mortem tissue is not suitable for the physiological assays involved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animals for the duration of the projects is based on:

our preliminary observations and previous experience of performing both behavioural and biochemical analysis in order to minimise the number of animals needed to see meaningful differences between the groups, and two different approaches to determining the numbers of animals used in each experiment, making use of both the NC3R experimental design app and the G*Power 3.1 programme. Numbers estimated have also taken into consideration that some animals may need to be excluded as ‘non-responders’ in the behavioural tests.

If through the course of the experiments we find that we can gain significantly relevant information with fewer animals, the study will be changed accordingly.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal studies were designed using the NC3R's Experimental Design Assistant (https://eda.nc3rs.org.uk/), an online tool for improving the design of animal experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

By combining behaviour and brain biochemical changes (by taking the brains form the animals following behavioural testing for post-mortem biochemical analysis) we have optimised the experimental design to gather the most possible data from each animal. In addition, all tissue from each animal will be banked as a resource to other investigators to reduce replication of studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Frontotemporal dementia Tau mouse strain, these mice display the neuropathological and behavioural phenotypes evident in patients with frontotemporal dementia. Specifically accumulation of aggregated tau protein.

Alzheimer's disease APP mouse strain, these mice display the neuropathological and behavioural phenotypes evident in patients with Alzheimer's disease. Specifically accumulation of extracellular deposits of aggregated amyloid.

Parkinson's disease Alpha-Syn mouse strain, these mice display the neuropathological and behavioural phenotypes evident in patients with Parkinson's disease. Specifically accumulation of intracellular deposits of alpha synuclein protein.

Motor neurone disease Q331K mouse strain, these mice display the neuropathological and behavioural phenotypes evident in patients with motor neurone disease. Specifically, accumulation of intracellular deposits of aggregated TDP-32 protein.

While most dementias display evidence of multiple pathologies, the models chosen only display a single pathology thereby minimising suffering and distress. All the models chosen present with a non- aggressive phenotype and a single pathology. The methods chosen to study are standard behavioural studies and will cause limited distress and no lasting harm to the animals. The method of application of the therapeutic was chosen as the least invasive method to deliver the therapeutic to the model.

Why can't you use animals that are less sentient?

Neurodegenerative diseases are largely age-associated as the pathology that develops in the brains that give rise tot he clinical symptoms takes many years to develop in humans. Similarly, animal models of these diseases also take time for the pathology to develop. The models we have chosen to study develop pathology slowly and so a more immature life stage would not have the pathology present to cause the behavioural symptoms. The proposed project aims to address both the pathology and behavioural symptoms of these conditions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All procedures are of the minimum severity level needed to provide the required effects. All behavioural tests are mild and will not put the animals under an unnecessary stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will make use of the Laboratory Animal Science Association publications to refine my experiments, specifically the LASA Position paper: 3Rs : Replacement, Reduction, Refinement 9216). Guiding Principles on Behavioural Laboratory Animal Science. Avoiding Mortality in Animal Research and Testing.

I will be guided by the NC3Rs Resource Hubs, specifically Blood Sampling

I will make use of the ARRIVE Guidelines 2.0 as best practice for reporting the outcome of all experiments.

How will you stay informed about advances in the 3Rs, and implement these

advances effectively, during the project?

I will stay informed about advances in the 3Rs through the monthly NC3R newsletters. In addition, we have an active Biological Services Unit users' group of which I am a member and from where I can learn and share advance in the 3Rs

100. Studies to improve the welfare of pigs

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Animal welfare, Pigs, Social behaviour, Nutrition

Animal types	Life stages
Pigs	juvenile, adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Commercial pig production can result in a variety of challenges to pig health and welfare. We use behavioural and physiological indicators to investigate the causes and consequences of these challenges.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Animal welfare is high profile ethical concern of citizens and consumers, and various funders (including policy makers) seek evidence-based information on which to base decisions. Our research responds to these needs by providing scientific evidence to support changes to law or guidelines, or assurance scheme rules concerning management practices and housing systems.

What outputs do you think you will see at the end of this project?

Our research leads to: i) guidance on best practice for pig breeders, pig producers and veterinarians, or
ii) new technologies or techniques to be used on-farm iii) evidence base for policy makers and assurance schemes devising rules and recommendations for keeping pigs. Farmed pigs benefit through improved welfare, and this is seen as a benefit by citizens and consumers; pig producers may benefit through more efficient production with fewer loses (e.g. depressed weight gain from ill health or aggression).

Who or what will benefit from these outputs, and how?

Various actors in the pig supply chain will benefit, including breeders, farmers and veterinarians. Policy makers and assurance schemes will benefit from a greater understanding of best practice to improve pig welfare.

How will you look to maximise the outputs of this work?

We collaborate with industry partners (for example pig breeding companies, veterinary companies, animal feed suppliers) as part of the science we do. Findings are also published in refereed journals, and disseminated more widely to stakeholders through for example open days, events, agricultural shows, and articles for the specialist (pig industry) press (e.g. pig world) and websites (e.g. thepigsite.com)

Species and numbers of animals expected to be used

- Pigs: 4176

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The welfare problems we study require the whole living animal to be studied (e.g. to record behavioural responses), and non-animal alternatives are not available. We aim to inform on the welfare of pigs kept in commercial situations. We use pigs at the appropriate age (between birth and adult) for the specific scientific question being asked- studies of social development and behaviour include pigs between birth and ~4 months of age.

Typically, what will be done to an animal used in your project?

In social stress studies, pigs reared under commercial stocking density, and mixed with unfamiliar animals may experience stress and injury as a result of aggression.

For gut health studies, some animals may grow poorly or become unwell as a result of experimental diets.

For studies of needle-free vaccination, some pigs will experience the brief pain and subsequent discomfort of receiving a vaccination.

What are the expected impacts and/or adverse effects for the animals during your project?

For social behaviour studies, any severely bullied pigs will be removed from the pen and any injured pigs will be appropriately treated or euthanized on the advice of the NVS. During isolation for behavioural testing, some individuals may become stressed and continually try to escape- these pigs will have their test ended and returned to their home pen.

For gut health studies, pigs which grow poorly or become unwell (beyond mild and temporary diarrhoea) will be removed from the study for treatment or euthanized on the advice of the NVS.

For studies of needle-free vaccination, some pigs will experience the brief pain and subsequent discomfort of receiving a vaccination. We expect any impacts to be brief, and worse in needle-injected control animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Studies of gut health and needle-free vaccination are expected to be mild.

A minority of animals in social behaviour studies may experience moderate stress following mixing into a new social group (this is a common practice in pig farming which our studies replicate in order to better understand their impact). As such these studies are classed as moderate. After mixing, some pigs will typically fight to establish a new heirarchy. This can be physically tiring and result in skin scratches. Some losing pigs may be bullied by pen mates. Groups usually settle down and integrate over a few days. Other pigs manage to go through these situations with little in the way of physical interactions.

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studying pig behaviour, welfare and responses to supplementation requires that living pigs be used. Scientific literature from pigs and a variety of other mammals is used to ensure that experiments build on existing knowledge, have focussed hypotheses and that the work is genuinely novel (and not being unnecessarily repeated). Our research group also regularly undertakes and publishes surveys, reviews and systematic reviews of the literature to further this end. Also, our focus on behavioural studies, and on positive

behaviour means that we often carry out experiments that do not cause suffering so do not need to be regulated by ASPA. The findings of these studies complement and inform our regulated work. Nutrient supplementation studies are typically preceded by in vitro studies when supplements are being developed, so that only those most promising are employed in animal trials. In addition, cross- fertilisation of ideas between studies in poultry and pigs can refine hypotheses.

Which non-animal alternatives did you consider for use in this project?

None exist for experimental work. As stated above though, we make use of published literature reviews and meta-analyses, and carry these out ourselves, we also make use of information from other species where relevant. This minimises the need for new experimental work, and improves the focus and design of experiments which are necessary.

Why were they not suitable?

Animal welfare is an outcome of sentient animal minds, and our research is about pig welfare. As such we need to use living pigs as our research subjects. Also, our research involves behavioural phenomena such as social behaviour interactions between pigs. This requires actual living pigs to show these social interactions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A series of designed experiments have been planned for each of the four areas of work (protocols), and these total animal numbers emerged from those planned studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal use was reduced by using efficient experimental designs incorporating factorial design, blocking and randomisation, and by minimising animal numbers by using power analysis based on previous similar studies where information is available. Our studies are reviewed by an independent statistician.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

None of these are relevant here.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use a number of refined methods developed over the years. For example, where possible: pigs are habituated to handling prior to behavioural testing, saliva sampling rather than blood is used, or pin- pricks of blood rather than a larger sample, and ear tissue collected for DNA as part of routine ear tagging for ID purposes. Pigs are closely monitored when negative outcomes are expected so that they can be treated as soon as possible.

Why can’t you use animals that are less sentient?

Our studies are intended to relate to the behaviour and welfare of pigs, as such pigs must be used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our scientists and technical team are motivated to develop the most refined methods based on their own skills and experience. We have refined our methods over a number of years, including training animals to accept handling e.g. for weighing, refining the mix of drugs we use for sedation prior to euthansia, use of pin-prick blood sampling rather than jugular venipuncture, and the use of hair, saliva or faeces for cortisol sampling rather than blood.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Published on-line best practice guidelines prepared by NC3Rs will be followed. Peer reviewed papers have been consulted to ensure robust scientific use of the specific techniques described in the protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are aware of the training materials offered by NC3Rs, some of which are directly relevant to our protocols (e.g. best practice in ear vein blood sampling in pigs). We have confirmed that our protocols adhere to the available guidance. Our protocols are reviewed at pre-determined intervals and, at these review points, we will ensure that they are updated to reflect the most recent refinements in NC3Rs guidance. Technical staff associated with the work will also be encouraged to engage with the resources available for continued professional development of technical staff provided by NC3Rs.

101. In vivo models of joint degeneration

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

osteoarthritis, abnormal loading, inflammatory arthritis, knee joint, drug therapies

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to determine the mechanical and inflammatory factors that play a role in the maintenance, degeneration and regeneration of musculoskeletal tissues. Understanding these links will help identify new targets for therapy and help make decisions on surgery and rehabilitation to improve care of patients and animals with arthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By determining how these factors regulate responses to mechanical loading, interventions may resolve the degenerative processes associated with ageing and exercise. These objectives will also contribute to the understanding of how mechanical factors control and maintain the material and structural properties of musculoskeletal tissues. The data will be

used to advance the clinical management of high burden, high morbidity diseases such as osteoarthritis and rheumatoid arthritis through translation to clinical trials and inform on the management, rehabilitation and prevention of these debilitating conditions.

What outputs do you think you will see at the end of this project?

The outputs of this project will likely include:

the generation of novel data that will improve our understanding of the molecular mechanisms and the interplay of known risk factors i.e. altered mechanical loading, inflammation and genetic predisposition that underpin the development of osteoarthritis.

dissemination of the data in scientific publications, conference meetings and public engagement activities.

generation of pilot data to support the submission of grants to continue the research.

identification of new targets for therapy or re-purposing of existing drugs which have the potential to improve treatments for patients and animals with arthritis.

Who or what will benefit from these outputs, and how?

Our research focuses on an interdisciplinary ‘molecule to man’ approach to address major scientific questions in the arthritis field. As life expectancy and the incidence of obesity increases, the number of OA sufferers in the UK will continue to rise. There is no treatment for OA, except joint replacement surgery which has a limited lifespan and is associated with poor outcome in many patients (e.g. 20% of patients undergoing total knee replacement are unhappy with pain and function 6 months after surgery). It is known that abnormal weight bearing on joints causes diseases such as OA, whereas normal loading is essential to maintain a healthy skeleton. The forces associated with protective normal loading and destructive abnormal loading in humans, and the way in which these forces influence joint function, pain and inflammation are largely unknown. The mechanoresponsive pathways already identified in some of our projects directly regulate inflammation and therefore are also of considerable interest in the progression of inflammatory arthritis. Understanding the link between joint loading, inflammation and pain will identify new therapeutic targets and inform surgical intervention and rehabilitation strategies to improve care of patients and animals with joint degeneration.

Short-term impacts of the project i.e. within the 5 year period will include:

validation of existing mechanically-regulated therapeutic targets for bone and joint disease

development of new therapeutics and re-purposing of existing drugs to reduce arthritis progression *in vivo*.

Long-term impact i.e. beyond completion of the project, may provide an opportunity to:

Identify sufferers of arthritis earlier before joint damage is extensive thereby reducing the need for joint replacements

Devise interventions that alter loading patterns through diseased joints to slow disease progression

Develop drugs to abrogate harmful effects, and mimic beneficial effects of loading

Devise patient-specific treatments targeting pain and inflammation to delay requirement for joint replacement

How will you look to maximise the outputs of this work?

Project outputs will be maximised by:

ensuring the timely submission of research articles for publication in open-access journals to ensure a wide readership

attendance at international and national conferences to disseminate data findings

attendance at public engagement events to discuss use of animals in medical research

collaboration with other academic research groups with a shared interest in musculoskeletal mechanobiology and development of interventions for arthritis

collaboration with Pharma with a shared interest in 'drugging' molecular targets or potential therapeutics for human and veterinary purposes.

Species and numbers of animals expected to be used

- Mice: 1100
- Rats: 175

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents (rats and mice) will be used for these studies as their joint anatomy/physiology sufficiently resembles human. These model systems are well-defined with specific and rapid timeframes to enable therapeutic intervention at the point of injury or in the early inflammatory phase to be performed.
Skeletally mature (> 12 weeks of age) will be utilised for all protocols to ensure that the skeleton has fully developed and is representative of an adult.

Typically, what will be done to an animal used in your project?

Wildtype (mice and rats) and genetically altered animals (mice) will be acclimatised for one week to experience being handled, exposure to the environment and, if necessary, training in techniques that will be utilised as part of the measurement outcomes e.g. walking along an enclosed beam to measure gait and extent of weight-bearing on all four limbs. All four experimental protocols will involve administration of an anaesthetic via inhalation, with the possibility of an injection of painkiller whilst under anaesthetic. Depending on which protocol is used, animals may:

receive a non-surgical loading stimulus to their knee to either promote long-term degeneration of the joint over a 42 day period or to induce post-traumatic osteoarthritis over a 21 day period, or

have a surgical procedure performed which involves opening the joint and damaging the meniscus to induce joint instability over a 21 day period, or

be injected with an agent, typically six times over a 56 day period, which promotes a sustained inflammatory response in the joint to mimic inflammatory arthritis over a 91 day period.

Depending on the experiment, animals may receive an injection of a substance, typically a drug, directly into the joint whilst under anaesthetic which may occur during the procedure itself and/or at a defined point following initiation of arthritis. Following these procedures, animals will be allowed to recover, closely monitored for any immediate adverse effects and returned to their cage/cagemates for continued monitoring. Animals will undergo routine well-being measurements (daily during the 1st week and then every other day) including weighing, monitoring of lameness by two observers and measurement of knee swelling using fine callipers.

Other measurements that may be performed include assessing weight-bearing, pain and gait (walking along an enclosed beam, assessing weight distribution or recording pressure applied on each limb respectively), or whilst under anaesthetic the imaging of joints using scanners or withdrawal of fluids
e.g. blood and synovial fluid.

What are the expected impacts and/or adverse effects for the animals during your project?

Experimental protocols are well-established in our group, and therefore the likelihood of adverse effects are low. Furthermore, to reduce the likelihood of this occurring, we have stringent procedures in place to minimise risk/harm to the animals. The primary adverse effect is likely to be pain experienced by the animal after the specific procedure and once the arthritis has developed in the joint; therefore a painkiller will be administered at the time of the procedure and continuous monitoring of animal welfare will be conducted over the period of study. At the end of the study, or earlier if necessary, animals will be humanely killed and joint tissues processed to maximise the amount of information collected and analysed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

One of the loading experimental protocols is expected to be low severity with minimal discomfort to the animals and the remaining three experimental protocols are expected to have moderate severity as they could induce discomfort and/or distress to the animals. The proportion of animals that will be utilised in experiments classified as low severity is approximately 20% (mice) with the remaining 80% classified as moderate (mice and rats).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due to the nature of the project, animal replacement is not feasible. We have developed explant and cell based models to investigate the mechanisms of joint destruction and protection in specific tissues and use these models wherever possible. However, experiments carried out on isolated cells and tissues alone are unable to recapitulate the biomechanical environment and the biological interactions between the surrounding joint musculoskeletal tissues, and hence the complexities of how the entire joint responds to mechanical load. There are currently no whole joint non-animal models of arthritis available. Furthermore, validation of targeted interventions as therapies for arthritis treatment can only be truly assessed in *in vivo* models where we can directly measure how well they rescue the disease symptoms in the different joint compartments. This can only be addressed by conducting the proposed *in vivo* experiments.

Which non-animal alternatives did you consider for use in this project?

As indicated above, where feasible we have developed and utilised alternative *in vitro* approaches to animal studies. This has included the utilisation of material derived as a by-product of the meat industry (obtained from abattoirs) as well as the development of models involving isolated cells and tissues.

We are actively engaged in developing more complex 3 dimensional and multi-cell type models to increase the tools available to us, and other researchers, for *in vitro* studies. Such models are currently, and will continue to be, used where possible to elucidate cell specific mechanisms.

Why were they not suitable?

Due to the nature of the project, animal replacement is not feasible. An *in vivo* model system is required to recapitulate the biomechanical environment and the biological interactions between the surrounding joint musculoskeletal tissues, and hence the complexities of how the entire joint responds to mechanical load. The additional influences of interactions between the different tissues involved in joint loading, e.g. cartilage, bone, muscle, ligaments as well as the systemic effects, and how well drug treatments might rescue the disease symptoms can only be assessed by undertaking the proposed *in vivo* studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been estimated based on our experience and animal usage over the last 5 years under my previous PPL. Using this information, we have considered the number of animals required to further investigate a small number of specific molecular targets as we refine the course of our research plan moving forwards. A typical pilot experiment for Protocol 3, for one target, will involve a maximum of 120 animals to account for dosing regime, plus or minus load as well as the drug intervention and six time points. Numbers per experiment will then be less once we have identified optimal dosing regime. Lower animal numbers have been estimated for the remaining protocols because they will be used to validate the chosen therapy in the different models of arthritis that they represent.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs EDA was utilised to design the specific experiment in conjunction with the implementation of power calculations to ensure the minimum number of animals were used in the previous PPL. These have and will form the basis of our future pilot studies which will be refined, where needed, to inform on animal numbers required to investigate a defined number of identified molecular targets within this current PPL.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies (using appropriate power calculations) will be performed for any new studies to minimise animal number use, and in addition to this, where possible, we will utilise 'control' data from our previous experiments (under a previous PPL) to reduce the number of untreated animals required i.e. animals which have not gone through the protocol. Furthermore, we will ensure the sharing of tissue, either by harvesting other joint components or organs at the endpoint or providing histological sections of the joint for analyses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We intend to use four different models (Protocols 2 - 5), all of which induce an arthritic disease in both wildtype and genetically altered animals (Protocol 1) including:

A well-defined non-invasive loading model in living mice and rats that will apply mechanical loading to long bones and joints of one leg under general anaesthesia while the other leg acts as a control. The model will either recapitulate a loading regimen that mimics long-term degeneration of the cartilage, akin to that observed in human primary

'wear & tear' OA (Protocol 2), or it will elicit load-induced rupture of the anterior cruciate ligament, akin to that experienced in human post-traumatic OA after a sports injury/accident (Protocol 3).

A well-defined surgical model in living rats that, under anaesthesia, surgically destabilises the meniscus (a key component in the joint that protects the articular cartilage from excessive loads), akin to that experienced in human post-traumatic OA after a sports injury/accident (Protocol 4).

A well-defined inflammatory model of arthritis in which this disease is induced in rats and mice, akin to that observed in OA and RA pathology (Protocol 5).

Each of these in vivo model systems will allow us to determine how the pain and tissue degeneration is instigated in arthritis, thereby providing vital information to further our studies into developing therapies to treat arthritis in both humans and animals. Two of the protocols are classified as mild severity (protocols 1 and 2) with minimal discomfort to the animals and the remaining three protocols (protocols 3-5) are classified as moderate severity as they could induce discomfort and/or distress to the animals. The primary adverse effect is likely to be pain experienced by the animal after the specific procedure and once the arthritis has developed in the joint; therefore a painkiller will be administered at the time of the procedure and continuous monitoring of animal welfare will be conducted over the period of study to ensure animals do not experience unnecessary pain, suffering, distress or lasting harm.

Why can't you use animals that are less sentient?

Due to the nature of the project, animal replacement is not feasible, although we are developing explant and cell based models to investigate the mechanisms of joint destruction and protection in specific tissues and use these models wherever possible.

Experiments need to recapitulate the biomechanical environment i.e. animals need to be weight- bearing in a similar manner to humans, to mimic the complexities of how the entire joint responds to mechanical load. This can only be addressed by conducting the proposed *in vivo* experiments in rodents, which are considered the least sentient model in this research area. Also, animals need to be skeletally mature to be able to recapitulate how the disease manifests in human adults, thus more immature life stages would not address the key research questions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Measures are in place to minimise the welfare costs for the animals which include:

acclimatisation of all animals for at least one week prior to the initiation of protocols such that they become familiar with handling, surrounding environment, cagemates and measurement methods.

monitoring of animals on a daily basis after the induction of arthritis to ensure no adverse effects on their health and well-being e.g. weight loss, appearance and lameness.

provision of appropriate soft bedding and nesting material to cushion affected limbs and maintain their body temperature during this period to minimise unnecessary stress and/or discomfort.

provision of gel supplements in the cage to ensure animals with compromised mobility have appropriate access to food.

provision of additional cage items e.g. tunnels to provide refuge for those animals with compromised mobility.

provision of painkillers, where appropriate, and swift implementation of humane endpoints to minimise distress or suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In line with our previous PPL studies, we will ensure that all experiments conform to best practice by following the ARRIVE 2 guidelines (which our previous relevant publications adhere to), in conjunction with advice and guidelines disseminated by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will remain informed about 3Rs advances through our continued email 'sign-up' to the NC3Rs newsletter where good practice and regulatory updates are disseminated. We will also continue to attend the NC3Rs regional events and liaise with our regional NC3Rs manager to ensure effective implementation of advances. The PPL applicant currently sits on the NC3Rs Training Fellowship panel (2020 - 2023) and benefits from updates on good practice through this forum.

102. Reproduction Safety Tests on Agriculture and Industrial Chemicals

Project duration

5 years 0 months

Project purpose

- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Toxicology, Reproduction, Safety

Animal types	Life stages
Rats	juvenile, adult, pregnant
Mice	juvenile, adult, pregnant
Rabbits	adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project licence is to establish toxicological and safety data in animals following exposure to industrial and/or agricultural chemicals and veterinary products that Man may be exposed to. The studies performed will be designed to reveal any effects on mammalian development and reproduction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chemicals play an important role in daily life. Therefore, their safety for Man, other animals and the environment has to be considered carefully. By establishing sufficient toxicological and other safety data in animals, safe handling precautions may be determined thus protecting the health and welfare of hundreds (e.g. for a site limited industrial chemical

intermediate with limited potential for human exposure) to millions (e.g. industrial or agricultural product with world-wide market) of humans and animal species which may contact the materials concerned and facilitate the world-wide marketing and safe use of products. The projects performed under this licence provide safety data to facilitate sound regulatory decisions worldwide that protect the public and the environment from possible hazards. The regulated products have the potential to improve and enhance the health, well-being and quality of life of people and animals. For example, improved crop-protection increases food security, while development of safer chemicals and chemicals with reduced environmental impact is clearly beneficial for human and animal health and in environmental protection.

The projects undertaken in this licence use methodologies that are well established and known to produce accurate and reliable results that can be used in regulatory risk assessment. Furthermore, the studies can rapidly identify any overt toxicity which would cease the development of the test item and therefore enable the Sponsor to make a decision at the earliest opportunity to cease production: reducing the risk of possible human exposure and avoiding unnecessary expenditure and use of resources. The work performed under this licence will be undertaken in a GLP compliant laboratory thereby ensuring data integrity and accuracy.

What outputs do you think you will see at the end of this project?

Chemicals play an important role in daily life. Therefore, their safety for Man, other animals and the environment has to be considered carefully. By establishing sufficient toxicological and other safety data in animals, safe handling precautions may be determined thus protecting the health and welfare of hundreds (e.g. for a site limited industrial chemical intermediate with limited potential for human exposure) to millions (e.g. industrial or agricultural product with world-wide market) of humans and animal species which may contact the materials concerned and facilitate the world-wide marketing and safe use of products.

The outputs of this project will support the development and continued use of safe chemicals that do not impact on the reproductive health or well-being of humans. This includes data to inform of the potential risks on development and reproduction that may be induced by either direct or indirect exposure to the chemical.

The expected output from this project will be robust data, in the form of study reports, to enable the safety assessment. Study reports will be included in regulatory submissions to allow regulatory authorities (e.g. OECD, EPA, ECHA) to make judgements on whether to permit the licence of a chemical.

Who or what will benefit from these outputs, and how?

The projects performed under this licence provide safety data to facilitate sound regulatory decisions worldwide that protect the public and the environment from possible hazards. Regulated products have the potential to improve and enhance the health, well-being and quality of life of people and animals.
For example, improved crop-protection increases food security, while development of safer chemicals and chemicals with reduced environmental impact is clearly beneficial for human and animal health and in environmental protection.
How will you look to maximise the outputs of this work?

While much of the substance specific data generated is covered by confidentiality agreements, work on novel biomarkers, refinements in methodologies, protocols and techniques that permit a reduction in the number of animals required for specific study designs or to achieve specific end points are freely shared and discussed at Scientific conferences and other forums (e.g. attendance at regular NC3R meetings).

Although most studies will require the use of concurrent Controls to provide contemporaneous data for direct comparisons (to represent animals undergoing the same regulated procedures, administered the same vehicle, etc), data generated from Control animals is held in reference databases to provide information relating to normal biological variation, thereby enhancing interpretation of study findings.

Species and numbers of animals expected to be used

- Mice: 12,000
- Rats: 17,000
- Rabbits: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is generally accepted that the way in which a material is metabolised and distributed within a living body has a significant effect on how it works and its potential toxicity. Unfortunately, at this time, effects on complex interacting biological systems cannot yet be replicated using *in-vitro* or *ex-vivo* methods (non-animal models). Consequently, the use of animals is still an essential part of safety testing.

All studies performed under this licence will use the least sentient species practicable for achieving the study objectives. The majority of cases will involve the use of rats and mice as required by the regulatory guidelines. In embryo-foetal development studies only, a second mammalian species is required, with the rabbit typically selected and in terms of practicality and availability the rabbit is generally accepted as the preferred non-rodent species, as it is known to be sensitive to a range of toxicants.

Studies conducted under this Licence will allow exposure to mature adults and all stages of development from conception to sexual maturity to inform of potential effects on development and reproductive health.

Typically, what will be done to an animal used in your project?

The studies performed under this licence will use either pregnant or non-pregnant animals. Non pregnant animals are typically used on preliminary studies designed to assess the tolerance of the test material or to establish suitable dose levels for use on main studies which generally assess effects on the foetuses following exposure via the placenta. Animals will be acquired from designated suppliers. In many cases the supplier will provide animals which have been mated at specific timepoints so that the period of gestation is known. In pregnant rats and rabbits dosing will typically start on day 6 of the animal

gestation and continue up to the day before necropsy. Such studies will typically be terminated on day 20 in the rat and day 28 in the rabbit.

All animals will be dosed with the test chemical via a route that would mimic accidental exposure in man, typically in food, water or contact with skin at normally three dose levels and monitored closely for signs of toxicity.

During the course of the study the animals will be well cared for and will be closely monitored for reactions to treatment. Blood and/or urine samples may be collected in order to assess for treatment related effects and/or exposure to the test substance. Other end points will also be included as required to address specific concerns (e.g. functional observation tests).

At the end of the study the animals will typically be euthanised and a necropsy undertaken. This is essential because it is important to establish if the internal organs and or foetuses have been affected in any way and this can only be achieved by examinations by qualified personnel (Foetal Morphologist/Pathologist).

What are the expected impacts and/or adverse effects for the animals during your project?

It is anticipated that some animals will lose weight, or at least fail to gain weight at a rate consistent with normal weight gain. This may be attributed to a reduction in food consumption (also a potential adverse effect) but may be present even with normal food consumption.

Animals will be closely monitored for signs of discomfort and particularly signs of pain. Any animal showing such signs will be closely monitored and will be inspected by a Vet if considered necessary. No animal will be allowed to endure pain for long periods and remedial action which may include euthanasia will always be taken.

Where pregnant animals are used it is anticipated that foetuses exposed to the test material via the placenta may experience clinical reaction that may affect their well-being. Pregnant animals will be carefully monitored throughout gestation for signs that could indicate that pregnancy is being affected: for example, signs of distress or abortion.

Some study designs require assessments on the development and behaviour of the animals. Assessments include the monitoring of activity and behaviour and testing of an animals grip strength, these tests cause minimal discomfort only. All procedures performed on the animals are fully validated and established within the industry to cause the minimum distress and will only be undertaken by trained staff.

On completion of each study the animals will be humanely killed and a post-mortem performed in order to establish effects on organs and tissues which aid the evaluation of the toxicity of the chemicals.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that the majority of animals (circa 65%) will experience no more than Mild discomfort e.g. a small effect on clinical signs, body weight and/or food intake. Other effects are possible, but will be transient and will also fall into the category of Mild severity.

It is feasible that a further 30% of animals will experience effects considered to be of Moderate severity e.g. a more significant effect on weight loss and/or food consumption, as well as other effects such as lethargy and ptosis (half closed eyes).

In rare cases, certainly in less than 5% of all animals used, a more severe reaction to treatment may be experienced. This is typically due to unexpected toxicity in particularly susceptible animals. Animals reaching severe severity will be euthanised without delay in order to prevent further suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is generally accepted that the way in which a material is metabolised and distributed within a living body has a significant effect on how it works and its potential toxicity. In addition, effects on complex interacting biological systems cannot yet be replicated in *in-vitro* or *ex-vivo* tests. Consequently, for the majority of chemicals it is imperative they are tested on living animals in order to assess for toxicity to tissue, organs and systems e.g. the cardiovascular, respiratory and reproductive systems following repeated exposure. It's particularly vital that studies to assess the potential for reproductive and development toxicity are conducted in animals at this time due to the wide range of dynamic and interacting processes that take place throughout the life-cycle.

Which non-animal alternatives did you consider for use in this project?

Sponsors will typically utilise non-animal alternative assays as part of the development programme for a substance (e.g. *in silico* modelling and *in vitro* metabolism studies). Such assessments would not be conducted under this project, however, where available, these data would be used to guide the selection of the most appropriate species and to confirm the *in vivo* study design (e.g. to confirm the species which show similar patterns of metabolism to those expected in man).

Whilst information from these alternative assays will contribute to the overall safety assessment, they cannot replace the need for *in vivo* studies at this time.

Why were they not suitable?
The use of alternative methods, including the use of dead animals cannot, at this time generate relevant data which supports the submission of safety data to international regulators; this is particularly so for studies into the effects on pregnancy and development whereby there are a vast range of molecular processes that interact and could be affected. The fundamental aspects of the safety data we require involves assessing physiological,

behavioural and biochemical effects following the administration of a test substance and this can only be achieved by using live animals.

Alternative methods such as *in-vitro* techniques will be used as much as practicable to supplement the work involving protected animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The establishment maintains detailed records pertaining to the numbers of animals used on projects each year, as well as the number of study types undertaken. By analysing annual trends and having knowledge of industry requirements, it is possible to project the number of study types we will undertake during the life of this licence, thus enabling the estimation of the number of animals required. In addition, a new building will be in use which has increased the capacity for rodent work by approximately 30 %.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The minimum number of animals will be used, recognising the fact that reduction is not achieved by using too few animals to achieve the objectives of the study. For Regulatory studies, guidelines require the number of groups and animals per group to be adequate to clearly demonstrate the presence or absence of an effect of the test substance; core study designs are based on international guidelines where these exist. Otherwise, reference is made to internal guidance on study designs to provide the optimum number, balancing the need to achieve study objectives while avoiding excessive animal use. Project specific variations are used as required. The core study designs have been used extensively under the previous project licence and in other facilities and we have a track record of successful submissions and ability to eliminate unsuitable compounds. They are generally in line with those used throughout the industry.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Statistical input is sought, where appropriate, to strengthen the overall scientific quality and relevance of the studies to be performed, with power-sample size calculations performed for specific studies if necessary to determine group size. For preliminary studies, small groups are acceptable because of the potential use of overt toxicological endpoints. Where group sizes are sufficient data from definitive toxicity studies are analysed statistically.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The studies conducted under this project will typically use rats and rabbits, with mice also included where considered biologically relevant; these species are specifically requested by regulatory authorities due to their ability to identify possible reproductive and developmental toxicants, their good fertility, as well as due to the large amount of background data that has been accumulated.

It is generally desirable to use the same species and strain as in other toxicological studies. Reasons for using rats as the predominant rodent species are practicality, comparability with other results obtained in this species and the large amount of background knowledge accumulated. In the majority of cases outbred rodents and the New Zealand White Rabbit will be used as these strains have good fertility and provide sufficient foetuses/litter sizes for the assessment of test item-related findings.

In embryo-foetal toxicity studies only, a second mammalian species traditionally has been required; the rabbit being the preferred choice as a non-rodent species. Reasons for using rabbits in embryo-foetal toxicity studies include the extensive background knowledge that has accumulated, as well as availability and practicality. Where the rabbit is unsuitable, for example they do not show exposure, a second rodent species, for example the mouse may be acceptable and should be considered on a case by case basis.

Regulatory authorities require characterisation of toxicity at the Maximum Tolerated Dose (MTD) to ensure robust evaluation of safety before potential human exposure; it is, therefore, necessary to perform toxicity studies at high doses that produce overt toxicity, usually in terms of clinical signs or body weight loss or depression of weight gain against age-matched controls. Response to observed effects will depend on the objective of the study; on preliminary studies where the objective is to determine the MTD then doses will be increased until effects are evident; once clinical signs or extent of weight loss indicates that a dose is unsuitable for use on a definitive study then action would be taken to alleviate the clinical signs, usually this would involve termination of the sex/group or may involve reduction of the dose.

Definitive studies should also show evidence of toxicity and typically clinical signs or reduced body weight gain would be seen in the high dose animals following dosing: some clinical signs may be present for up to 8 hours after dosing but would be expected to show clear signs of recovery at this time. Generally clinical signs would be expected to be absent prior to dosing on the subsequent day although some animals may still show some moderate clinical signs. Clinical signs will generally be expected to be up to moderate in severity. However, because toxicity can become worse with increased duration of dosing or the exposure of animals to the test substance may increase over time, sometimes high dose animals and occasionally lower dose animals may show significant adverse effects and in this case action will be taken to alleviate the clinical signs such as withdrawal of the animal from dose, reducing the dose (if appropriate) or termination. In some cases, effects seen on definitive studies can differ from those seen on preliminary studies for no apparent reason. A single clinical sign is generally unlikely to be sufficient to warrant termination unless the presentation is severe and the combined effects of multiple signs will always be assessed for cumulative harm to the animal.

Preliminary studies when performed will allow the delimitation of appropriate intervention and humane end points. Definitive studies will be performed within a moderate severity limit, as the use of humane endpoints, careful monitoring and rapid response to observed effects will negate the need for a severe limit.

Where little is known about a substance, or a class of substances, before commencing preliminary studies consideration will be given to using staggered starts where the effects in one group are assessed before commencement of dosing groups at higher doses. In all cases, dose selection will be based on all available information, data from preliminary studies or in some cases, and data from published literature.

The methods (procedures) used will be validated, well established and commonly used within the research community. The administration of test substance, removal of blood, collection of urine for example will cause no more than transient discomfort or distress. Any signs of distress will be carefully monitored including the onset and severity of treatment related effects. Appropriate and swift action will be taken to avoid any undue pain or distress.

Why can’t you use animals that are less sentient?

The studies performed under the authority of this licence are primarily to assess the toxicity of materials when exposed to foetuses, as well as the parental animals. The use of immature life stages or species that are less sentient than these would not allow us to achieve the objectives of our studies.

Similarly, the duration of the studies which, in the case of multi-generation studies may be several months and studies often requiring behavioural assessments do not allow them to be performed under general anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures required will be undertaken by competent staff, each having undergone extensive training. Where necessary, current, industry accepted techniques for dosing and blood sampling for example, will continue to be refined under separate authority i.e. under another project licence, thus ensuring existing methods remain the most appropriate for minimising pain, suffering and distress to the animals.

Animals will be monitored immediately after undergoing a procedure for any signs of adverse effects and will continue to be monitored at appropriate intervals until it is deemed that further observations are not required.

Animals will be habituated to procedures whenever considered necessary i.e. when it is deemed that by habituating animals to a procedure distress will be reduced. Similarly, where appropriate animals may be trained to perform certain tasks thereby, minimising distress by removing the need to restrain an animal or involve direct contact during its performance.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The volumes administered to the animals and the volumes of blood taken will be in compliance with industry accepted guidelines. The primary guideline used is:

"A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes"; Karl-Heinz Diehl, Journal of Applied Toxicology J.Appl. Toxicol. 21 15-23 (2001).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Staff maintain a proactive attitude towards the 3R's. Several members of staff are already participants in Industry Forums which discuss the 3R's in some detail and report any advancements to relevant persons. These advancements will be discussed further and implemented into our standard practices, where appropriate. The company is an established leader in the development and application of the 3Rs in toxicology studies.

103. Disease-modifying therapy for amyloidosis

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

amyloidosis, monoclonal antibodies, immunotherapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop effective treatments for amyloidosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiac amyloidosis is a progressive and ultimately fatal disease that is now known to be much more common than previously thought. Promising treatments are in clinical development, but their mode of action is to inhibit amyloid deposition and disease progression. They are not expected to reverse organ damage, which is usually very advanced at the time of diagnosis. The treatments we will work to develop have the potential to remove existing amyloid deposits and restore organ function, thereby preserving and improving quality of life.

What outputs do you think you will see at the end of this project?

We expect to have identified monoclonal antibodies and immunotherapy treatments which can elicit amyloid clearance, as candidate medicines for the treatment of human amyloidosis.
We expect to have evaluated the potential of anti-amyloid antibodies for diagnosis and monitoring of amyloidosis.

We expect to have applied for one or more patents.

We expect to publish our findings in the scientific literature.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries will be the pharmaceutical industry, the academic community and, through engagement activities, amyloidosis patients.

The intended long-term beneficiaries of these outputs will be amyloidosis patients and their families, the pharmaceutical industry and healthcare providers.

How will you look to maximise the outputs of this work?

Patent protection will be sought, as appropriate, to maximise the likelihood of successful development of therapies and imaging reagents.

Commercial collaboration(s) will be established for clinical development of treatments and diagnostic reagents. Findings will be made available to other scientists through publication in open-access journals and presentations at scientific conferences and meetings.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used because it is possible to model human amyloidosis accurately, and because of the wealth of knowledge, genetic resources and reagents that enable successful use of mice. Adult mice will be used by necessity because the disease takes months to develop in mice.

Typically, what will be done to an animal used in your project?

Genetically altered mice will be bred and adults will typically receive an injection, into a vein. After allowing time for accumulation of amyloid (typically one month to six months), antibodies will be injected into the abdomen (typically twice or three times) to elicit resorption of the amyloid, and the mice will be killed (typically within one month of antibody injection) for evaluation of the response.

Some mice will receive larger numbers of antibody injections. Small blood samples (up to six) will be collected from some mice.

What are the expected impacts and/or adverse effects for the animals during your project?

The genetically altered mice are, on average, smaller than their wild-type littermates; this difference is benign. Most of the mice used for experiments will have amyloid deposits, but in smaller amounts than are typical for symptomatic clinical amyloidosis. For most animals, the impacts are expected (at worst) to be the minor and transient discomfort caused by injections and blood sampling. A minority of the mice used will be subject to repeated injections and/or blood sampling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold: 65%; Mild: 15%; Moderate: 20%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development, evolution and resolution of pathology causing clinical diseases in living organisms are extremely complex. Although increasingly sophisticated in vitro and in silico models are being developed, none individually or in combination are capable of adequately modelling the enormous complexity of the in vivo situation.

Which non-animal alternatives did you consider for use in this project?

Our overall plan of work includes appropriate in vitro studies, but for the questions we will address in this project, there are no suitable in vitro or in silico alternatives. There is no alternative to use of living animals to achieve the level of knowledge and understanding of these processes which is necessary for the new approaches to treatment which we are developing to be taken into clinical testing in humans.

Why were they not suitable?

see above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use only the standard experimental protocols with which we have extensive experience that we have established to provide robust, statistically rigorous results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experimental protocols are based on our decades of experience with relevant experimental models, which will guide experimental design so that the minimum appropriate numbers of animals are used. Experimental design will be informed by power calculations, to ensure statistically and biologically significant results.

We have lately developed a new highly reproducible animal model which resembles the human disease much more closely than previous models. These features reduce the numbers of animals required to give robust and valid outcomes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will manage our colonies of genetically altered mice to match as closely as possible the requirements for experiments, while ensuring the security of the colonies.

Where compatible with the primary purposes of experiments, additional samples will be collected for use in other studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project we will use a newly developed transgenic mouse model of cardiac amyloidosis closely resembling the human disease. We will only use simple non-surgical techniques, thus greatly reducing potential pain, suffering, distress or lasting harm to the animals.

Why can’t you use animals that are less sentient?

The newly developed mouse cardiac amyloidosis model is the only one that exist in mammals. There are no relevant models of amyloidosis in other types of animals. In order to achieve our goal of modelling the treatment of the human disease with new drugs, there is currently no suitable alternative to the use of live mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The welfare costs will be taken into account at the experimental design stage. The least harmful procedures appropriate will be used. Monitoring for any adverse effects, including pain, will be the highest priority, although the procedures do not cause more than minimal discomfort, for which pain relief medication has not previously been required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The guidelines issued by LASA and NC3Rs will followed as closely as possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult NC3Rs resources (website, publications, etc.), engage with our local NC3Rs Regional Programme Manager, maintain a dialogue with the NACWO and other staff who support animal research within the University, and we will stay up to date with the literature in the amyloidosis field. Advances in the 3Rs that may be relevant to the present programme will be implemented if they do not interfere with validity of experiments.

104. Drug and immunity studies

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

leishmaniasis, cancer, drug, vaccine, phototherapy

Animal types	Life stages
Mice	adult
Rats	adult
Hamsters (Syrian) (Mesocricetus auratus)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project is to identify novel treatments for leishmaniasis and cancer, develop novel delivery systems to improve drug, targeting with the focus being on non-invasive routes of administration, and develop vaccine candidates for leishmaniasis. These two models allow the effect of changing the drug/vaccine formulation on delivery in different sites in the body to be studied.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many diseases or conditions require multiple treatments using a variety of drugs as the condition does not respond well to the clinically used drug/drugs. One way to improve treatment is to target the drug to the site of infection/condition so that a higher drug dose can be used locally. Targeting can be achieved by using a drug delivery system to deliver a drug to the local area, and minimising any adverse effects on healthy cells/tissues. In this project different conditions, namely leishmaniasis and cancer, are used as they are clinically important and they occur at different sites in the body. This allows targeting of drugs to different areas of the body to be studied and extends the findings of this project to other conditions. Leishmaniasis is an important neglected disease which is caused by infection with the protozoan parasite, *Leishmania*. It is transmitted by the sandfly vector and the World Health Organisation estimates that there are more than 1 billion people living in areas endemic for leishmaniasis are at risk of infection. An estimated 30,000 new cases of visceral leishmaniasis and more than 1 million new cases of cutaneous leishmaniasis occur each year. Visceral leishmaniasis is associated with an enlargement of the spleen and liver and it often associated with fever, weight loss and anaemia. It is fatal if untreated. Cutaneous leishmaniasis results in skin lesions which can be single or multiple and often occur at the site where the sandfly feeds. These lesions can become infected with bacteria and cause dry or wet sores. The lesions are generally not life threatening but they can cause scarring and disfigurement which can cause social stigmatism and affect a person's mental health and well-being. In this project model of visceral leishmaniasis caused by infection with *Leishmania donovani* or *L. infantum* and cutaneous leishmaniasis caused by infection with *L. major*, *L. mexicana* or *L. amazonensis* may be used. This allows delivery to cutaneous sites and the spleen, liver and bone marrow (visceral leishmaniasis) to be studied. There is no clinical vaccine to prevent leishmaniasis or many type of cancers, therefore another component of this project is to investigate the ability of novel vaccines given alone or with different immune stimulators (substances that enhance the immunity) to prevent infection. Different types of cancer may be used but the primary focus will be on using a murine model of lung cancer. This allows delivery to the lungs using different routes of administration to be studied with the primary focus being on non-invasive therapies. Cancer is a major health problem and there were an estimated 19.3 million new cancer cases and almost 10.0 million cancer deaths occurred in 2020. Infections often modulate the host's immune response to enhance the survival of the pathogen or to allow the condition to progress in an individual. Therefore, the effect of treatment on host immune responses will be studied to give insights into what how host immunity is affected by cancer or leishmaniasis and to determine if it is possible to identify immunological markers that can be used predict successful treatment. In this project we will also study the ability of novel light treatment to treat cutaneous leishmaniasis as this may allow patients to self-treat their skin lesions and has the added benefit that it should make it less likely for parasites to develop resistance to this type of therapy as it does not use any drugs.

What outputs do you think you will see at the end of this project?

The primary output will be to publish the findings in high-ranking academic journals and at international conferences. This in turn will support applications for research funding. Work using novel drug candidates can help identify new compounds that have not been considered as anticancer or antileishmanial agents before and highlight these to other researchers. The identification of new drug candidates would be beneficial for both cancer and leishmaniasis. There are a limited number of clinical drugs for leishmaniasis and cancer and the use of the ones available are associated with adverse side effects, use multiple drug doses and their use is associated with the emergence of drug resistance. Achieving antiparasitic/anticancer levels at the site of infection or tumour cells is key to successful treatment and the ability to target the drug/drugs to this site is influenced by

how a drug is administered to a patient. Ideally non-invasive routes should be used as these would be more patient- friendly but this would usually mean packaging a drug in a delivery system. Understanding how the delivery system modifies the delivery of the drug is essential and we now have access to imaging systems that can allow us to track delivery to cancer/parasite cells and study their effect on parasite/tumour burdens in the same animal over time. There is no clinical vaccine recommended for leishmaniasis and identification of a suitable vaccine candidate would not only reduce the risk of people being infected but would also help global initiatives to eradicate the diseases. Leishmaniasis is also a veterinary problem so a vaccine candidate would also prevent infection in animals, particularly dogs. These animals can act as a reservoir of infection for visceral leishmaniasis. Studies completed in this project would also characterise the type of immune response associated with protection by determining antibody and cellular immune responses. This is important to know as it can help identify the type of immune responses that the treatment should induce in humans/animals and give specific markers to show if the treatments cause similar protective immunity in people/other animals. *In vivo* imaging studies from this study would be used to illustrate successful drug/vaccine efficacy and the role of internal processes in therapeutic outcome/susceptibility to disease. This can add to what is known about immune mechanisms and help other researchers understand immunological processes in these two conditions. In this project we will also investigate a novel light therapy for the treatment of cutaneous leishmaniasis. This type of treatment has the potential to remove the need for drug treatment for cutaneous leishmaniasis and could be instrumental in reducing the risk of drug resistance developing in these *Leishmania* species.

Who or what will benefit from these outputs, and how?

As this licence is for 5 years the long-term outputs are a contribution to the body of knowledge in the area.

Short term benefit: information for these studies would provide can be used to identify what effect changing a chemical's structure can have on anticancer or antileishmanial efficacy which can assist in rational design of compounds for other researchers. Novel carrier systems can provide a method to overcome some of the problems faced by other researchers using novel compounds e.g. solubility issues, ability to target to specific tissues in the body. The results from vaccine studies can assist in identifying the type of immune response associated with protective immunity and give important information on the effect of vaccine dose and dosing regimen on host immune responses. Phototherapy gives the opportunity to treat cutaneous lesions using a non-invasive method and can provide a method to combat drug resistant strains, as it will act via a different mechanism compared to current clinical drugs. There should be minimal risk of adverse effects because the wavelength of light we will use is less damaging than other wavelengths.

Midterm benefit: Data from these studies is of commercial interest and we seek patent protection for the intellectual property (IP) generated in studies. This can lead to collaborative studies or a licencing agreement with industrial partner to assist in the development of new anticancer drugs, or use of the delivery system for bespoke purposes, or development of a vaccine for leishmaniasis. The data from these studies will be published in scientific journals and presented at conferences so that the results can be shared with the scientific community. These studies will demonstrate the delivery systems used in studies which can act as platforms for other types of diseases. This would expand the impact of this research. In addition development of a vaccine for leishmaniasis would also develop technology that could be used for other conditions. For example, a production method has to be identified that allows larger scale manufacture of a recombinant protein

vaccine and this could be used for other recombinant protein vaccine. Leishmaniasis requires cell-mediated immunity rather than antibody based immune responses, therefore adjuvants that work in this model may also be suitable for other types of infections e.g. viruses, bacteria.

Long term benefit: The long-term goal of this project is to identify new and better treatments for leishmaniasis and cancer and thus ease the suffering of people who have these conditions, and reduce the mortality caused by these conditions. The results from these studies would not just be limited to cancer and leishmaniasis as the drug delivery systems could be used for other types of drugs.
Therefore, they can also be exploited to produce better formulations for drugs that treat other conditions
e.g. targeting a drug to the liver for liver cancer treatment or to the lungs for treatment of tuberculosis. The studies from this project would also benefit health care providers by reducing the number of patients requiring long term treatment. The ability to treat cutaneous leishmaniasis using light therapy would reduce drug use and stop any one from suffering from the adverse side effects caused by clinically used anti-leishmanial drugs, as all the drug currently used are associated with adverse side effects. A reduction in drug use would reduce the induction of drug resistance in endemic parasite populations and thus extend the clinical life of existing therapeutic drugs.

How will you look to maximise the outputs of this work?

I collaborate with colleagues within the University, in the UK and internationally to promote the research in identifying what immune responses are important in protecting against leishmaniasis, development of novel drug candidates for leishmaniasis and cancer treatment and investigating what factors are important in drug resistance in leishmaniasis. I also collaborate with companies in research projects to develop drug candidates against leishmaniasis and cancer and studying the effect of novel adjuvants on vaccine efficacy. The findings of our studies will be published in peer-reviewed journals for other researchers in the field and we will disseminate our findings through presentations at national and international conferences. Thus there are ample opportunities to share data and results with the international community. We also aim to promote public understanding of immunology, leishmaniasis and cancer via our outreach activities.

Species and numbers of animals expected to be used

- Mice: 1100
- Rats: 300
- Hamsters (Syrian) (Mesocricetus auratus): 550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Mice and hamsters are used as they provide well characterised animal models for *Leishmania* and cancer studies. Adult animals will be used as they have a fully competent immune system. Rats will be used for pharmacokinetic studies as they can provide a larger animal model and a larger blood/tissue sample for assessing drug levels after dosing compared to mice.

Typically, what will be done to an animal used in your project?

The exacts timings used in experiments may vary but an indication of the type of studies completed under this project licence is given below.

In drug studies *Leishmania* infected or animals given cancer and uninfected/normal controls will be treated with a drug formulation or vehicle alone by various routes e.g. intravenously, subcutaneously, orally, topical, intranasal, by inhalation. This may be a single treatment or multiple doses of a drug formulation. The animals will then be killed and the effect of treatment on parasite/cancer burdens determined. Most experiments are completed in 14 days but some experiments may continue up to 10 months so that the effect of treatment in chronic infections can be studied or to show that treated animals do not relapse. Animals may be imaged under general anaesthesia over the course of the experiment to determine burdens in the mice or assess internal processes e.g. recruitment of neutrophils or macrophages to the site of the infection, usually once/week. An imaging session usually last 15-20 mins for an individual animal and they recover within 10 minutes and show no ill signs from the procedure. Blood samples may be taken from animals at different time points.

In vaccine studies mice or hamsters are normally given two doses of a vaccine alone or with an immunostimulant by various routes e.g. subcutaneous injection, orally, intranasal, inhalation, normally with 2-3 weeks between immunisations. Animals are infected with *Leishmania* 2-3 weeks after the last immunisation and then humanely killed 2-4 weeks post-infection. The effect of vaccination on *Leishmania* parasite burdens is then determined. In phototherapy experiments mice with cutaneous leishmaniasis will be treated with light for a set period, normally less than 30 mins, and the effect of treatment compared to control determined. During experiments, animals may be imaged to monitor parasite/tumour burdens over the course of the experiment and to determine the effect of treatment on macrophages or neutrophils recruitment. This is usually once a week over the course of an experiment and an imaging session usually last 15-20 mins for an individual animal and they recover within 10 minutes and show no ill signs from the procedure. Blood samples may be collected at various times during the experiment from mice, usually once a week, to determine specific antibody titres after vaccination.

Hamsters and mice are also used to provide stock *Leishmania* parasites and these studies usually last 4-8 weeks for cutaneous Leishmania species (mice only) and usually 8-12 weeks for visceral leishmaniasis species (hamsters only). Animals are injected with the parasite once and then humanely killed when it is time to harvest the parasites for an experiment or if they show any signs of ill health before then.

In light treatment experiments, animals with cutaneous leishmaniasis are exposed to the light treatment under general anaesthesia so the animals keep still. The temperature of the skin is monitored to ensure that the animals do not get exposed to an amount of light that could damage the skin. The effect of light treatment on parasite burdens may be monitored by imaging the mice or by measuring the lesion size. Most studies would be completed in 3 weeks.

Rats used in pharmacokinetic studies are usually injected once with a drug formulation and then blood and samples collected from the same animal over a 24-hour period, or they may be killed at set times so that tissues can be harvested at different times. The animals usually show no signs of ill health.

What are the expected impacts and/or adverse effects for the animals during your project?

The effect of drug/vaccine treatment on animals will depend on how the drug is administered e.g. injection but it will cause transient pain that lasts a short time. Animals will be humanely killed before they harbour significant tumour burdens as imaging studies allow tumour burdens to be assessed from day 3 post inoculation for lung cancer studies. Most experiments using cancer cells are completed within 14 days. Blood samples will be collected from animals in some experiments to determine antibody levels but this is usually just once/week and will only cause transient, mild discomfort to an animal.

Phototherapy will be carried out under anaesthesia and may cause warming of the foot, but the temperature will be monitored to ensure it cannot cause a burn.

Anaesthesia should have no adverse effect on the well-being of the mice as the sessions are short and the frequency is kept within inhouse guidelines.

An imaging session to determine parasite/cancer burdens or internal processes e.g. recruitment of neutrophils or macrophages is usually last 10-20 mins for an individual animal and they recover within 5-10 minutes and show no sign of ill effects from the procedure. Injection of cancer cells to induce cancer is not associated with any obvious adverse effects on animal health and well-being as the imaging used can detect cancer cells before large or numerous tumours. Most studies only last up to 14 days for control animals. Experimental animals may be kept longer to show that a treatment cures an animal and it does npot relap

Animals with cutaneous leishmaniasis develop skin lesions (nodules), which are normally painless, even when sometimes they ulcerate. Animals will be killed if lesions have a diameter greater than 10 mm or have any sign of a secondary bacterial infection (usually manifested with pruritus and/or pus). Mice infected with visceral leishmaniasis do not normally shown any adverse signs due to infection, even at a year post-infection. Hamsters infected with visceral leishmaniasis will normally be killed at 8- 12 weeks post-infection, before they show adverse effects such as severe wieight loss of weigght gain (fluid retension). Nevertheless, all animals will be closely monitored and culled if they show any signs of ill health (e.g. weight loss, abdominal distension).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In most cases animals may be in the mild severity over the course of an experiment. However, it is not always possible to predict what effect a novel compound, formulation or drug combination has *in vivo*. In some cases *L. donovani* infection can be more severe effects in some hamsters and cause moderate effects, and this may reflect the outbred nature of the hamsters. There is no obvious effect in mice infected with *L. donovani* despite the fact that these animals have hepatosplenomegaly.

The adverse effect for each genetically modified mouse strain will be dependent on the specific genetic modification of the mice but it’s not expected to result in gross phenotypic abnormalities, the animals are expected to reproduce normally and mature to full age as wild type mice. The expected severity is mild (> 95%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Normal naive mice or genetically altered mice with modifications of specific genes or cells of research interest will be used in this study as they help identify what components of the immune response are important in controlling an infection. For example, we have shown that the cytokine interleukin 4 must be present for antimonial drug treatment to be fully effective. Certain strains of mice can be used as a host for *Leishmania* species and provide models of cutaneous and visceral leishmaniasis. For example, BALB/c mice are very susceptible to infection with *L. major, L. mexicana*, *L. amazonensis*, *L. donovani* and *L. infantum.* However Golden Syrian hamsters have to be used instead of mice to provide stock *L. donovani or L. infantum* parasites as mice cannot provide enough parasites. Many researchers use these rodent models as they have similar characteristics to human infections and they have been used in studies to develop clinical drugs e.g. amphotericin B formulations for the treatment of visceral leishmaniasis or in studies to identify vaccine candidates.

Mice will be used in cancer studies as they can be injected with luciferase-expressing cells that initiate a particular type of cancer. For example, mice given B16 F10 cell develop lung cancer and it is possible to monitor the cancer progression by imaging mice.

Rats will be used in pharmacokinetic studies as these animals allow a larger blood and tissue sample to be collected compared to mice.

Mice are the lowest vertebrate group where models of parasitic infection have been developed and refined and give repeatable results of low variability and high quality. The models used in this study have also been refined to reduce suffering to the minimum levels likely to give satisfactory result.

Only adult animals can only be used as the immune system of younger animals is not sufficiently mature to generate appropriate responses.

In all cases animals are required as the effect of treatment on multiple systems is required e.g. cellular and humoral immunity or we need to know the effect of a drug on a particular site and its effects on off target organs.

Which non-animal alternatives did you consider for use in this project?

We always screen any drug compounds *in vitro* before we perform *in vivo* studies so that only compounds with high efficacy and low cytotoxicity are used in *in vivo* studies. We screen the ability of serum from infected animals to recognise our vaccine candidates so that we know they can be recognised as part of a normal immune response and are

antigenic to the host. I have checked relevant databases such as AnimAlt-ZEBET or AltBIB and I have not found any useful alternatives for the intended animal studies.

Why were they not suitable?

At present there is no alternative that mimics the *in vivo* pharmacokinetics, the effect of other cells or cellular products on drug stability or site-specific activity as effectively as *in vivo* studies. The efficacy of a vaccine candidate depends on it being taken up by antigen presenting cells and the presentation of the antigen determinants to specific B and T cells within the body. Current immunological knowledge cannot predict exactly where this will take place and the influence other cell types, or what effect the infecting organism at challenge will have on the final immune response.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals will be used in each protocol below are based on current usage and potential research interests through collaborations.

Protocol 1: Identify parameters important in drug delivery. Hamsters 100, Mice 200, Rats 300 Protocol 2: Efficacy and immunological studies. Hamsters 300, Mice 800,
Protocol 3: Stock infections, Hamsters 150, Mice, 100

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This project licence will continue the studies from my current project licence PF669CAE8 and continues on from studies undertaken in project licences PPL60/3525, PPL60/3740, PPL 60/4252, and PPL 60/4334. Data from these studies gives data on drugs and their doses and will be used to design similar experiments. In addition to detecting significant differences between treatments at 80% statistical power and a 5% significance test level then a minimum of 6 animals/group are required if lung cancer is induced using B16 F10 cells, and previous experience has shown that we need a minimum or 4 animals/group in *Leishmania* studies. However in new studies using different study design online tools such as the NC3R's Experimental Design Assistant will also be used in designing studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies using 3 mice/hamsters will be used when testing out a new entity e.g. drug compound/adjuvant where there is no available data on its *in vivo* safety. Animals used in this project are from commercial, approved or in-house breeding colonies as breeding animals are not part of this project licence. Sharing tissue from animals is routinely used e.g. to obtain bone marrow derived macrophages. I have developed novel luciferase-expressing *L. donovani* strains i.e. paromomycin resistant cell lines, miltefosine resistant

cell lines and antimony resistant cell lines. These are used to test novel drugs/drug formulations in *in vitro* drug screening studies. Unfortunately, these parasites have lost some of their infectivity and can only be used for short term experiments (approximately 14 days). Studies are still ongoing to try and increase their infectivity as they would be a very useful for *in vivo* studies and allow more data to be obtained in studies e.g. tracking parasite burdens over time in vaccinated mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In *Leishmania* studies both wild-type and luciferase-expressing parasites will be used. Luciferase- expressing parasites allow parasite burdens to be monitored in the same animal over time and this model results in lower parasite burdens in *L. donovani* compared to infection with wild-type parasites, so it is a less severe model as parasites can be detected much earlier post-infection. For example, in cutaneous *Leishmania* studies and cancer studies using luciferase-expressing cell lines it is possible to detect cells by day 3 post-inoculation so that it is possible to use a less severe model for screening drug compounds. Conventional methods would not allow lesions in the footpad to be detected until day 14 post-infection. This model also allows more data to be collected from animals as conventional methods only allow burdens to be determined by using callipers to monitor tumour size or lesion size (*Leishmania*) weekly.

Animals given cancer will be kept in barrier conditions so that any chance of acquiring airborne infections is minimised.

Animals will be housed in cages that have their environment enriched with houses and nesting material. Where possible animals are housed in groups so that animals are not housed alone but this is not possible if animals have to be separated due to fighting.

Why can’t you use animals that are less sentient?

Adult animals have to be used in studies because they have a fully mature immune system. *Leishmania* will only develop in certain animals and mice and hamsters are the two recognised models for this species. The cancer lines used in studies have been commercially developed for use in mice and the B16 F10 cell line homes to the lungs so that site-specific drug delivery can be studied.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Most drug studies last 2 weeks and vaccine experiments are usually terminated 14-21 days after infection. Stock infections for cutaneous leishmaniasis are terminated before lesions reach a set size. Stock hamster experiments usually run for a maximum of 8 weeks

and they are terminated early if the hamsters show clinical signs. All experiments will be kept to the minimum length needed for the experiment to acquire the necessary data.

We use an improved administration protocol (e.g. preparing the injection site and needles, prior to administration of substances, carefully avoiding the leakage of injection reagents).

The use of *in vivo* imaging systems (IVIS) will allow us to determine disease onset at earlier time points and thus terminate procedures before the disease reaches a severe stage.

In cutaneous leishmaniasis studies we use footpad infections with luciferase-expressing parasites instead of rump injections as we can detect infections much earlier, probably because the parasites are in a small concentrated area. These parasites do not grow well in the rump so these parasites must be injected into the footpad to survive. I suspect the inserted gene makes these parasite less able to grow in the skin.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance from the NC3Rs of animals in research, LASA good practise guidelines, and advice from RSPCA for laboratory animals, and in-house guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I currently receive the NCR's newsletter about new developments and I will learn advances in the 3Rs through various opportunities such as the University annual 3Rs symposium.

105. Cancer development, growth, detection and treatment

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Angiogenesis, Metastasis, Translation

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Most solid cancer related deaths are a result of resistance to therapy and metastasis. Identifying patients who have a high risk of progression and determining alternative strategies to treat them is required. Exploring the molecular mechanisms that promote resistance and metastasis at different stages of the disease may provide the best potential targets for therapeutic intervention.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This research will inform us better about human cancer and how to detect and treat it efficiently, and, in the future, allow us to test potential new treatments. In recent years it has been established that cancers that develop in different organs, behave differently thus requiring individual treatment strategies. By understanding the cellular and molecular mechanisms that drive tumour growth and metastasis in different cancer types we can identify new strategies to treat cancer and prevent millions of deaths each year.

What outputs do you think you will see at the end of this project?

Our proposed studies are directly relevant to improving our understanding of the mechanisms of cancer progression, resistance to therapy and metastasis, possibly indicating improved identification of patients with increased risk of progression. These studies should also result in the publication of peer reviewed papers in high impact journals.

Who or what will benefit from these outputs, and how?

By making target discoveries in human cancers and testing these in mouse models of cancer, our research will have clinical relevance.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work, we have continued support of postdoctoral fellows and the technical expertise required for the research. Importantly, this research has been built around a team of internationally recognised co-investigators and collaborators who have helped design the research and will provide clinical, scientific and technical expertise to support its success.

Species and numbers of animals expected to be used

- Mice: 32,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Tumour growth and spread is a complex process involving several cell types and different cellular interactions. This complexity cannot be recapitulated in any *in vitro* system or lower organismal system such as flies or fish, hence the need to use mice for this research. Although it is possible to use lower organismal system such as flies or fish to study cancer, the mouse has many similarities to humans regarding anatomy, physiology and genetics which is lacking in flies and fish. Around 90% of the genes in mice are the same as in humans, making them the ideal model for studying cancer and its spread. Mice are also better for studying complex biological systems found in humans such as the immune system, playing an important role in fighting cancer, which is more primitive in fish and flies. The majority of experimental mice will be used between 3-6 months old. This is because prior to 3 months, mice are continually growing rapidly, but this stops at around 3 months. After 6 months of age the maturation rate of mice is 25 times faster than humans. Therefore between 3 and 6 months, the mouse is considered to be mature and not yet

aged. After 6 months, cell senescence and other age-related issues may affect our biological readouts.

Typically, what will be done to an animal used in your project?

A typical experiment follows the described steps below :

Injection of tumour cells and/or injection of chemical to induce deletion of candidate genes. This may include surgical procedures for injection of tumour cells directly into the organ of interest.

Monitor tumour growth using manual measurements (Caliper) or minimally invasive imaging such as Magnetic Resonance Imaging (MRI).

Administration of chemotherapy drug (injection) or radiotherapy.

Monitor tumour growth using calipers or minimally invasive imaging until tumours reach reach humane endpoint established in this license or mouse shows signs of clinical sickness.

Examine primary tumour growth and metastasis to distant organs.

Depending on the mouse model, experiments can last for between 2 weeks - 4 months

The number of procedures varies from 1 to 30 (e.g. for minimally invasive dosing of therapeutic treatments), depending on the experimental design.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects are unavoidable but are not expected to be severe. Adverse effects due to surgical and genetic interventions that are necessary to achieve the objectives, and adverse effects associated with tumour growth in our untreated control animals, will be minimised using a careful and considered monitoring approach, particularly where the animal begins to show any signs of disease.

Possible adverse effects may include weight loss, digestive impairments, pain after surgery, or abdominal pain linked to pancreatic tumour growth or early ulcerations of subcutaneous tumours. The duration of these effects will be minimised by close monitoring of the animals and setting up clear humane endpoint to avoid any progression beyond temporary moderate severity. . Any animal showing any of the above symptoms/signs, although likely to occur very rarely in well-designed experimental studies will be killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the severities will be mild to moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tumour growth and spread is a complex process involving several cell types and different cellular interactions. This complexity cannot be recapitulated in any in vitro system. Although it is possible to use lower organismal system such as flies or fish to study cancer, the mouse has many similarities to humans regarding anatomy, physiology and genetics which is lacking in flies and fish. Around 90% of the genes in mice are the same as in humans, making them the ideal model for studying cancer and its spread. Mice are also better for studying complex biological systems found in humans such as the immune system, which plays an important role in fighting cancer, which is more primitive in fish and flies.

Our research group has a very strong history using animals in cancer research, so our choice of mice is the simplest mammal that through years of research by ourselves and others provides us with confidence that our experimental designs are likely to be as close to our therapeutic goals as possible. This will allow us to achieve a successful project, described in ths application.

Which non-animal alternatives did you consider for use in this project?

Although we cannot use non-animal alternatives to study tumour growth and metastasis, at all stages throughout the project simplified models for cell growth in culture, culture of an organ collected from an animal assays or assays where tissue is removed from the animal to examine blood vessel growth in culture will be used. We will also utilise established cell lines and primary cells. These will help to identify the molecular mechanisms that underlie the in vivo characteristics of cancer growth and spread. Additionally, we have access to human tissue banks to obtain human tissue to examine cellular responses during tumour growth. This will help to clarify the relevance or our results to human physiology and pathology.

Furthermore, to avoid duplication of in vivo work we will consult both the IMPC (International Mouse Phenotyping Consortium) and KOMP2(Knockout Mouse Program) prior to undertaking any in vivo studies.

Why were they not suitable?

Non-animal alternatives are not wholly suitable because tumour growth and spread is a complex physiological process involving several cell types, complex interactions between different cell types and de-regulation of hundreds of molecules. Furthermore, tumour growth is a dynamic process which changes as the tumours grow larger.Therefore, this complexity cannot be recapitulated in any in vitro system. Although it is possible to use lower organismal system such as flies or fish to study cancer, the mouse has many similarities to humans regarding anatomy, physiology and genetics which is lacking in flies and fish. Around 90% of the genes in mice are the same as in humans, making them the ideal model for studying cancer and its spread. Mice are also better for studying complex

biological systems found in humans such as the immune system, which plays an important role in fighting cancer, which is more primitive in fish and flies. Thus the utilisation of mice for in vivo experiments is essential to our proposal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Sample size calculations will be performed before each experiment so that experiments are adequately powered statistically, in consultation with our in-house statistician, Dr Adam Brentall. Many of these are already done for the experiments planned in this proposal. Using the appropriate numbers of animals is essential to answer reliably the questions we are addressing. This ultimately avoids wasting animals and repeating experiments unnecessarily. To further limit animal wastage we will utilise the optimum breeding strategy to minimise over-production of animals as well as only breeding the numbers of mice required to produce the correct numbers of animals needed for our experiments. We have a dedicated named colony manager who oversees our colony management.

We will share our animals/tissue resources with other research groups within the Institute to maximise outputs. We will also maximise the amount of information we obtain from each animal by harvesting all tissues.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experimental protocols will include the following:

clear aim

detailed description of the experiment including treatment regimes, experimental groups and experimental material to be collected and endpoints

outline of the method of analysis of the results

blinding and randomisation of experimental groups will be used to avoid bias

Imaging technologies will be a vital tool in reducing the number of animals required for each experiment as this removes the need to kill animals at time points to observe tumour progression.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All experiments will be carried out following good laboratory practice. All experiments will be designed after careful examination of the literature, with regards to treatment ie. drug dosage, treatment regime. Pilot studies will also be performed to help refine our

experiments and determine the variables that can impact upon experimental results and the sample sizes required to accurately determine statistical significance. We will also use PREPARE guidelines when planning experiments (https://norecopa.no/media/7832/prepare-guidelines.pdf).

When reporting on *in vivo* experiments for publication we will conform to the ARRIVE guidelines to minimise unnecessary studies.

We will archive genetically modified mouse lines as frozen sperm or embryos to reduce the number of living mice we have to maintain and to allow sharing of these lines between researchers, providing further opportunity for reduction.

Imaging technologies will be a vital tool in reducing the number of animals required for each experiment as this removes the need to kill animals at time points to observe tumour progression.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically Modified Mice (GEMM) will be used. Some of these mice will naturally develop cancers of interest (including pancreas, breast and lung) so that we can investigate the biology of the developing disease and test our treatments in a model that most closely matches human diseases. For most models the mice do not develop any pain or discomfort as a consequence of their developing cancers and we terminate the animals before such discomfort occurs due to tumour size. MRI monitoring of deep tissue tumours provides confidence we can deliver this intention.

Mice injected with transplanted tumour cells/tissues will also be used: Cells or tissues derived from mouse or human tumours will be injected or implanted into mice via various routes including subcutaneously (sc), intravenously (iv) (to examine metastasis), intraductal into the mammary fat pad, as required by the scientific question. Injections will be carried out by experienced handlers thus minimising pain and discomfort to mice. Mice will require anesthesia and surgery for orthotopic injections and implantation of organoids and will receive analgesia post-op to minimise discomfort. In some cases genetically manipulated cells that contain bioluminescence or fluorescence will be used so we can accurately monitor tumour development and response to therapy using non-invasive methods so as to minimise pain and harm to animals.

All experimental mice are routinely examined for their health status and any behaviours or appearances that suggest pain or discomfort will be monitored closely with the personal licencees, the local BSU staff and as required, the NACWO and NVS.

Why can’t you use animals that are less sentient?

Most of our experiments require that tumours will develop over a time period. Tumour growth requires the complex interaction between different cell types that cannot be recapitulated in less sentient animals. Because of this, it is also not possible to use animals that are kept for a long term under terminal anaesthesia. We also need to closely reflect as much as possible the biological processes in humans that we are trying to investigate, which can be best mimicked in mice. Use of non-mammalian models (drosophila, xenopus, zebrafish) would not recapitulate the biology that occurs in humans. Our choice of mice is the simplest mammal that through years of research by ourselves and others provides us with confidence that our experimental designs are likely to be as close to our therapeutic goals as possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Imaging technologies, such as MRI, are a vital tool in refining the number of animals required for each experiment as this removes the need to kill animals at time points to observe tumour progression. It also allows us to recruit mice that have a similar tumour volume at the start of an experiment.

We already are successfully implementing MRI and other imaging methods (high resolution ultrasound) at our Cancer Institute to improve the analysis and monitoring of deep tissue cancers that occur either through orthotopic tumour growth in transgenic mice. Such imaging techniques have the immediate benefit that there is limited chance that an animal develops an internal tumour that exceeds home office limits. This has also improved how we apply experimental therapeutics as we can now 'recruit' mice that have similar volume tumours at Day 1 of a protocol, instead of starting therapy on a cohort at a predetermined time interval after injection. This also allows longitudinal studies that formally required cohorts of mice to be killed at intervals, thus saving many mice.

By internal talks and eventual publication we are sharing these improvements with our local and wider scientific community.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines outlined in the manuscript "Guidelines for the welfare and use of animals in cancer research" Workman et al; 2010. We also follow the ARRIVE guidelines (https://arriveguidelines.org/arrive-guidelines), PREPARE guidelines (https://norecopa.no/media/7832/prepare-guidelines.pdf) and UKRI guidelines (https://www.ukri.org/about-us/policies-standards-and-data/good-research-resource-hub/use-of- animals-in-research/).

We will take advantage of the free Experimental Design Tool (https://eda.nc3rs.org.uk) when designing animal experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will have regular discussions with the NVS, NACWO, NIO, the AWERB and animal technicians regarding our current practices and whether we need to review these. We will follow all the guidelines from the following;

https://www.ukri.org/about-us/policies-standards-and-data/good-research-resource-hub/use-of- animals-in-research/

https://www.cancerresearchuk.org/about-us/we-develop-policy/our-policy-on-supporting-science/the- use-of-animals-in-cancer-research

We will also make use of NC3R webinars, events and workshops as and when necessary.

106. Breeding, maintenance and supply of Genetically altered and harmful mutant rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo
Rats	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to breed and maintain high health status rats and mice with genetic alterations and harmful mutations and to supply them for research into the control of disease, ill health or abnormality and/or the study of normal and abnormal physiology, biology or behaviour. They will be used for the discovery and development of new medicines for the treatment and prevention of human disease.

Potential benefits likely to derive from the project, for example how science might be

advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The use of GAA has grown worldwide over the years, not only have new lines been created but also as new uses are being discovered for existing lines.

Similarly, many of these lines are of interest to many different research groups and to have a single source with the ability to distribute to worldwide locations reducing the number of breeding colonies required, in turn reducing the numbers of animals produced and minimising waste.

Many establishments do not have the facilities, equipment or expertise to import, breed or maintain GA colonies which results in the continued international transportation of large experimental groups. Where appropriate the provision of importation, animal facility space and colony management/breeding services may improve animal welfare by removing the need to regularly transport large numbers of animals over considerable distances.

The maintenance of high health status animals also ensures that high quality animals are produced, improving the quality of experimental data and scientific results and reducing the number of animals required. In having the ability to re-derive lines we aim to improve animal welfare standards and breeding efficiency by removing contaminants that are detrimental to research, animal facilities and breeding performance and maintain an availability of high health status animals removing the necessity to breed lower health status animals elsewhere. As the project is for the provision of services and supply of genetically altered and harmful mutant rodents, we do not benefit from the scientific work undertaken on the animals bred or distributed.

What outputs do you think you will see at the end of this project?

The supply of our genetically altered rodents has already contributed to the development in vaccines for dengue fever more recently there has been a need to study the aetiology of the Zika virus, and our strains of mice have fitted this market well. It is clear that IFN-α/β plays a significant role in preventing viral replication and protecting against Zika virus disease.

The continuation is supply would further assist in scientific insight underpinned by this project and will lead to a greater understanding of these viruses ,research publications and advances in the prevention of viral diseases of man.

Who or what will benefit from these outputs, and how?

The Supply of transgenic mice will continue help enhance knowledge in developing vaccines for areas of research such as dengue fever and Zika virus, our transgenic mice are also continual uses within virology, oncology, cardiovascular and pulmonary diseases, inflammatory and immunological diseases and neuropsychiatric disorders will aid in the discovery and development of new medicines for the treatment and prevention of human disease.

How will you look to maximise the outputs of this work?

The purpose of maintaining a breeding colony is to supply a range of customers around UK and the rest of the world, who are working on various research involving our specific GAA rodent strains. We will collaborate on a supplier level and gain insight into future demand, along with continued forecasting updates to allow for the continued supply.

Species and numbers of animals expected to be used

- Mice: 125000
- Rats: 50000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Genetically altered rodents are currently in widespread use in biological, medical and veterinary science and have shown to be of great value in interpreting the function of genes and pathways in a wide variety of biological, physiological and pathological processes.

To supply genetically altered rodents, the chosen life stages for the breeding and maintenance by means of conventional breeding methods are required to enable us to continue and add value in these areas.

Typically, what will be done to an animal used in your project?

Animals bred and maintained on this project will be used for continued use in breeding programmes by conventional methods and supply of stock animals, for scientific use or distributed for use on other project licences within the UK or in bona fide research establishments outside of the UK.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals produced for this project license are not expected to exhibit any harmful phenotype, and thus are not expected to exhibit pain, weight loss, tumours, or abnormal behaviour.

Any animals exhibiting any unexpected harmful phenotypes will be killed in by an appropriate method accordance to Schedule 1 of the A(SP)A.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The likely/expected level of severity for breeding and maintaining the colony will be mild.

Retired breeding stock and any animals exhibiting any unexpected harmful phenotypes will

be killed in by an appropriate method accordance to Schedule 1 of the A(SP)A.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Use of live animals is required for breeding purposes and as embryo donors and recipients.

Which non-animal alternatives did you consider for use in this project?

Cryopreservation and the archiving of embryos will remove the need to maintain live colonies.

Why were they not suitable?

Live Animals are required for continued use in breeding programmes and the supply of live mice to establishments within the UK and worldwide who do not have the facilities, equipment or expertise to import,breed or maintain GA colonies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experience of supplying Genetically altered rodents under previous Breeding, maintenance and supply of Genetically altered and harmful mutant rodents project licences, has given insight into future demand, this along with continued forecasting updates will allow breeding programmes be maintained to optimise breeding levels in order to reduce numbers of animals produced and minimise wastage.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Long standing experience and the use of proven protocols for the supply Genetically altered rodents under previous project licenses, has given insight into optimal numbers required to maintain colonies and ensure minimal requirements.

What measures, apart from good experimental design, will you use to optimise the

number of animals you plan to use in your project?

Breeding programmes will aim to optimise breeding performance in order to reduce numbers of animals produced and minimise wastage.

Production data relating to animal breeding performance will be collected and analysed on a regular basis to determine production targets, assess customer demand and to monitor and reduce any wastage.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered mice will be used for the breeding, maintenance and supply to bona fide customer establishments. Standard protocols, methods and reagents have been optimised for this species and there are acknowledged benefits from their use. Rats are less commonly used but their larger size may make them a more suitable model if surgical interventions are required or historical/background data is predominantly in this species.

All animals will be regularly observed for signs of ill health or distress, with the appropriate action being taken as required. Records will be maintained of all strains held detailing their husbandry requirements and data will be collected on the clinical, behavioural and welfare effects of the transgene in these animals. This information will be made available as appropriate. Animals with clinical, behavioural and welfare effects will not be kept without prior consultation with the Home Office.

Why can’t you use animals that are less sentient?

Live Animals are required for continued use in breeding programmes and the supply of live mice to establishments within the UK and worldwide who do not have the facilities, equipment or expertise to import,breed or maintain GA colonies

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The specific details of each line maintained will be determined by current demand and trends but also by individual customer requirements.

Only animals of a high health status will be bred and to ensure that high welfare standards are maintained background information relating to the origin, health status, genetic status, welfare and husbandry requirements of each line will be obtained. Animals will be housed in accommodation designed to maintain their health status and prevent infection.

What published best practice guidance will you follow to ensure experiments are

conducted in the most refined way?

Animal breeding will operate under guidance and in accordance with The Animals (Scientific Procedures) Act 1986 (ASPA). As well as a guidelines and recommendations provided by NC3R's website such as Colony management best practice and Breeding and colony management.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular review of guidelines and recommendations provided by the recent reports on the NC3R's website such as Colony management best practice and Breeding and colony management will be sort. Any advances will be discussed with the Animal Welfare and Ethical Review Body (AWERB) for implementation and reviewed at recorded AWERB committee meetings to determine effectiveness.

107. Genes and environment at the interface of inflammation, immunity and metabolism

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Inflammatory bowel disease, Immunity, Metabolism, Cancer

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to elucidate how risk genes of human inflammatory diseases operate, and how they contribute to disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Enormous efforts have been made to identify inherited risk factors of disease. The inflammatory bowel diseases Crohn's disease and ulcerative colitis have been amongst the most successfully studied in this regard, with now >250 spots in the genome identified that increase risk for disease. What is often overlooked is that only a handful of those identified genomic loci are biologically well understood, meaning that it is known how they mechanistically contribute to disease. For some of these risk loci, not even their basic function is known. Our group has a long track record in deciphering major mechanisms of Crohn's disease and ulcerative colitis by studying genetic risk factors. As examples, by studying specific genes, we have defined how two cell biological processes, called

'endoplasmic reticulum stress' and 'autophagy' contribute to the disease process. In this study we will investigate how further IBD-associated genes, which we have identified as intricately linked to cell metabolism, contribute to disease pathogenesis.

Variants of a number of risk genes predispose for Crohn's disease and ulcerative colitis, two inflammatory bowel diseases; for primary sclerosing cholangitis, a chronic inflammatory liver disease; Still's disease, a childhood fever syndrome with debilitating arthritis; and leprosy, a chronic bacterial infection of the skin. They hence predispose for major human diseases spanning 'autoinflammation' and 'autoimmunity', meaning diseases where the immune system appears to attack the body and organ. Ulcerative colitis and primary sclerosing cholangitis are also the diseases with the highest risk of developing inflammation-associated cancer.

Our studies will identify key mechanisms of disease, a prerequisite to develop effective treatments. All of these conditions remain poorly understood, and for some of them, such as primary sclerosing cholangitis, there is not even a single approved medical treatment available. Insight gained from our studies are very likely to have ramifications way beyond the diseases the risk genes are associated with, given how fundamental for cellular energy metabolism their function is.

Studies such as ours are key to fill 'risk coordinates in the genome' with 'functional life' - a prerequisite to allow for the genomic revolution in medicine, an area where the UK is world-leading, and one that is the very focus of the government's life sciences strategy.

What outputs do you think you will see at the end of this project?

We will generate new insight into the major biological processes underlying inflammatory diseases. We will publish these insights in scientific journals, and present them at conferences.

Who or what will benefit from these outputs, and how?

Projects such as ours are the very basis for future therapeutics. Patients suffering from Crohn's disease, ulcerative colitis, primary sclerosing cholangitis, Still's disease and leprosy, as well those suffering from cancer, will ultimately benefit from these outputs. Mechanistic insight into major disease processes has been the basis of breakthrough treatments for these diseases - examples are new dugs that target inflammatory mediators called Interleukin-12 and Interleukin-23. We expect very similar outcomes and hence benefits from our research here, too.

More immediate beneficiaries will be the scientific community, both in academia and in industry. This research will advance insight into major disease processes. Given the specific focus, there is also a high likelihood that insight gained through this programme will be important well beyond the inflammatory diseases the genetic association is with. Specifically, we think that outputs from this programme will be important for researchers working to understand cancer and metabolic diseases.

How will you look to maximise the outputs of this work?

We extensively collaborate and share new results early-on. Large data-sets will be deposited at databases for other scientists to use and exploit. We present our work at conferences prior to publication. We often report on unsuccessful approaches and non-significant data, too, since these are often as valuable as successful experiments and their

results. We typically publish our work in major journals, which maximises the visibility of our work.

As we have in the past, we will seek patent protection where and when appropriate. This enables the development of new therapeutics, exploiting our discoveries.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the most appropriate animal to investigate human genetic risk factors of disease. In the mouse, genes can be altered, which allows us to alter those that are involved in human disease. The immune system and metabolism are very similar between mice and man, and our understanding of mouse physiology is very deep. There are also many experimental tools, such as genetic models, recombinant cytokines (these are molecules that signal between cells) and antibodies, available for mice.

We investigate risk genes for human autoimmune/autoinflammatory diseases. The risk genes we are interested predispose for the inflammatory bowel diseases Crohn's disease and ulcerative colitis; a childhood arthritis with recurring fever that is called Still's disease; the liver disease primary sclerosing cholangitis; and the chronic bacterial infection leprosy.

All of these diseases arise from a complex environment - gene interactions. They involve numerous different cell types and organs. An example is the gastrointestinal tract, which contains many different cell types in a particular architecture within the organs. These include the intestinal epithelium, which is the inner barrier of the body, and which itself is composed of several different cell types; multiple types of immune cells, such as macrophages, dendritic cells, T and B lymphocytes; fibroblasts, endothelial cells (cells that cover the inner lining of vessels), neurons, etc. They are all involved in the disease process. The intestinal tract also contains the intestinal microbiota, an enormous accumulation of diverse bacteria, viruses and fungi that actually outnumber the cells of the human (or mouse) body. Over the last decade it has emerged that the microbiota has a huge impact on many diseases, including a particular large one on those we are studying.

Unfortunately there are no cell culture systems in a dish that come any close to modelling this vast complexity both on the host side, and on the microbial side.

Regarding life stage, we will generally study adolescent and adult mice.

Typically, what will be done to an animal used in your project?

We will generate, breed and maintain genetically-altered mice in this project.

Almost all of the mice we generate will carry genetic alterations. These genetic alterations are typically not harmful or even noticeable, and mice breed and develop normally.

Only few mice will carry mutations that lead to spontaneous phenotypes, specifically mutations that result in tumour development.

Small tissue samples will be taken to determine the genotype of mice. This is typically done at an early age (3-4 weeks).

Most genetically altered mice will not have *any* further interventions performed on them. They will serve as donors of tissues or cells, commonly harvested at an age of 8-16 weeks. Cells and tissues will be obtained from dead animals or during terminal anaesthesia. Most of our investigations will be reliant on primary cells and tissues obtained from these mice. Cells and tissue will then be studied in the laboratory in primary cell cultures in a dish, or analysed for gene or protein expression, or for metabolites.

Only a minority of animals will undergo further procedures:

In some mice, their metabolism will be characterised. This may require housing them for 2-5 days in special cages that monitor energy consumption. Occasionally, single mice will be housed in individual cages. Few mice will be fasted for up to 18 hours, and small amounts of blood will be taken from the tail vein at several time-points after metabolic 'fuel' (e.g. glucose) has been administered.

Some mice will be housed in special isolators that prevent colonisation with microbes. Such 'germ-free' mice generally develop normally. They may then be colonised with specific microbes, which are typically administrated through the mouth via oral gavage.

Mice may also be injected with agents, administered into the tummy (i.e. into the 'peritoneum') or underneath the skin. Or agents may be administered through the mouth via drinking water, food, or per gavage; or via the nasal route. Agents may include substances such as drugs, metabolites, immune- stimulating reagents. They may also include microbes such as viruses or bacteria. Colonisation experiments may last several weeks, infection experiments typically 1 to 4 weeks, depending on the agent.

On few mice we will conduct imaging studies, such as computer tomography. This may require administration of imaging agents.

Depending on the route of administration and type of agent, we may apply a local or general anaesthetic prior to the agent.

Some animals will be injected with tumour cells to study tumour growth and how this can be treated. These experiments typically last 3 to 4 weeks.

Very rarely we will induce overt disease in mice by administering agents that cause colitis (inflammation of the gastrointestinal tract) or arthritis (inflammation of the joints). The duration of these models varies from few days to few weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of mice will not experience more than mild and transient discomfort. This is due to when a tiny piece of tissue is taken for genotyping.

Most of the genetic alterations we will study do not cause spontaneous harmful phenotypes.

Mice prone to develop intestinal tumours may stop gaining weight or may lose weight. Tumours typically develop slowly over many (12-20) weeks.

Administration of immune-stimulating reagents, infectious pathogens or colitis/arthritis-inducing agents can cause abnormal behaviour, reduced food intake, pain and weight loss. The duration of clinical symptoms varies between models, typically lasting from few days to few weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice will fall under the 'sub-threshold' or 'mild' severity banding.

A minority of animals will develop 'moderate' symptoms. We will not pursue experiments that would fall under the 'severe' banding.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our research programme uses a wide range of approaches to elucidate disease mechanisms. These range from the atomic/molecular (e.g. structural biology), protein-based (e.g. enzymology), to cell culture in a dish. The latter includes 'permanent' cell lines (typically meaning cancer cell lines that can indefinitely be grown in a dish), genome-edited human pluripotent stem cells (iPSCs), and the *ex vivo* experimentation with 'primary' cells and tissues that are isolated from mice.

For every question we ask, we always use the simplest model system that is available.

We only use animals (mice) when there are no other suitable models available to answer specific questions that arise from our overall research programme. In fact, research involving animals are only a small part of our overall research programme into mechanisms of human disease. We use them judiciously and carefully when no alternatives exist to answer an important question.

The very nature of the biochemical mechanisms we investigate limits the use of *permanent* in vitro cell cultures. This is why we have to rely in these instances on 'primary' cells (meaning, these are taken out of a living organism - e.g. from humans or mice). It is important to appreciate that the proteins we study are 'polymorphic' in the human population, meaning the protein sequence differs at specific amino acids between

individuals. To demonstrate what the consequences of this variation is, we have genome-edited the corresponding parts of the mouse genome. This allows us to study them on an identical genetic background.

Many aspects of human disease processes cannot be modelled *in vitro*. This is very apparent for intestinal inflammation, which involves multiple different cell types (various T and B lymphocytes, macrophage and dendritic cell types, innate lymphoid cells, natural killer cells - these are all immune cells; fibroblasts, epithelial cells and their subtypes, endothelial cells, neuronal cells, and many others) and involves complex interactions with the intestinal microbiota, the enormous amount of diverse bacteria (and other forms of life) in our intestine that actually outnumbers the actual human cells. Neither the host side, nor the microbial side can be modelled *in vitro* to any meaningful extent. Whilst a microbiota involvement might be most obvious for intestinal inflammation, it has become very clear that it plays a similarly huge role for inflammation at other sites, for the organisms' metabolism, and may even determine the effectiveness of differnt types of cancer treatment.

The extremely high conservation between mouse and man of the genes and pathways we study, and the close similarity of the mouse and human immune system and metabolism in general render the mouse the most appropriate model system. Finally, the biochemical mechanisms we have discovered and that underpin our research programme have huge ramifications for organ and inter-organ physiology. Again, this could not be studied in a more reductionistic system than an in vivo model.

Which non-animal alternatives did you consider for use in this project?

Mouse experimentation forms only a small part of our overall research programme into human disease mechanisms. Our mouse work is embedded in a much larger research programme that uses a wide variety of technology.

We are using structural biological methods, protein chemistry, enzymology, metabolomics, and various other approaches to gain fundamental insight into mechanisms of disease. These are methods that let us study the proteins themselves that we are interested in. They let us often study even single atoms and help us understand how these proteins work. These studies form a central and large part of our overarching research programme.

At a further level of complexity, we want to understand how these proteins operate within a cell. For this we use cell culture in a dish. We employ permanent cell culture of various (cancer) cell lines (these have names such as MODE-K, Caco2, HEK293, THP1, B16, etc), as well as complex 'organoid' cell cultures (these are 3D cell cultures that can resemble the basic architecture of the cell type that is characteristic of a specific organ), including those derived from human induced pluripotent stem cells (iPSCs). We have experience in using gene-editing techniques to edit the genome of human iPSC to toggle the put the human gene variants into their genomes. Such 'toggling' is important to study what consequences a specific human variation has.

We also perform studies with cells isolated from peripheral blood from healthy individuals. The latter allows us to identify individuals who are homozygous for either variant of the polymorphic genes we study.

Experimentation involving primary cells from genetically-altered mice, and *in vivo* experimentation in mice form only a small part of our overall research programme and are used when absolutely necessary.

A large part of our work involves the activity of the immune system. Since the molecules that present antigens are highly polymorphic (this means they are different between every human) makes many studies of antigen-specific immunity impossible in cells from cohorts of humans - even when disregarding that the site of primary immune-stimulation is in tissue which would generally not be accessible for experimentation in humans.

We have extensive experience in all of these methods and use them on a regular basis. We constantly re-assess what the most appropriate experimental approach is.

Why were they not suitable?

As already alluded to above, many aspects of human disease processes cannot be modelled *in vitro*. This relates to the variety of cell types involved; the environmental signals/cues; the microbiota and many others. Many relevant cell types are not accessible at all in e.g. peripheral blood from humans. An example of the challenges we are facing is the intestine. While 'organoids' are useful model systems, these are clearly not mini organs. For example, intestinal organoids show a 3D structure reminiscent of the intestinal epithelium (the cell type that forms the single-layer cellular interface with what is inside the lumen of the intestine, meaning the enormous amount of bacteria alongside the food that is being ingested and digested), but they do not contain the myriad of immune cells, muscle cells, vessels, fibroblasts and neurons that form our intestine. They clearly also do not contain the unique ecosystem of bacteria, viruses and fungi that is present inside our intestine.

A particular challenge in our case is that the proteins we are studying are polymorphic, hence we would need to 'pick' healthy individuals for homozygosity of the risk and non-risk genotypes. We have indeed conducted select experiments with the support of individuals, but for reasons that are obvious these individuals could not possibly supply our research programme with a continuous supply of primary cells. Since a large part of the project involves studies of the immune system and the antigen presenting molecules and the receptor that recognise these antigens differ from person to person (they are highly 'polymorphic'), it would be impossible to find individuals that have either of the variants of interest, but are identical for the immune receptor.

Finally, the very nature of the biochemical mechanisms we investigate limits the use of *permanent* in vitro cell cultures, albeit we use them extensively whenever this is possible. These in vitro models also have obvious major advantages for mechanistic studies, due to the simplicity of their pharmacological or genetic perturbation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

By keeping our experimental conditions well controlled we are able to perform highly reproducible and statistically meaningful experiments using the minimal number of

animals. The experimental approaches described herein have been vigorously evaluated over the past two decades, thereby providing us with a wealth of data that help us optimise experimental design and achieve robust data from the minimal number of mice used. We have extensive experience in experimental design and statistics. Post-doctoral scientists in our group have been on experimental design courses to help understand sources of bias and variation and how best to reduce them. We also have access to external advice on statistics, if required, to help guide experimental design. Where possible in our design we blind people to genotype/treatment groups with different people doing infections or analysis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For our various experimental approaches, be it *in vitro* experimentation on primary cells, or *in vivo* experimentation in particular models, we have extensive data from various contexts. These insights are invaluable for designing robust experiments with the minimal number of mice required. We have used the NC3R's experimental design assistant for work we have done on previous studies, and will continue to use it in future studies. The PREPARE and ARRIVE guidelines have been consulted for formulation of this project, and these will be followed to ensure continued communication between animal facility and our team, and reporting data from our experiments. We also collaborate extensively, seeking input and advice from colleagues who are experts in particular models.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When required and as part of this programme, we will use pilot studies to inform us on the control experimental conditions we need to use. We have extensive experience in the *in vivo* inflammation, infection and tumour models in this project, and thereby access to a wealth of data that make predictions of effect sizes and optimisation of experimental strategies easier. In an iterative way, we are thereby able to continually improve and optimise our strategies.

Please also note that these experiments involving genetically-altered mice is embedded in a much larger research programme that uses a wide range of different techniques to elucidate mechanisms of disease. These range from 'atomic resolution', using structural biology approaches, to enzymology, assays on recombinant proteins expressed in various in vitro expression systems, to a wide range of cell culture work, also involving human induced pluripotent stem cells that are being genome-edited. It is a typical feature of our programme that results from e.g. structural or enzymological experiments raise hypotheses that trigger experiments in cell culture or in cells from genetically-altered mice; and *vice versa*. This integrated, comprehensive and iterative approach allows for very judicious use of animal experimentation, with the constant aim to reduce the numbers of mice needed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The vast majority of genetically altered mice generated on this license will not undergo any procedures apart from genotyping, hence will not experience pain, suffering, distress or harm. These mice, once dead or terminally anaesthesised, will serve as donors of primary cells and tissues. The genetic modifications we study do typically not cause spontaneous phenotypes.

A small minority of mice will undergo procedures. These include adminstration of reagents or cells; infections with pathogens; induction of inflammation, such as colitis and arthritis; and induction of tumours. We believe that the similarities in the mouse and human genomes are such that we can infer between the two, and we have closer links than ever before with patients suffering from these conditions. Over the years we have gained tremendous experience with our models and, through careful observation, we are able to minimise the potential suffering of the animals. We have been able to identify key clinical signs that indicate illness and consequently such animals can be quickly and humanely killed.

Why can’t you use animals that are less sentient?

As noted above, most of the mice generated on this license will be used as organ, tissue or cell donors when they are dead, or after terminal anaesthesia.

It is not possible to model all aspects of tissue inflammation, such as in arthritis or colitis, of organ and systemic infection, tumour formation, and tumour immune responses outside of the whole animal. The mouse is a very good model system as it closely resembles human physiology. More sentient systems, such as Drosophila or fish, have very different immune systems and lack defining parts of the human (and mouse) immune system.

Complex interaction of various host cells and -metabolites, and with the environmental cues and the microbiota are critical in the disease processes we study. There are no 'more reductionistic' model systems available that would reproduce the processes in human disease to a meaningful extent. We recognise that our mouse model systems have limitations and cannot reproduce all the conditions associated with human disease. However, mice have many similarities to humans, including in terms of their immune system and metabolism.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice are monitored throughout all interventional experiments and we collect daily scores composed of a set of physical signs of illness such as piloerection (raised hair as a sign of pain or discomfort), hunched walk and mobility along with weight loss. The cut-off for these physical signs lies within the guidelines for mild, and in a few contexts, moderate severity, i.e. loss of pre-set percentage body weight being our main indicator, along with mobility (ability to feed and water). The scoring for piloerection etc. are also used as secondary indicators. My team are experienced in animal models and are trained to the high standards that I expect. The technicians that work in our holding facility and do the majority of the animal husbandry will also be trained by my team and will communicate abnormal behaviours in the mice early. At our establishment we have dedicated Named Animal Care and Welfare Officer who are impartial and can give advice / make decisions

on animals that lie outside of the normal adverse effects expected for the infections outlined within this project.

Potential refinements include increased monitoring if test animals show earlier clinical signs or weight loss. We will give wet mash food to animals that lose more weight quickly. Floor food will be given to animals that are to be infected to limit weight loss from the start of the infection.

Any evidence in pups not developing or litter losses will be discussed with NVS and appropriate actions taken. All animals will be given environmental enrichment and be socially housed to encourage natural behaviours and reduce stress. Males will be monitored for increased aggression and additional enrichment added to combat or appropriate splitting of fighting animals if needed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use guidance from the NC3Rs website and the Laboratory Animal Science Association (LASA) to ensure experiments are conducted appropriately. In particular we will follow the 'Guiding principles on good practice for Animal Welfare and Ethical Review Bodies'.

We will follow the PREPARE guidelines for planning experiments and will follow the ARRIVE guidelines reporting of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will keep informed on advances through the NC3R’s website, Norecopa website, our establishment website and newsletter. We will discuss any advances with the relevant people at our establishment and implement them accordingly.

108. Biobehavioural basis of the individual vulnerability to impulsive/compulsive spectrum disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

emotion, motivaiton, impulse control, addiction, individual vulnerability

Animal types	Life stages
Rats	juvenile, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the environmental, psychological and biological factors that contribute to individual vulnerability to develop the compulsive behaviours that represent the hallmark features of Impulsive/Compulsive Spectrum Disorders (ICSDs) such as Obsessive-Compulsive Disorder or drug addiction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The cost incurred by ICSDs to our society and the burden they put on our health care system reflect mainly the limitations of our current knowledge of both their pathophysiology and aetiology. This limited understanding thereby prevents the development of novel,

more effective preventive and therapeutic strategies.

It is therefore of paramount importance to better understand the biobehavioural basis of the individual vulnerability to develop compulsivity.

Thus, why only some individuals exposed to stress, experience distress or take addictive drugs recreationally lose control over their behaviour and go on to develop compulsivity remains a key question to be addressed that goes beyond the understanding of the neurobiological adaptations to distress, chronic stress or drug exposure. Indeed, since we are all subjected to these challenges it is pivotal to dissociate the psychological, neurobiological and environmental mechanisms that support adaptive coping strategies and impulse control from those which, in vulnerable individuals, aberrantly support the switch to compulsivity.

Additionally, this work will shed new light on our understanding of adaptive coping strategies which current and future generations will need to deploy in the face of new challenges, such as social media or globalisation.

What outputs do you think you will see at the end of this project?

This research will deliver new knowledge that will enhance our understanding of the biobehavioural basis of the vulnerability to develop Impulsive/Compulsive Spectrum Disorders (ICSDs) and identify new drug targets.

Outputs for all objectives are primarily behavioural and data collected through performance on specific procedures aiming to operationalise in the rat impulsive or compulsive behaviours or associated behavioural traits of vulnerability that have heuristic value with regards to the human situation.

Our understanding of the neural and cellular substrates of these behaviours will come from associated neurophysiological outputs such as neuronal activity patterns and circuit mapping in behaving or anaesthetised rats. Our understanding of the molecular mechanisms of these behaviours, within the identified neural circuits, will stem from investigations of the expression of specific molecules (such as metabolic products, mRNAs, proteins, small molecules acting as neuromodulators) within brain tissue assessed post mortem. Usually, molecular data are generated using the same procedures as for behavioural data, but animals are killed at a specific experimental time point whereas the investigation of neurophysiological and neuropharmacological processes in non-behaving animals is performed under terminal anaesthesia. Thus, for some of our objectives, the brains of the rats will be harvested for subsequent post-mortem analyses (using a wide array of contemporary neuroscience techniques, such as in situ hybridisation, RNAscope, immunohistochemistry, western blot, qPCR, next-generation omics, single-cell transcriptomics...).

Who or what will benefit from these outputs, and how?

The intended overall benefit of this research will be directed to Society as the intended increased understanding of the biobehavioural basis of ICSDs will have far reaching social and economic implications.

The first beneficiaries of this research will be the scientific and clinical communities. The publication in journals with Open Access, which, for basic research, remains the most effective route to communicate research findings and rapidly to gain international impact

and prominence, will only be the first step in a wider dissemination and communication strategy aiming to immediately increase our impact on the general public. Our goal is to help the general public realise that compulsive disorders, and especially addiction, are indeed psychiatric conditions that are not simply the behavioural manifestation of poor willpower, a view that has long contributed to a damaging prejudice towards those who suffer from these conditions.

The second beneficiaries would be the patients themselves as the output of this research will help improve the awareness of ICSDs as brain disorders, and facilitate their prevention and treatment by personalising medicines and other interventions, including at school, in those individuals deemed most at risk from developing maladaptive coping mechanism and/or harmful levels of drug use in the future. Such long-term benefits will depend on the efforts we continually make to provide to inform the general public and clinical policymakers.

We also intend to impact pharmaceutical company policy as they return to medications development for disorders such as addiction. We have therefore recently developed a jointed research project on drug addiction with a pharmaceutical company.

How will you look to maximise the outputs of this work?

We are fully committed to communicating our research as widely as possible to academic and scientific communities. The outcome of our research (may the results be positive or negative) will be published and disseminated to the scientific community in both high-impact scientific journals with Open Access and at national and international meetings and summer schools. Our results will be targeted for publication in peer-reviewed high impact journals (e.g., Science, Current Biology, Nature Neuroscience, Neuron, Biological Psychiatry, Neuropsychopharmacology, Journal of Neuroscience, Molecular Psychiatry). We have a strong track record in maximising the output of our work, with the systematic publication of negative results.

Manuscripts accepted for publication will be made open-access and archived in an institutional repository to ensure the widest possible accessibility and impact of our work, thus meeting the new HEFCE policy on peer-reviewed articles and conference proceedings. We will also continue to publish conceptual papers and commentaries which are often highly cited and increase the profile of our work and the field in general. This activity greatly increases the research profile of my group and enables the rapid communication of new findings to a wide scientific community.

Our results will be disseminated through presentations (plenary lectures, symposium lectures, poster presentations) at international and national conferences and summer schools.

We are fully committed to communicating our research as widely as possible to non-scientific communities. The publication in journals with Open Access will only be the first step in a wider dissemination and communication strategy aiming to immediately increase our impact on the general public. Our goal is to help the general public appreciate that compulsive disorders, and addiction especially, are psychiatric conditions and not simply the behavioural manifestation of a poor willpower, a view that has long contributed to a damaging prejudice towards those who suffer from the condition. Thus, we will rely on publicisation of our work by local and national media groups.

We will continue actively to participate in local and national public engagement events to

educate the public about our work, including teachers and students at schools and other educational institutions.

We will also use other means to increase our impact, especially through the powerful vehicle that represents arts.

We are fully committed to communicating our research as widely as possible to clinically active scientists and clinicians. We intend also to have an impact on approaches to treatment. Addiction theory and computational models have also evolved to incorporate notions of inhibitory control, actions and habits rather than earlier assumptions that the key to addiction is to be found exclusively in the dopamine reward pathway, which is instead the point of entry of addictive drugs to exert their rewarding effects.

We will investigate the translational potential of our findings in human subjects as a way to validate our discoveries in rats. The successful demonstration of cross-species convergence would enable targeted interventions to be developed based on candidate neural markers.

Species and numbers of animals expected to be used

- Rats: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The majority of individuals in the world are exposed to stress, or use drugs recreationally, may it be alcohol, tobacco…, sometimes itself as a means to deal with stress, a so-called coping strategy.
However, around 10% of those who take drugs eventually lose control over their intake and develop the compulsive relapsing pattern of drug seeking and taking that characterises addiction. In other words, we are not equally vulnerable to developing maladaptive coping strategies and/or drug addiction.

The environmental, psychological and biological factors contributing to this individual vulnerability to lose control over coping strategies or drug use, which results in Compulsive Disorders such as Obsessive Compulsive Disorder or drug addiction, remain poorly understood. This prevents the development of novel, more effective therapeutic or preventive strategies for these debilitating disorders that affect millions of individuals worldwide.

Thus, our research interests itself with the identification of the environmental, psychological, neural and cellular factors that contribute to the individual vulnerability to develop Impulsive/compulsive Spectrum Disorders (ICSDs) across several nosological boundaries.

This research is only possible with the use of animals because human studies (e.g., brain imaging studies) are useful but can only provide correlative data that do not address causation and short fall of identifying the detailed mechanisms in the brain that support the

vulnerability to develop Impulsive/Compulsive Spectrum Disorders. Furthermore, it is not ethically possible to study the genetic and/or environmental factors that underlie predisposition to, and the development of, neuropsychiatric disorders in humans.

Similarly, it would not be possible to develop new treatments for brain disorders without testing them in animal models first. In vitro models (e.g., rat brain slice preparations) or computer simulations cannot be used because the modelling of behaviour in these systems is not sufficiently advanced.

Thus, we use rats because they are the least sentient species which allows the investigation of individual differences in sophisticated behaviours that capture core features of these neuropsychiatric disorders. Additionally, the brain circuitry implicated in many neuropsychiatric disorders is highly conserved between rats and humans. The study of the environmental, psychological and biological basis of the vulnerability to develop as debilitating a psychiatric condition as OCD or drug addiction requires the establishment of these conditions in the animal model. However, our experimental approach has been refined so that the overall suffering induced by the development of these compulsive behaviours

In order to uncover the biobehavioural basis of the vulnerability vs resilience to ICSDs across the lifespan, we will carry out investigations, deploying large array of intracerebral measurements and manipulations on juvenile and adult wild-type and genetically modified rats. It is therefore important that such procedures, which are invasive, are optimised prior to being deployed on large experimental cohorts of rats.

For this, we have a dedicated optimisation and maintenance licence the purpose of which is to optimise and refine each of the procedures that will be used on relatively large cohorts of animals under the present one. The identified need for optimising our procedures stems from our commitment to animal welfare. Indeed, most of our animals run in long-lasting behavioural experiments in which they perform tasks for food or drug reward, and experience procedures, when fully optimised, that produce only transient discomfort and no lasting harm, achieved by a constant refinement of administration techniques by well-trained personnel.

We take the welfare of the animals very seriously. Most of our animals are exposed to long-lasting behavioural experiments in which they perform tasks for food or drug reward, and experience procedures, e.g., injections that produce only transient discomfort and no lasting harm, achieved by a constant refinement of administration techniques by well-trained personnel.

Animals are monitored and handled frequently (often undergoing daily testing). In the case of drug self- administration procedures, the daily monitoring of the status of the port area is facilitated by a severity scale developed in collaboration with previous Named Veterinary Surgeons that is used as a visual reference by all members of staff to monitor the animals. Any adverse effects are discussed with the Named Veterinary Surgeon. If these cannot be quickly ameliorated then animals are killed to preventsuffering.

We are fully committed to using the minimum number of animals required to obtain data that are statistically and biologically meaningful. We carefully design our experiments to maximise the behavioural data collected from each animal, and to minimise distress. Each of our experiments is designed on the back of a robust statistical approach that relies on state-of-the-art statistical tests and models.

Typically, what will be done to an animal used in your project?

Rats used in this project (including GA animals with no adverse phenotype) will be exposed to several sets of behavioural and experimental procedures the cumulative severity of which never extends beyond moderate severity.

The various procedures rats will be exposed to aim at measuring their individual performance in tasks that operationalise, for instance, attention, behavioural flexibility, impulse control, anxiety trait, decision making, boredom susceptibility, interest in appetitive outcomes and sensitivity to negative ones (such as mild electric foot shocks) as well as goal-directed or habitual instrumental responding. Testing in these tasks, as well as coping-related tasks sometimes requires rats to be exposed to food restriction and single housing conditions for the entire duration of an experiment (up to 12 months).

Rats (no more than 30%) will be exposed to procedures that enable the assessment of adaptive, or maladaptive (compulsive) coping strategies in the face of distress; these procedures require that rats are food-restricted (between 80% and 85% of their theoretical free-feeding weight) and singly-housed for a period of at least 15 days and up to 12 months overall.

Our research also focuses on the contribution of interoceptive mechanisms to the vulnerability to develop ICSDs. For this we use a drug discrimination task that requires systemic administrations of a drug over multiple daily sessions. Thus, no more than 40% of the rats may receive multiple systemic administrations of substances that trigger specific interoceptive states or dependence. These may also be administered with substances that counteract these dependent states.

In the case of drug self-administration, rats (no more than 50% overall) are given the opportunity freely instrumentally to respond for a bolus of cocaine, heroin or other addictive drugs delivered directly into their bloodstream through an indwelling catheter connected to a syringe. Most rats maintain control over their drug intake, as humans do, but some, those which underlying psychology and neurobiology we seek to understand, eventually develop drug seeking habits that persist despite adverse consequences (such as exposure to response-produced, hence escapable, mild electric foot shocks), the hallmark of the compulsive nature of addiction in humans. These shocks are always avoidable and their maximum intensity kept very low. There is no alternative to such procedure to measure the persistence of a behaviour despite negative consequences that characterises compulsive disorders.

Rats (no more than 40% overall) may be exposed to several stressors such as maternal separation, social defeat and/or mild unpredictable stress to measure the influence of stressful events on their subsequent resilience or vulnerability to develop impulsive/compulsive spectrum disorders (ICSDs).

Alone, or in conjunction with any combination of the previously described procedures rats (up to 50%) may be subjected to intracerebral manipulations either while behaving or under terminal anaesthesia. Thus, they will receive up to 2 intracranial procedures, prior to any additional procedure performed under terminal anaesthesia.

Rats lay also be implanted with subcutaneous minipumps or slow-release formulations in order chronically to influence a central or peripheral system and/or trigger dependence. Half the animals that will have developed dependence will then experience precipitated withdrawal.

The investigation of endophenotypes of vulnerability requires blood samples to be collected from peripheral vessels from the animals (no more than 30% overall). No more than 10% of total blood volume will be collected in any 24hr period and not more than 15% in any 28-day period.

Rats (no more than 10% overall) may experience experimentally-induced Parkinson's disease because the study of the individual vulnerability to develop Impulse control disorders in Parkinson’s Disease requires a Parkinson’s Disease state is induced in behaving rats.

The investigation of specific cellular mechanisms requires the decapitation of the rats in a conscious state.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of our animals on this project (75%), we anticipate no more than transient discomfort and no lasting harm.

When rats undergo surgical procedures, they tend to recover very rapidly and they are provided with post-operative care, including the use of analgesics.

When rats are trained to self-administer drugs, some (up to 25%) may develop several behavioural characteristics similar to those presented by human beings suffering from a drug addiction, including lack of interest in other sources of reinforcement and associated weight loss, decrease in self-care (their fur becomes dirtier).

A very small number of animals we see them self-harm in the same way that drug addicts do when they are when given extended access to heroin. This is because high levels of heroin intake can cause changes to the way nerves in the face and mouth behave: heroin is an analgesic (i.e., it affects feeling and pain perception). When rats can no longer feel the pain, some start to nibble their toenails and toes can inflict damage to their paws. While there is no alternative to these side effects of chronic exposure to heroin, these adverse effects are minimized by early end points.

The study of the biobehavioural basis of drug addiction that intends to have a real impact on the life of the millions of individuals who suffer from this debilitating psychiatric disorder requires the identification of compulsive, maladaptive behaviours in a subset of animals exposed to the drug for long periods of time. As a matter of fact, over the past two decades, all the behavioural, psychological and biological mechanisms that have been identified in the rat to underlie this vulnerability to develop compulsive drug seeking and taking using our methodology have been subsequently demonstrated I humans, thereby demonstrating the clear translational value of our multidimensional and heuristic approach.

When rats have become dependent on a drug, such as heroin, upon induction of withdrawal they display typical signs of physical withdrawal, including wet dog shakes, or piloerection, but as in humans, these signs wear off rapidly (within 24 to 48 hours). There is no alternative to the induction of dependence and withdrawal to study the cellular and molecular basis of these phenomena and their contribution to compulsive behaviour.

When rats are encouraged to develop coping strategies in the face of distress, some (no more than 30%) lose control over their coping strategy and progressively develop

behavioural manifestations that are similar to those shown by individuals suffering from Obsessive/Compulsive Disorder. Thus, these rats show excessive ritualised behaviours such as grooming and adjunctive drinking behaviour. These behavioural are not harmful to the animal.

In the case of the induction of Parkinson's Disease, rats tend to present a transient lack of motivation that is associated with the neurodegenerative process of the dopamine neurons, hence they need to be supplemented by highly palatable food or feed (including by oral gavage) until they recover (between 3 and 12 days overall).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1: Moderate, 100%

Protocol 2: Moderate, 100%

Protocol 3: Moderate, 100%

Protocol 4: Moderate, 100%

Protocol 5: Moderate, 100%

Protocol 6: Moderate, 100%

Protocol 7: Moderate, 100%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not yet possible to achieve our objectives without using animals, and, especially, rats. Our research investigates the individual vulnerability to develop impulsive/compulsive spectrum disorders, which results from an alteration of many complex, intricate, brain mechanisms and associated cognitive (understanding and perception) and emotional processes which we do not yet understand, even remotely, enough to be able to contemplate modelling them using algorithms or Artificial Intelligence.

The nature of our research therefore requires we use a species whose brain, cognition and behaviour are similar enough to humans to offer insights into the psychobiological basis of human neuropsychiatric conditions.

The rat is by far the best species to establish the neural and neurochemical mechanisms underlying inter-individual differences in behaviour, cognition and neuropsychiatric disorders which cannot be investigated in humans.

The rat is so far the only species in which individuals have been shown to have representation of the relationship between their actions and their consequences, to establish coping strategies, to differ in impulse control and in their propensity to take drugs, even to develop maladaptive habits and compulsivity.

Most of our animals undergo long duration behavioural experiments (which last up to 14 months) in which they perform tasks for food or drug reward, and experience procedures that, provided they are fully optimised, produce only transient discomfort and no lasting harm. It is therefore fundamental to optimise these invasive procedures, and procedures carried out under this PPL will have systematically be optimised, including using our optimisation Licence.

Which non-animal alternatives did you consider for use in this project?

We use alternative strategies some of which involve humans, some are computer-based models and some use Artificial Intelligence. For instance, having shown in rats that a high impulsivity trait predicts and exacerbated vulnerability to develop early-onset Parkinson's Disease, we have established sibling studies combined with brain imaging analyses in human populations to further investigate the biological and environmental basis of such vulnerability. We have shown that the siblings of early-onset PD patients were more impulsive than those of late-onset PD patients, thereby confirming in humans the striking observation originally made in rats. Similarly, having shown in rats that the development of maladaptive habits results in an exacerbated vulnerability to relapse mediated by negative urgency, we have designed longitudinal studies in humans combined with EEGs to further the neural correlates of the influence of negative urgency on craving and relapse. In addition, we use cell culture (i.e., cells grown in a dish in the laboratory) and ex vivo organoids (i.e., cells that grow in a dish and form into organ-like structures) in order to identify responses to drug exposure at the cellular level that do not require a behaving organism.

Why were they not suitable?

As our objectives, which will be achieved through the use of a complementary project licence, require complex behavioural tasks allowing for the identification of individual vulnerability to compulsive disorders, we cannot rely on in vitro (non-animal) models because these cannot reproduce the integrative function of the brain across the lifespan that is the focus of this research.

Human studies cannot allow for a lifetime longitudinal study addressing causal mechanisms of neuropsychiatric disorders, they yield only correlative data and rely very often (if not exclusively) on retrospective analyses which prevent the identification of factors of vulnerability measured prior to the development of the disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals required for these experiments is based upon the historical usage of animals in our laboratory. Overall, with a requirement of 48 to 96 rats per experiment, we have used ~6000 rats in the last five years in spite of the COVID pandemic. In the next five years we will therefore use a maximum number of 6400 rats. These numbers reflect the absolute maximum range of the estimated numbers for the next five years.

Provided our research is mostly based on inter-individual differences, when the distribution of the population allows for an objective criterion to select specific groups such as a bimodal distribution, the group size is dependent upon the distribution. In the other cases, the groups used to perform between- subject analyses will be selected in the upper and lower quartiles of the population.

In order to maximise the differences between the experimental groups, we will, therefore, carry out experiments with cohorts of 24 n animals, with 1<n<4 for each experiment. We do not foresee the use of cohorts of more than 48 rats for any of our experiments.

Our group sizes (n= 5-12) are based both on power statistics and reference to the established scientific literature that are necessary to obtain statistically and biologically meaningful data with an initial target of alpha = 0.01. By applying this strategy, we are very confident that results will be statistically relevant even if, especially with protracted self-administration experiments, we have to kill animals during the experiment.

For experiments for which we can make no predictions about the size of the behavioural effect a manipulation can cause or how a behavioural difference relates in terms of neurophysiological or cellular processes, these experiments are conducted over several runs, and the early runs are used to calculate effect sizes and to perform power analysis to inform the final group sizes.

If we typically anticipate n = 5-12 animals per group, our between-subject design analyses will always be computed along with dimensional (correlation, regressions, factorial regressions, PCA, cluster analyses) analyses in order to make the maximum use of each individual within a design aiming at emphasising inter-individual differences.

We have recently implemented a new strategy whereby each study that requires a final cohort of 48 rats is often (wherever appropriate) ran in two independent experiments. Thus, not only do we ensure internal reproducibility of the effects observed between the two runs, but provided we reach a statistically and biologically meaningful result at the end fo the first experiment we are in a position not to run the second experiment and spare half the number of animals initially planned.

Wherever possible, we use within-subjects experimental designs (e.g., testing the effects of different drug doses on a specific ongoing behaviour in a Latin-square design) as this increases statistical power and reduces the numbers of animals required.

Where between-subjects comparisons have to be made (e.g., where each animal’s behaviour can only be manipulated once without compromising the interpretation of subsequent data) there are a minimum of two experimental groups (one control group and one experimental group), and sometimes additional controls (e.g., if we need to

demonstrate that a drug given systemically is acting in the brain to influence behaviour, then a similar drug that does not cross the blood-brain barrier may be given to another control group). If the vehicle for the peripherally-acting drug and the centrally-acting drug differ, then another vehicle group may be included for the peripherally-acting drug).

For all experiments, we use the minimum number of control groups that we can in order for the experimental data to be interpretable. Nevertheless, we will make sure our group size is big enough to start with in order to avoid having to replicate an experiment in which only specific individuals (i.e., upper and lower quartile) are taken into considerations for between-subject analyses, which would run counter to the principles of the 3R's. We are indeed familiar with the PREPARE and ARRIVE guidelines (https://proecopa.no/prepare; https://arriveguidelines.org) and will ensure all our experiments are designed in adherence to these guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are committed to, and have succeeded in, using the fewest animals required for statistically and biologically meaningful results. Recent publications in high impact journals, the data of which were acquired under the current PPL, report highly novel and impactful results with relatively low sample, but big effect (e.g., partial eta squared values) sizes.

Our approach, based on inter-individual differences, inherently makes uses, and capitalizes on individual variability, rather than trying to control for it, alongside a highly standardized behavioural neuroscience methodology that dramatically minimizes external sources of variability that contribute to decreasing the power of our experiments.

We will continue to design our experiments using the minimum number of animals deploying a range of strategies that we have implemented over the years and were previously validated by a biostatistician. The key principles on which our statistical design relies are:

Aiming for an overall statistical level of significance of $p < 0.01$ and large effect size (partial eta squared values (>0.14) which we report systematically in our publications) between individual groups, i.e., animals showing vulnerability, and those showing resilience to, neuropsychiatric disorders, generally selected in the upper and lower quartiles of the population or between experimental conditions, i.e., chemogenetic inhibition of a specific neuronal ensemble vs non inhibited control.

Combining between (or within when possible) subject design with dimensional analyses in order to strengthen the power of the overall conclusions. We have been very successful in applying various descriptive analyses including cluster analyses, factorial analysis or Principal Component Analysis with either simple, multiple or factorial regression analyses to draw firm conclusions from relatively small samples.

Optimising animal use through conducting 'pilot' experiments under our maintenance and optimisation licence to verify that brain manipulations or biological measurement are producing the intended effects at a neural level, and to calculate effect sizes (and statistical power) to identify how many animals are required for analysis.

Using within-subjects designs whenever possible, as these have greater statistical power than between-subjects designs and require fewer animals.

Blinding the experimenter to the behavioural data for the post-mortem histological verifications or interrogations of the neural, cellular and molecular substrates or correlates of the psychological and behavioural mechanisms under investigation.

Over the past year, we have developed new machine-learning-assisted classifiers to characterise rats that are resilient to, or at risk of developing addiction irrespective of the cohort to which they belong.
This new tool (publication under preparation) will be deployed in all our experiments to further reduce, wherever possible, the size of the cohorts we initially train to study identify those individuals that eventually develop ICSDs.

We have much expertise in experimental design and statistics, ranging from parametric to non- parametric analyses, sophisticated analyses of variance and covariance, and associated post-hoc tests, dimensional analyses, such as multiple and factorial regressions, as well as data mining such as k-means clustering, principal component analysis and distribution fitting. However, if further advice is needed, we will consult statisticians.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have implemented a standardized approach of training cohorts of 48 rats at the same time, allowing us to obtain at least 5 to 10 rats (depending on the nature of the compulsive behaviour under investigation) with extreme behaviours from a cohort with a very similar history, may it be related to handling, behavioural training, housing conditions or surgery and peri-operative care.

To this aim, we have developed highly standardized procedures and high throughput surgical techniques under aseptic conditions. The latter is also very important for ensuring that catheter/cannulae/probes life expectancy of the animals undergoing surgery first is not reduced by the number of days of surgery spent on subsequent animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project, we will use several animal models and methods, the combination of which will enable us to identify the factors of vulnerability to develop compulsive disorders across a wide range of conditions and their biological basis in the brain.

Our methods mostly rely on awake, freely moving animals performing complex behavioural tasks for rewards (e.g., food, or drugs of abuse) and are subject to invasive recordings or manipulations of the brain while performing these tasks.

We are fully committed to minimising the cumulative severity of all our procedures as much as possible and have been constantly refining all our procedures in order to minimise the distress to which our animals are subjected.

We will use models of inter-differences in impulse control (high impulsivity trait), Obsessive-Compulsive Disorder, drug (alcohol, cocaine, heroin….) addiction and Parkinson's Disease.

We have, over the years, refined our models so that we can study the psychological and biological basis of profoundly debilitating and distressing disorders in humans such as OCD or addiction, with minimal adverse consequences in our rats.

In the case of OCD for instance, rats tend to display compulsive behaviours for no longer than 1 hour per day, and these have overall no other negative consequences. To study Obsessive-compulsive Disorder, we primarily rely on a procedure that requires rats to be food deprived to 80% of their free- feeding body weight. These rats are absolutely fine and display no behavioural or physiological signs of distress. Alternatives, such as genetically engineered SAPAP mouse, display profound adverse phenotypes such as excessive self-grooming-induced skin lesions.

When rats are food restricted, they often need to be singly housed as the dominant would otherwise experience no food restriction and the expense of the subordinate. Similarly, when rats have received intrajugular and/or intracranial implants, they often need to the single housed in order to prevent them from playing with and damaging each other's implant.

Isolated animals tend to gain more weight than controls; they are more responsive to stimuli predicting reward (in specific behavioural tests) and are hyperactive as measured by specific behavioural tasks. Additionally, we have shown that rats raised in an enriched environment are more vulnerable to develop compulsive disorders. Indeed, we have demonstrated that rats raised in a highly enriched environment are less likely to engage in high levels of cocaine self-administration than rats raised in standard conditions, but instead, they demonstrated higher vulnerability to switch from controlled cocaine intake to addiction. Thus, of all the 48 rats (24 from a standard condition, 24 from an enriched environment) trained to self-administer cocaine for over 80 days in this experiment, 6 became addicted to cocaine, and they were all from the enriched environment. In addition, we demonstrated that the exacerbation of the vulnerability to develop compulsive drug use in rats by environmental enrichment generalised to alcohol since rats raised in an enriched environment are more likely than rats raised in a standard environment to relapse to alcohol drinking after abstinence and to compulsively do so, in that they would persist in drinking alcohol at relapse even if it is adulterated by the bitter tastant quinine.

For drug addiction, we implemented procedures that enable us to measure the compulsive nature of drug seeking and taking that characterises addiction (in other words the drug is used despite disastrous negative consequences for the user and their relatives/carers) without overall harm to the animal. To study drug addiction, rats initially trained to self-administer drugs through an indwelling catheter implanted into their jugular vein. We have refined this procedure so that it lasts no more than 10 minutes and rats recover very rapidly with no signs of distress. All our surgeries are performed under aseptic conditions and rats are given appropriate analgesia prior to, during, and after the surgery. There are no alternatives to the use of these procedures, but our constant refinement has helped us achieve an attrition rate of almost 0% by 80 days of daily training while the average worldwide is over 5% by two weeks, with only two other laboratories in the world reporting

chronic self-administration experiments lasting more than 6 weeks, but with an attrition rate of over 15%.

For Parkinson's Disease, the procedures we use enable the rats quickly to recover from the initial motivational effects of the sudden development of the condition and ensure they do not develop too profound a motor deficit.

We use a wide array of methods in our research. One is the testing of rats in behavioural tasks in which they are given the opportunity to solve puzzles, work (press levers) to obtain food rewards. These tasks, that are designed to investigate specific psychological or behavioural mechanisms, are not regulated, meaning they do not cause any distress or harm to the animal. However, it can be the case that rats have to be slightly food restricted to engage with the task. In that case food is delivered every day following the behavioural session. Food is given in quantities large enough to maintain the animal body weight between 90 and 100% of their free-feeding weight. It is also better for the animal's health as there is strong evidence that as in humans, free-feeding, in rats results in decreased longevity.

We will use systemic administration of drugs either through experimenter-delivered injections, or via previously implanted subcutaneous minipumps or slow-release formulations (like some forms of pills in humans). In this case, each drug will be prepared with double distilled water or sterile vehicle, in autoclaved glassware and subsequently filtered prior to use. Dosing procedures will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm and is the minimum consistent with the scientific objectives.
We have implemented specific methods to deliver intraperitoneal injections to rats without restraining and stressing them and only highly trained researchers perform these injections.

We will use blood sampling procedures. In that case, no more than 10% of total blood volume in 24hrs and 15% of total blood volume in any 28-day period will be taken.

We will use methods designed to measure or manipulate the activity of specific brain areas while rats are behaving, and/or expressing OCD, drug addiction, impulsivity. For this, we need to insert probes, electrodes inside the brain that can be connected to external devices that enable the measurement of brain function. We also rely on pharmacological manipulations of brain functions and for this cannula are lowered into the brain and we use injectors to infuse tiny amounts of drugs that interfere with a specific brain mechanism inside the brain. We will also use the technology of virus-mediated expression of genes in the brain to measure of control brain function. For all these methods, the surgical procedures are all carried out under aseptic techniques and the rats are habituated to be connected to external devices and are always free to move when connected. We use the least invasive methods drawing in fast-evolving state of the art techniques and systematically ensure to procedures are optimised and refined (which is the very purpose of this project licence) before using them on larger cohorts.

In order to determine the role of stress during neurodevelopment and or adolescence/adulthood, rats will be exposed to maternal separation stress and/or one of two types of stress during adolescence and/or adulthood. Our stress procedures have all been refined and are far superior to alternatives that, for most of them, require exposure to inescapable shocks, restraint and/or forced swimming.

Overall, we are geared towards optimal refinement, from our choice of animals, to our

methods, procedures and skills. First, and foremost, the present licence will enable us to optimise and refine on small groups of rats the intracerebral and pharmacological procedures that will subsequently be used on large experimental groups. The present project licence is therefore a testament to our commitment to refinement.

Additionally, I make sure that we maintain our high standards in order to ensure all our refinements are actually implemented. Thus, I review all procedures and skills of the licenced researchers working in my laboratory, under my supervision, regularly and discuss project licence-related matters at each of my weekly lab meetings.

Why can't you use animals that are less sentient?

Rats are the least sentient organism that enable the measure of inter-individual differences in the behaviours of interest with some individual displaying behavioural manifestations that have high heuristic value with regards to the Impulsive/Compulsive Spectrum disorders we are investigating.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any new procedure, or combination of procedures, used under this project licence will systematically be previously optimised using my dedicated optimisation licence.

All our current procedures are constantly being refined.
When rats have to be singly housed for the purpose of protracted self-administration or behavioural training, not only are they handled at least twice a day, during behavioural training, at least 5 days a week (in average), but they are also brought to test boxes several hours per day, at least five days a week.

We have experimental evidence that these housing conditions, as opposed to so-called enriched environments, do actually protect rats from developing disabling compulsive disorders such as addiction to cocaine. Thus, our recent work on environmental enrichment has actually shed new light on the rather anthropomorphic view of the benefit of enriched environments for rodents, as it is likely more difficult to define what is an enriched environment for rats than it is for humans, for whom the definition is very much specific to each individual. Indeed, we have demonstrated that rats raised in a highly enriched environment are less likely to engage in high levels of cocaine self-administration than rats raised in standard conditions, but instead demonstrated higher vulnerability to switch from controlled cocaine intake to addiction. Thus, of all the 48 rats (24 from a standard condition, 24 from an enriched environment) trained to self-administer cocaine for over 80 days in this experiment, 6 became addicted to cocaine, and they were all from the enriched environment. Similarly, we have shown that environmental enrichment exacerbates the vulnerability to relapse to alcohol drinking and to persist in doing so despite the adulteration of acohol by a bitter tastant such as quinine.

For repeated intraperitoneal injections we ensure that the smallest needles and volumes of pH-neutral injections are used and use procedures we have developed and refined, and validated by our Named Veterinary Surgeon, whereby stress is minimised delivering these injections without restraining the animal.

Each of the unique procedures undertaken under this licence will have previously been optimised and refined, either as part of our ongoing refinement strategy or using my optimisation licence. Thus, rats on this licence undergo neural manipulations (brain

surgery) and/or implantation of intravenous catheters for long-term self-administration of drugs of abuse that will have been systematically optimised. Indeed, we take great care to minimise suffering following surgical procedures and minimise the risk of infection and/or catheter damage by using the most elaborate techniques (the present licence is actually designed further to optimise each bespoke intracranial manipulation to further decrease its potential impact on the animals) that have been developed and constantly refined in collaboration with the Named Veterinary Surgeon.

We routinely administer peri-operative analgesia (i.e., pain killers after surgery) and use scoring sheets to monitor animal welfare for a minimum of three days post-surgery. The specific analgesics used varies between different types of experiment and the strategies we have now in place to ensure continuous analgesia through the perioperative period have been designed with the Named Veterinary Surgeon.

We have been investing a lot of time and effort in refining our skills, techniques, procedures and equipment, and we will continue to do so over the next five years. Over the past years, we have developed and refined, together with our Named Veterinary Surgeon, a scale to enable the daily monitoring (using an electronic reporting system we have also implanted and refined) of the status of the back-mounted cannulae ports in rats trained to self-administer drugs. We have also substantially improved our aseptic techniques adopted from the principles of the Laboratory Animal Science Association (LASA) guidelines, to comply with our high throughput requirements.
We have progressively engineered a better catheter for self-administration experiments. Relying on a stepwise, iterative empirical strategy, we have decreased the size of the mesh that is inserted under the skin to secure the port, in order to decrease the surface it occupies under the skin, hence the risk of irritation and physical damage to the surrounding tissue. Having verified, in collaboration with the Named Veterinary Surgeon that this change yielded positive outcomes in terms of damage to the skin around the port, we then increased the rigidity of that mesh to stop it being grabbed and stretched by the rats, which on some occasions resulted in local irritation. Having observed another improvement, we then decreased the diameter of the port cannula (tube) which reduced the overall size of the device.

We predominantly use Sprague Dawley rats, and not the Lister-Hooded strain which was historically used, as the former demonstrate fewer skin lesions, and tolerate the effects of long-term drug exposure better than the latter. The very low incidence (actually the absence) of adverse effects around ports in 200 rats that had the new monitoring procedure illustrates the improvements made by my laboratory and we will endeavour to further the refinement of this, as well as all the other procedures used in my laboratory. All improvements will be disseminated as widely as possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our research is constantly guided by, and adheres to the Laboratory Animal Science Association (LASA), the PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) and the ARRIVE (Animal Research: Reporting In Vivo Experiments) Guidelines. Not only do we follow the LASA guiding principles of aseptic surgery (http://www.lasa.co.uk/wp-content/uploads/2017/04/ Aseptic-surgery-final.pdf), but we have furthered these principles wherever possible as part of our constant refinement strategy, especially in the case of intra-jugular catheter implantation procedures.

We will receive direct updates on best practice from the N3CRs as I have subscribed to their mailing list.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have several lines of information that enable me to stay informed about advances in the 3Rs in order to implement them effectively.

First, I have registered to the NC3Rs newsletter and follow them on Twitter.

Secondly, as all the project licence holders at our establishment, I receive tremendous support from the staff at the establishment, and I receive regular critical updates from the Named Information and Compliance Officer to which I pay the utmost attention and that I share with all the members of my lab.

I hold project licence-related workshops at least twice a year with all the members of my laboratory to discuss the changes in procedures.

I have an excellent working relationship with the animal care staff in my animal facility, which facilitates the implementation of advances in the 3Rs.

109. Development of peptide drug conjugates for cancer therapy

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph b

Key words

cancer, pancreatic, glioblastoma, therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

All the cells that make up a human have an outer layer (the cell membrane), a little like a very strong soap bubble, that is made up of a mixture of different building blocks (lipids). Scientists have collected a lot of data over the last 10 years that indicate that the outer layers of cells in cancer tumours have different building blocks from healthy cells. The aim of this project is to see if it is possible to make cancer drugs which can stick only to these unusual building blocks and not to the building blocks seen in normal healthy cells. If this is possible then we can use them to target cancer therapies only to a patient’s tumour so that they don’t suffer from serious side effects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a very common illness: one in every two people will suffer from it at some point in their lives. Even though many treatments have been discovered and some types of

tumours are now treatable people still suffer from unpleasant side effects. In addition, there are many types of cancer which are still as serious now as they were more than 40 years ago as they have proven difficult to treat well.
Pancreatic cancer is an example of one of these. Only 7% of people who are diagnosed with pancreatic cancer are still alive after 5 years.

From information we have gathered so far, we think that potential cancer drugs which target the differences in the outer layer of tumour cells could work very well for most cancers but particularly for pancreatic cancer and for cancers which have come back after being treated with currently available medicines.

What outputs do you think you will see at the end of this project?

The work we have planned for this project is designed to answer the following questions:

Do our potential cancer drugs only go to tumours and not to healthy parts of the body?

If they only go to tumours, do they shrink or get rid of the tumour?

Are they likely to be safe enough to be tested in human volunteers?

This information will help us decide if it is worth developing these molecules further towards becoming a drug that can be available to people suffering from cancer.

Who or what will benefit from these outputs, and how?

In the short term (1 - 2 years), our work will help scientists decide if this is a way of treating cancer that deserves further investigation. This will be a benefit to us as it will allow us to decide whether to focus time and money here or to investigate other potential treatments. In a medium term (3-5 years) we will be able to publish our results, either negative or positive, to allow other researchers to benefit from the
data generated which may lead to new ideas but also prevent others repeating work unnecessarily. These results will also form part of the information which helps scientists decide if the molecules are safe and effective enough to be tested in volunteers with cancer, giving patients early access to new medicines. In the long term (6 - 10 years), after further development and trials in humans, positive results in these studies could be developed into a new way of treating cancer which will benefit patients with difficult to treat tumours or cancer that has come back after treatment.

How will you look to maximise the outputs of this work?

We are collaborating on this work with two academic groups in the UK and will be sharing our results through these collaborations as well as by publication of results. We are also seconding researchers to one of these institutions so that they can share the methods and techniques we are developing.

If the project is successful, we will license the project to a drug developer to ensure the research has a high chance of resulting in improved medicines for cancer patients.

Species and numbers of animals expected to be used

- Mice: 870

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have already tested our potential medicine (compounds) on cancer cells in the laboratory and have found that the compounds attach to cancer cells, but not to normal cells and do not appear to damage normal cells. We now need to test the compounds in a way that is more similar to treating a tumour in a human patient. The options for this are to use a laboratory animal such as a zebra fish or a mouse. We have chosen to do this study in adult mice as previous work in the scientific community has used this model. This means we have a higher confidence that we will generate useful information and that we can compare our results to other scientists' work to make sure that we understand the results.

Typically, what will be done to an animal used in your project?

Typically, the mouse will be injected with some tumour cells just under the skin on its side. As this is expected to cause discomfort the mouse will be given anaesthetic. After about one to three weeks the tumour will have grown to approximately 5 to 12 mm in diameter. At this point a solution of the compound will be injected into the mouse. The mice will then be humanely killed after 0, 30 and 60 minutes (or similar). The tumour and other parts of the mouse will be dissected and examined to see if the test drug is going to the tumour. Alternatively, the mice will be monitored for two to three weeks after having the drug to see if the tumour stops growing, gets smaller or disappears. At the end of this period, the mice will be humanely killed and the tumour and tissues analysed to look at the effect of the drug.

What are the expected impacts and/or adverse effects for the animals during your project?

When the mice are injected either with tumour cells or the compound we are testing, they will experience brief discomfort similar to that which a person might feel when getting a vaccination. As part of the study, the mice will grow tumours just under the skin. We do not expect these to grow large enough to cause the mouse significant illness. Some mice will also be treated with cancer medicines which may cause them to feel unwell in a similar way to a human cancer patient. At the end of the study each mouse will be humanely killed in a way designed to cause the minimum of stress or discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?
Most of the mice (estimated 75%) will experience mild procedures (causing only brief discomfort like a vaccination would for a person). The remaining 25% of mice may experience moderate severity, if for example their tumour grows very quickly, or they feel ill from the chemotherapy given to them.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A key aim of the project is to determine whether the compounds concentrate in tumours. To be able to investigate this it is important to inject the compounds into a living animal so that we can follow what happens to the compound as it travels around the body. We will then be able to see if the compounds go to the tumour and do not go to the healthy parts of the body.

In addition, we want to check that when the compounds go to the tumour, the tumour is reduced in size. Cancer tumours are very complicated, and it is difficult to accurately reproduce them outside of a living animal.

Which non-animal alternatives did you consider for use in this project?

We have reviewed the published scientific literature to identify potential replacements for animals. We have considered using tumour cells, tumours grown in the laboratory and artificial “bubbles” made with the same building blocks that appear in cancer cell walls (liposomes). As a result, we have used tumour cells and artificial “bubbles” (liposomes) in our own laboratories to conduct experiments before using animals.

Why were they not suitable?

Although laboratory models can give an indication of the behaviour of a compound in an animal or a human, they do not have the full complexity of a living organism and are not accurate representations of a tumour or of normal healthy tissue. For example, tumour cells grown in the laboratory do not have a blood supply and models of healthy cells always have changes which allow them to survive in the laboratory but do not make them a good model of normal cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

We have calculated how many animals are needed for each experiment to make the result reliable and how many experiments we will need to conduct over the next 5 years to achieve the objectives of our research and so fully test whether the drugs we are investigating could help cancer patients.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs Experimental Design Assistant and publications from specialist statisticians working in cancer to develop experimental designs which maximise the information obtained while minimising the number of animals used. This includes studies designed to minimise the variation caused by, for example, differences in cage environment and also designs to test multiple factors in one experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will be getting the mice from a large breeder so that we are only using the animals we need to carry out the study and therefore minimising inefficient breeding which produces too many animals. Prior to starting these studies, we have carried out small pilot studies to identify important factors such as rate of growth of the tumour, how much of the compound to give the mice to see an effect and to check we are able to analyse the results properly.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using mice that have been specially bred to be able to carry tumours made from human cells without it causing them to reject the non-mouse cells. The cells are injected just under the skin. This means that the mouse is not growing tumours inside its organs or bones that could cause it suffering but carries the tumour under the skin on its side. This model causes the least amount of suffering to the mouse but gives useful data as the tumour is made of human cells.

Why can’t you use animals that are less sentient?

We have considered using flies or fish, but it is difficult to implant human tumours into these animals. The adult mouse is a mammal with a similar biology to humans and makes a more accurate model and will generate more meaningful data.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will make sure the mice are given time to get used to being handled so that injections and blood samples are as stress free as possible. Any animals that do not adapt to handling will be removed from the study. Where pain is likely to be experienced, we will use anaesthetic. The growth of the tumour will be monitored so that it does not grow big enough to cause the animal distress. We will also monitor the weight and condition of the animals and any showing signs of ill health will be humanely killed. Animals will be housed

in small groups in cages with comfortable bedding and nesting materials as well as shelters and toys so that they are comfortable and occupied when not being studied.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow “ARRIVE” and “PREPARE” guidelines which have been written to assist scientist to conduct good quality studies and to share the results. We will use the LASA “Administration of Substances Guidelines” and the “Code of Practice for the Housing and Care of Animals Bred, Supplied and Used for Scientific Purposes” to ensure the animals are well cared for. In addition, we are following the recommendations set down in “Guidelines for the welfare and use of animals in cancer research” published by P Workman in the British Journal of Cancer in 2010.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will review the scientific literature every three months to identify any new work which we could use to reduce or refine the study we are carrying out. In addition, we will be advised by our local animal welfare committee (AWERB), training officer (NTCO), named information office (NIO) and vet (NVS) and review the newsletters originating from organisations such as NC3Rs.

110. Haematopoietic stem cell mechanisms and therapies

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Haematopoietic stem cells, Blood cell production, Haematological diseases, Aging, Cell and gene therapy

Animal types	Life stages
Mice	adult, embryo, aged, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to discover novel biological and genetic regulators of blood-forming haematopoietic stem cells, define how genetic mutations alter haematopoietic stem cell activity, and identify new approaches to use haematopoietic stem cells in cell and gene therapies. The ultimate goal is to develop new stem cell-based therapeutic strategies for haematological diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work has the potential to improve the treatment options and even cure (or prevent) many haematological diseases. This includes a range of haematological malignancies and

age-related diseases (e.g., myelodysplastic syndrome, acute myeloid leukaemia) as well as inherited blood diseases (e.g., sickle cell disease, immunodeficiencies, Fanconi anaemia). Together, haematological diseases represent a major disease burden worldwide, and there are few safe curative treatment options available for most blood diseases.

What outputs do you think you will see at the end of this project?

The outputs of this project are expected be:

Discover new biological and genetic regulators of blood stem cells self-renewal and multipotency

Establish new therapeutic approaches to treat and cure haematological diseases

Contribute to peer-reviewed publications

Generate pre-clinical data to support the initiation of clinical trials

Who or what will benefit from these outputs, and how?

Beneficiaries of these outputs will be:

Biomedical researchers. Through peer-reviewed publication and dissemination of our findings from this project, we hope to help other researchers (interested in stem cell biology, haematological diseases, and/or cell and gene therapies) make further discoveries and technical advances in this field.

Patients suffering from haematological disease. We hope that this work will ultimately benefit patients through provide new and safer clinical treatment options.

How will you look to maximise the outputs of this work?

The outputs of this work will be maximised by:

Peer-review publication. We will publish our findings and approaches in peer-reviewed publications in order to share our discoveries with the biomedical research community and public. This will include unsuccessful approaches to help other research avoid repeating our work.

Presentation at scientific meetings. To further disseminate our findings within the biomedical community, we will present our work at scientific meetings.

Collaborations. We will actively collaborate with other academic biomedical researchers to share knowledge and expertise from our project. Synergistic collaborations can be powerful way to maximise research productivity. Where appropriate, we will also collaborate with industry.

Intellectual property protection. Where appropriate, we will protect intellectual property from this project through our technology transfer office. This will help to maximise the benefit of the research and allow for external investment to fully develop new therapeutic approaches while disclosing the intellectual property with the public.

Species and numbers of animals expected to be used

- Mice: 15000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are one of the least sentient mammalian species. As we are investigating the mammalian haematopoietic and immune systems, simpler animal species cannot be used. Additionally, decades of scientific research and development mean that numerous mouse experimental protocols (cell type markers, culture protocols, genetic engineering methods, etc.) are readily available and we can maximise the welfare of these animals in our experiments. To avoid confounding effects of puberty, we use 8-12 week old mice as "young adults". For experiments where we are investigating aging, we use ~18-month old mice as "aged adults". Use of these timepoints also allow us to compare our results with historical datasets, which have used these ages.

Typically, what will be done to an animal used in your project?

Typical animal experiments used in this project will be:

Breeding and maintenance of mice, including breeding of genetically altered mice. Most of these mice will be killed for harvesting haematopoietic cells. Some mice will be used for breeding and then killed, or used as recipient in transplantation assays (see below). Transplantation assays. This involves injecting donor haematopoietic cells into a recipient mouse. In some cases, the recipient mice will be pre-conditioned using radiation to help support donor cell engraftment. Donor cells are tracked over time through periodic bleeding of the recipient mice. At the endpoint, recipient mice are killed to allow for bone marrow and organ analysis. Transplantation assays can be performed using mouse or human cells.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts and/or adverse effects for the animals on this project are:

We will be using genetically altered animals as models of human diseases, e.g., Fanconi anaemia and sickle cell disease. Complications from these diseases are expected in a small number of cases and can lead to death; these mice will be killed.

The radiation used to pre-condition mice in transplantation assays causes radiation damage. In most cases, this causes a transient radiation sickness and weight loss at 1-2 weeks post-treatment, from which the mice recover. On very rare occasions, this can cause death. Mice that do not recover will be killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 35% subthreshold, 60% mild, 5% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project needs to use animals because:

Haematopoiesis (blood formation) is a complex cellular process that requires numerous local and systemic signals from the bone marrow microenvironment and other tissues, that cannot be accurately modelled in vitro or in silico.

The functional potential of haematopoietic stem cells can only be determined by assessing their activity in transplantation assays. Haematopoietic stem cells currently cannot be generated through in vitro methods.

Which non-animal alternatives did you consider for use in this project?

We considered in vitro assays as alternatives for this project including in vitro use of haematopoietic cell lines and in vitro differentiation of pluripotent stem cells into haematopoietic cells. We also considered ex vivo culture of primary haematopoietic cells and in vitro colony forming assays to assess differentiation potential. All methods will be used where appropriate to reduce the use of animals.
However, none of these alternative methods can fully replace the use of animals.

Why were they not suitable?

In vitro haematopoietic cell lines are not suitable because they are transformed (cancer) cell lines that do not recapitulate the normal activities of primary haematopoietic stem cells. For example, transformed cell lines are usually genetically abnormal and fail to differentiate.

In vitro pluripotent stem cell differentiation into haematopoietic cells is not suitable because these methods cannot generate functional haematopoietic stem cells. Additionally, these methods generate embryonic-like haematopoietic cells that are distinct from adult haematopoietic cells.

Ex vivo culture of primary haematopoietic cells and in vitro colony forming assays will be used where possible. However, these methods are not suitable to evaluate the full functional activity of haematopoietic stem cells, which are defined by their ability to reconstitute the entire blood and immune system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experimental cohort sizes will be estimated based on previous experience with these experiments. Breeding calculations have been utilised to estimate the number of animals required to produce cohorts of relevant genotypes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

This programme will take advance of recent developments in ex vivo expansion culture technology for mouse haematopoietic stem cells. This new technology allows us to expand haematopoietic stem cells ~900-fold and therefore substantially reduces the number of donor animals required for HSC isolation. The NC3R's Experimental Design Assistant was used during the experimental design of this project.

We will comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines) when publishing the work coming from this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Measures to optimise the number of animals planned to be used in the project include:

For commonly used inbred mouse strains (such as C57Bl6/J and its CD45.1 allotypic derivative), we will purchase these mice from centralized breeding colonies. These colonies are maintained at scale and regularly re-started from frozen stock to minimize genetic drift and bottlenecks, thereby maximizing the reproducibility of results over time, reducing the need for repeating experiments.

To minimize the number of animals used, breeding strategies will be optimized to generate as few surplus animals as possible. This will be accomplished by designing crosses that generate experimental and control animals in equal proportions, and as few mice with genotypes that are not useful as is possible.

Cryopreservation will be used where possible to store transgenic mouse colonies without wastage.

When performing irradiation, we will split the dose over two sessions to reduce radiation toxicities.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Inbred wild-type and genetically altered mice will be used in this project. Decades of scientific research and development has established the mouse as the most suitable model for studying haematopoiesis and key procedures such as bone marrow transplantation and genetic modification have been most refined in mouse as compared to other species.

Breeding and maintenance of genetically altered mice: We use standard breeding techniques to maintain genetically altered mice for investigating the genetic regulation of haematopoiesis.
Conditional mutagenesis will be used wherever possible to restrict phenotypes to the relevant cell types and tissues, ensuring that any suffering is minimized.

Bone marrow transplantation assays: Most refined methods available will the used, including use of split dose radiation and use of individually ventilated cages. Additionally, where feasible for the experimental goals, we will perform transplantation assays without the use of irradiation (the most toxic step of the procedure), e.g., by using antibody-mediated conditioning or performing transplantation in the non-conditioned setting.

Why can’t you use animals that are less sentient?

Mice are one of the least sentient mammalian species. As we are investigating the mammalian haematopoietic and immune systems, simpler animal species cannot be used. Additionally, decades of scientific research and development mean that numerous mouse experimental protocols (cell type markers, culture protocols, genetic engineering methods, etc.) are readily available and we can maximise the welfare of these animals in our experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To refine the procedures to minimise the welfare costs for the animals in the breeding and maintenance of genetically altered animals, we will:

Closely monitor genetically altered mice for signs of disease presentation or pain. Mice will be killed where pain cannot be managed. Mice will be weighed regularly to detect weight loss.

Where possible, minimise breeding to reduce animal wastage.

To refine the procedures to minimise the welfare costs for the animals in bone marrow transplantation assays, we will:

Closely monitor recipient mice following radiation for signs of pain and distress. Mice will be killed where pain cannot be managed. Mice will be weighed regularly to detect weight loss.

Where possible, avoid use of radiation. This may be through the development and use of antibody- mediated conditioning. In certain cases, we will perform non-conditioned transplantation assays.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published best practice guidance available here: www.nc3rs.org.uk https://norecopa.no https://www.lasa.co.uk. We will also regularly consult with our Named Information Officer, Named Veterinary Surgeon, and Named Animal Care and Welfare Officer to ensure our best practice guidance remains up to date.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs through:

Attending internal 3R meetings

Regularly read the latest literature

Regularly check up on the NC3Rs website

Regularly interact with the NC3R's regional manager and our Named Information Officer

Where relevant advances in the field occur, we will seek to effectively implement them during the project through revising our approved animal protocols. New techniques will be initially piloted to compare it with the establish technique. Where the new technique successfully refines our protocol, these will be implemented.

111. Parasite culturing in farm animals and farm birds, excluding coccidia

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Parasite culture, Liver fluke, Parasitic nematode, Ectoparasites, Protozoa

Animal types	Life stages
Cattle	juvenile, adult
Sheep	juvenile, adult
Goats	adult, juvenile
Pigs	adult, juvenile
Domestic fowl (Gallus gallus domesticus)	adult, juvenile
Domestic poultry	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to provide a service to commercial clients (in addition to our ‘in-house’ research groups) for the supply of parasites for use as controls in veterinary diagnostic testing, quality assurance, and research projects requiring such materials.

In order to ensure the parasite production complies with ASPA, we will:

Determine whether the parasites required are to be used for a qualifying purpose;

Determine whether the type and/or quality specification the parasites requires the use of live animals or whether parasites could be supplied from post mortem or from archived material;

Supply timely, high quality samples of parasites that meet the quality specifications for the work;

Refine and/or validate existing/new animal models/techniques in support of 3Rs initiatives and the purpose of this project.

This will be achieved using a client request form, the information provided being first reviewed by the PPL Holder for acceptability and conformance with a pre-agreed list with the AWERB, to help ensure compliance with the terms of the licence and to ASPA. Specifically, the client request form will identify the particular background, objectives and potential benefit of each request. The purpose for which the service is provided will be for a permissible purpose under ASPA and is specified in the project licence. An example of the Request form template has been uploaded as an attached document in ASPeL and includes the questions that will be asked of clients to inform our decisions about the suitability of their request.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Organisations conducting research on parasites can access a source of parasites with known origin and characterisation. The parasites cultured are of high quality, pure cultures and produced with high welfare standards.

What outputs do you think you will see at the end of this project?

Financial income for the company which will enable us to carry out further contract research projects involving parasites. We contribute to fundamental research which is used at world class institutes via the publication of scientific papers. We contribute to the understanding and control of liver fluke and produce material for use by other external customers.

Who or what will benefit from these outputs, and how?

We will benefit through the income generated by the use of cultured parasites in internal research projects and also by selling cultures to external customers. Research institutes, commercial businesses, farmers and animals via new products will all benefit from culturing work being carried out.

How will you look to maximise the outputs of this work?

We collaborate with academic organisations, publish scientific papers, attend relevant conferences and we play an active role in creating guidelines in this area of research.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 200
- Other birds: No answer provided

- Cattle: 40
- Sheep: 250
- Pigs: 15

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

No in vitro substitute for the host species currently exist to successfully culture the desired pathogens for in house use and external consumer use. We normally use young, weaned animals as they are the most naive to the parasite infection but produce the maximum yield with fewer adverse effects.

Typically, what will be done to an animal used in your project?

Infected orally, in feed, water or using a gavage. Infected via the skin for ectoparasites and the nematode Bunostomum in cattle. The host animals will be maintained to allow parasite development. The parasites will normally be recovered either at post mortem, via skin scrape or brush or from the faeces.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of our helminth experimental models are well developed and aim to allow the animals to remain clinically and behaviourally normal. When using a new parasite a new experimental model may be developed and we may encounter effects within the mild category. The duration of these effects could be several weeks meaning the severity category could increase to moderate.

Likely adverse effects and likely incidence:

The levels of infection/infestation chosen should not cause clinical disease of beyond mild but the duration ofinfection may increase severity to moderate.

Withdrawal of feed could result in stress to individual animals.

As far as possible, ectoparasite infestations will be maintained within the mild category, but work particularly with mites and blow flies, despite being carefully controlled, may be moderate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild and moderate. 40% mild. 60% moderate (see full breakdown in protocols). The maximum expected severity is moderate with any animals that reach this threshold being treated or euthanased as appropriate before they reach the severe threshold.

Animal types	Est. numbers (mild)	Est. numbers (mod)	Life stages
cattle	16	24	Adult and Juvenile
sheep	100	150	Adult and Juvenile
pigs	6	9	Adult and Juvenile
birds	230	345	Adult, Neonate, Juvenile

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not entirely possible to raise the parasite species outside of its host organism. We continue to look at NC3Rs website and relevant literature to assess if any non-animal alternatives are available.

At present there is no in vitro substitute for host species. We normally use young weaned animals as they are the most naive to the parasites but produce maximum yield with less adverse effects.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use a combination of tools to estimate the numbers of animals needed. This normally includes the NC3Rs Experimental Design Assistant, VICH and WAAVP guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used.

Peer-reviewed journals and advice from external peers together with in-house experience and historical data over a number of years is used to ensure that animal numbers are adequate.

We are fully committed to reduction, nonetheless the exact numbers of animals required will vary with the particular project needs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have many years of experience of parasite culturing and historical yield data from host animals to ensure the minimum number of animals are being used. Due to our experience we have highly optimised the process of culturing and storage of parasites to maintain higher parasite yields. We also utilise the NC3Rs Experimental Design Assistant, VICH and WAAVP guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We only produce as many parasite infected animals as we need to maintain our own parasite stock collections or produce as much as is required for a customers' order. We will not unnecessarily use animals in this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use animal models designed not to produce any clinical signs as far as possible, thus the severity category is within the mild or moderate bracket. We try to use in feed methods of helminth parasite administration to reduce animal stress and we allow a period of time for the animals to become accustomed to procedures before starting, for example, wearing a dung collection nappy prior to the collection starting. Refinement of animal experimentation through defined animal welfare codes covering husbandry conditions, regular health checks, appropriate therapy, defined end points and other areas will be developed. Where necessary we slaughter animals using schedule 1 of the establishment licence (XFD0F8970) or other permitted methods contained within the establishment licence.

The severity levels achieved are predictable and are designed to minimise adverse reactions. We refine and/or validate existing/new animal models/techniques in support of 3Rs initiatives and the purpose of this project.

With ectoparasite infestations, where necessary parasite populations can be partly removed to reduce severity.

Why can't you use animals that are less sentient?

We have to use these hosts due to the nature of our parasites being passaged through their natural hosts. However the design of our experimental models mean that the severity to the animals is maintained at sub-threshold/ mild with helminth infections, and as low as possible for ectoparasite infections.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We minimise suffering by examining each planned culturing activity to identify opportunities to reduce handling by, for example, using experienced and knowledgeable staff, habituating animals to procedures where necessary, meeting or exceeding codes of practice and current guidance or literature suggestions for enrichment.

The animals used are the target species for the desired parasite to be cultured. In addition, animals will have a heightened level of observations immediately after and in the days following administration of any substance and/or parasite. Our standard level of monitoring is a minimum of twice daily. Frequency of observations are increased on an as needed basis based on animal observations and behaviour. For example, observation frequency would increase to hourly, overnight monitoring following the appearance of clinical signs associated with parasitic infection. Observations would normally be general health observations but these are supplemented with clinical observations by our NVS (or similar), monitoring of temperature and other parameters as necessary.

If it is believed an animal is approaching and likely to breach the predetermined severity category then we have a well-established process. This includes seeking veterinary advice from our NVS or another veterinary surgeon, discussions with the NACWOs, PELh, PPLh, PILh and Study Investigator. This group of people decide the best next steps in terms of animal welfare. This could be either, immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, and increased monitoring if the animal is unlikely to breach the severity limit by the conclusion of the study if appropriate.
If an animal breaches the predetermined severity category for the study then immediate action is taken. This often includes rapid discussions with the NVS, PELh, PPLh and PILh alongside the study investigator. We would also, if possible, contact an ASRU inspector. The course of action could be immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, maintaining and closely monitoring the animal if the scientific need is justified and the end of the study is within a short time frame, if agreed by an ASRU inspector. All decisions are taken on a study by study basis and will differ with treatments and species.

We will also continually review our procedures and refine as much as possible with guidance from, for example, VICH, EMA, WAAVP, and other relevant organisations and published literature.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

World Association for the Advancement of Veterinary Parasitology (WAAVP) guidelines for best practice. These guidelines are now seen by most regulatory authorities as the standard by which parasite-related protocols are written, and consider numbers of parasites required for study purposes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly reference the NC3Rs website, published literature, attend relevant conferences and employees are members of The Royal Society of Biology and other relevant organisations.

112. Evaluation of new treatments for polycystic kidney disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Kidney, Treatments, Cysts, Genetics

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to identify novel therapeutic strategies to treat Polycystic kidney disease. Treatments are tested for their ability to reverse or slow down kidney cyst formation and improve overall kidney function. The aim is to also minimise adverse effects compared with current therapies, in order to improve the quality of life for PKD patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Polycystic kidney disease (PKD) is a debilitating disorder characterised by progressive kidney cyst formation leading to end stage renal failure. It affects about 70000 adults and children in the UK and accounts for 1 in 8 people in need of a kidney transplant. This work is expected to provide new information on mechanisms regulating kidney cyst formation, which will be used to identify new therapies with better efficacy and fewer side effects. As well as improving symptoms of the disease, the hope is to delay the progression to end stage renal failure, therefore negating the need for a kidney transplant.
What outputs do you think you will see at the end of this project?

This work is expected to provide new information on mechanisms regulating kidney cyst formation, which will be used to identify new therapies with better efficacy and fewer side effects. This project is key to triaging compounds discovered within the company for efficacy and tolerability in the whole animal system, a key step before potential testing in man.

Who or what will benefit from these outputs, and how?

Ultimately kidney disease patients will benefit from this project, improving their quality of life. This will hopefully translate as improving symptoms of the disease and delaying the progression to end stage renal failure, therefore negating the need for a kidney transplant. Data generated will also feed back into the research cycle to optimise drug candidates going forward.

How will you look to maximise the outputs of this work?

Findings will be made available to other company scientists at presentations and internal meetings to further our understanding of the disease. We will take as many tissues as possible at study end which will be made available to other company researchers, allowing the maximum amount of data to be generated from the animals.

Species and numbers of animals expected to be used

- Mice: 22000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use both neonatal and adult mice. It is known that cysts are already present in the foetus in severe cases of PKD, so it is therefore important to study how age affects disease progression, and how intervention with a therapeutic can affect the symptoms at these different life stages.

Mice will be used as the broad anatomy and physiology of this species is well understood and provides the best compromise in terms of correlating with human biology whilst exhibiting the lowest level of sentience.

Typically, what will be done to an animal used in your project?

Mice will typically receive injections of therapeutic to investigate the effects on reducing cyst burden in the kidney. These injections will be typically sub-cutaneous as we need to dose over the course of the disease. This may be for a couple of weeks in a short aggressive model, or up to 3 months in a longer chronic model. Total kidney volume can be measured non-invasively and longitudinally every month, to track the disease course.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice are expected to experience transient pain from injection of therapeutic agents. Imaging techniques to track disease progression are painless, but animals are briefly anaesthetised for these procedures so imaging is performed as infrequently as possible. As kidney disease develops and affects the wellbeing of the animal, especially in the quicker models, weight loss may become a concern. This is monitored and the animal humanely culled if it drops below a threshold.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - Moderate - 40% Mild - 60%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Polycystic kidney disease (PKD) animal models are required to assess the effect of a test compound on kidney cyst formation, total kidney volume and global renal function.

Cell and ex-vivo assays can give a good indication of the potential ability of a compound to modulate the formation of cysts, but they cannot fully predict in vivo efficacy on global renal function or disease progression. In vivo models are therefore an absolute necessity to relate in vitro data to efficacy in order to predict a potential clinical benefit. In addition, how the drug will behave in the body and how it will be broken down, driven by absorption, distribution, metabolism and elimination, cannot be accurately modelled in vitro.

Finally, for PKD, proven in vivo efficacy data is a prerequisite of the regulatory bodies who have the authority to approve or reject a new drug application.

Which non-animal alternatives did you consider for use in this project?

Alternative approaches within the company, including the use of kidney organoids and cell culture to screen compounds for efficacy and toxicity. Human diseased kidney tissue has also provided useful project information. Ex-vivo embryonic kidneys have provided useful screening information but require an animal initially to generate them.

Why were they not suitable?

Cell and ex-vivo assays can give a good indication of the potential ability of a compound to modulate the formation of cysts, but they cannot fully predict in vivo efficacy on global renal function or disease progression. In vivo models are therefore an absolute necessity to

relate in vitro data to efficacy in order to predict a potential clinical benefit. In addition, how the drug will behave in the body and how it will be broken down, driven by absorption, distribution, metabolism and elimination, cannot be accurately modelled solely in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on previous in-house studies. We have extensive experience in using these models and can therefore accurately estimate the number of animals we will need per group to obtain statistically valid results. As we generate more results, we will continually assess group sizes to see whether the number of animals can be further reduced from those currently proposed. We will also use the latest statistical methods for data analysis to keep sample sizes to a minimum.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have made use of all local support including our statistician and the wealth of knowledge from my in vivo colleagues who have years of planning experience. Ultrasound monitoring and measuring of disease burden longitudinally in the same animal has also reduced animal usage, as well as increasing statistical power.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our use of cell culture systems will reduce the number of experiments that need to use live animals. All compounds will be triaged as much as possible through in vitro screens so only the ones with the most favourable chance of success are progressed to the in vivo models. We will conduct pilot experiments where necessary to ensure that our experimental systems are optimised before conducting full cohort studies. Colleagues with expertise in drug metabolism work closely with us, so we can share tissues with them to reduce the total number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Various polycystic kidney disease models will use mice from neonates up to adults, with varying levels of disease severity (from acute to chronic). In the acute model the effect of

treatment on kidney volume and cystic burden is measured from the tissues at a set disease endpoint, allowing for a rapid assessment of therapeutic benefit without long term suffering. Longer chronic models better recapitulate the disease progression in humans, and are therefore necessary to ascertain that our approaches will lead to superior patient benefit than the standard of care in the clinic, tolvaptan. To minimise harm and animal numbers per study, disease progression is monitored longitudinally with ultrasound. Models use human cell implants to assess the efficacy of our therapeutic approaches on human cells, in order to improve translation to man. Before implanting cells under the kidney capsule, which is more invasive, a subcutaneous approach will be used.

Why can’t you use animals that are less sentient?

The models used are based on the gene mutations that have been shown to cause PKD in human patients, therefore improving the likelihood of translation from efficacy observed in these models to the clinic. Moreover, studies in rodents deliver robust, reproducible data and so it is often unnecessary to evaluate efficacy of new compounds in higher species. As we need to monitor disease progression chronically over time it isn't appropriate to perform studies in terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At all stages of the project, we will conduct welfare assessments on the animals to evaluate the impact of procedures. This will determine if any aversive procedures can be minimised without adversely affecting scientific outcomes. We will also seek advice from the named veterinary surgeon and named animal care and welfare officer, as well as other scientists working in the in vivo area. Specific health monitoring paradigms are in place for all models performed under this licence.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will refer to published guidelines issued by NC3Rs and liaise with in vivo colleagues, our named veterinary surgeon and named animal care and welfare officer, to ensure our studies are performed in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will keep up to date by reading scientific articles/attending conferences and liaising with colleagues. I will also liaise frequently with the named veterinary surgeon and named animal care and welfare officer who will give advice on how to implement any advances.

113. The effect of dietary protein restriction on the development of the neuromuscular system

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

protein restriction, skeletal muscle, ageing

Animal types	Life stages
Mice	aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This study is using an established model of reduced pre-natal (i.e. maternal) and postnatal protein intake in mice in order to determine the effect of reduced in utero or early post-natal protein intake on neuromuscular junction structure, muscle fibre number, mass and function in the offspring during ageing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In utero and early postnatal protein restriction are associated with poor ageing, reduced muscle mass and function (termed sarcopenia when it reaches clinically relevant severity) and a shortened lifespan but little is known about the mechanisms involved. Our hypothesis is that in utero and early postnatal protein restriction adversely affects muscle

homeostasis leading to a reduction in the myofibre number and size; this in turn leads to premature sarcopenia.

The research proposed is of high importance as the outcomes of this study will lead to a greater understanding of the role that diet plays on the processes underlying the loss of muscle mass and neuromuscular function in older individuals and hence to the logical development of interventions to correct these processes.

What outputs do you think you will see at the end of this project?

The findings of this project will be published in peer reviewed journals and presented by the applicant at national and international scientific conferences targeted to research audiences interested in nutrition, ageing and frailty in addition to those studying other disorders associated with denervation and muscle atrophy such as motor neurone disease (ALS), diabetes, incontinence.

Who or what will benefit from these outputs, and how?

This research will contribute to the body of scientific knowledge on the processes underlying the involvement of malnutrition in age-related weakness and loss of function of skeletal muscle fibres and motor units and will be of particular interest to those scientists and clinicians researching nutrition, frailty and weakness in the elderly. The current research is also likely to be of interest to researchers studying epigenetic changes related to ageing. In the longer term and in combination with other studies it may lead to a redirection of the approach taken in interventions to maintain skeletal muscle function in elderly humans and animals. It will therefore be of interest to nutritionists, neuromuscular physiologists, gerontologists and clinicians interested in maintaining health in the elderly.

How will you look to maximise the outputs of this work?

The applicant is committed to build and sustain collaborations and currently has multiple active national and international research collaborations. The applicant has published high impact manuscripts in this area and is frequently invited to present at international conferences on skeletal muscle and ageing (e.g. European Society for Free Radical Research, British Society for Research on Ageing). The applicant also regularly gives lay presentations to the public and schools in association with charities such as Age UK and provide material for relevant local and national TV and radio programmes.

Species and numbers of animals expected to be used

- Mice: 12

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These animals continue from a previous study. If not used, all mice will be wasted.

We will study the effects of in utero and post-natal protein restriction on neuromuscular structure and function in older mice.

The mouse is the lowest species that demonstrates comparable nerve-muscle interactions. Hence we have rejected any other animals models that might reflect dietary restriction effects approximating to the same developmental stage in humans.

Most of the intrinsic and extrinsic changes regulating muscle ageing in humans have also been observed in rodents, indicating that mice are models of human sarcopenia. Ageing humans and mice show loss of muscle fibres with ageing, particularly in the muscles proposed for use in this study, including the gastrocnemius, tibialis anterior (TA) and extensor digitorum longus (EDL). Denervation also contributes to loss of muscle mass in humans and rodents and loss of muscle fibres is associated with a loss of motor units in humans and mice.

Typically, what will be done to an animal used in your project?

These animals continue from a previous study and are currently ageing. Mice will be culled at 18 and/or 24 months of age. Some mice will undergo grip strength measurements. This will allow us to determine whether mice exposed to a low protein diet in utero or during lactation develop early onset of sarcopenia.

What are the expected impacts and/or adverse effects for the animals during your project?

Some mice on the low protein diet may show signs of ill health or reduced weight loss in comparison to their respective controls.

Ageing phenotype: Hair loss, sometimes due to over grooming is common in ageing mice especially if they are a BL6 strain or background. It is also noted that genetically-modified transgenic mice with high levels of fluorescence can have problems with skin conditions. This is often recognised by red, inflamed skin that may break due to scratching. Treatments include cleaning area with 1% chlorhexidine solution and applying green clay to soothe skin or prescribed drugs (for example: anti inflammatory, steroid based creams) as prescribed by the vet.

Loss of general condition due to ageing process includes loss of muscle tone, tumours and development of cataracts. Developments of any tumours are a humane end point and the animal must be culled. Cataracts are fine as long as the animal can still eat and drink freely. Such welfare issues can be recognised by piloerection, staring coat, weight loss, slightly hunched appearance and altered gait but still mobile and able to get to food and water freely.

Other adverse effects may be associated with muscle weakness and resulting (sporadically) in change in movement. These will be monitored for through observing the mice daily, weighing the mice. Any significant changes or moderate changes lasting more than 3 days will result in animal cull by an authorised method and tissue collection. At the end of the protocols, animals will be killed using an authorised method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity is expected for more than 50% of the animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due to the nature and complexity of the experimental design and in particular the need to reduce protein intake during pregnancy and during lactation of the offspring it is not possible to use human tissue, therefore the proposal requires the use of in vivo studies in mice. In addition, because of the need to study the interplay between nerve and muscle cells and ageing of post-mitotic tissues, it is not feasible to use a cell culture based approach. Nerve-muscle co-cultures remain immature. It is not possible to imitate the innervation of muscle ex vivo. The rodent is the lowest species that demonstrates comparable nerve-muscle interactions. Mice are the lowest vertebrate group possible in this study and the availability of genetically altered mice will provide definitive data necessary to achieve the objectives for this study. Other species have been considered but deemed unsuitable for these experiments, such as Zebrafish, drosophila or nematode.

Which non-animal alternatives did you consider for use in this project?

Cell culture.

Why were they not suitable?

Ageing is a whole organism phenomenon. The ability to examine the effect of age on muscle structure and function is not possible in cell culture. The alternative is the use of primary culture to generate muscle from aged mice. However, this raises the problem of the lack of a suitable model to perform muscle force measurements in culture. In addition, age-related functional decline is due to loss of individual muscle fibres as well as an atrophy and weakness of remaining fibres. The mechanisms responsible for this are not understood and a cell culture approach would not be possible at this stage.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These animals are currently ageing in order to complete a previous experiment that begun on a previous project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of mice were minimised by performing multiple assessments/analyses on the same mouse. The original proposal was designed with the help of statistical advice to minimise the number of mice used overall.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

These animals will complete previous experiments that begun on a previous project licence where appropriate power calculations and statistical advice was sought. Tissues from these mice will be made available to other researchers and data will be shared.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are chosen for these experiments due to the similar physiology between mouse and human muscle. The mouse is relatively short-lived with an average lifespan of 2 - 3 years, therefore the effect of age on muscle structure and function can be fully documented over a relatively short timescale.

Studies will be undertaken in wild type (WT) mice or mice expressing fluorescent proteins in neuronal cells (with no expression in non-neuronal cells and no apparent toxic effects). The transgenic mice (purchased originally from commercial breeders) express yellow or cyan fluorescent proteins in high levels in motor and sensory neurons, as well as in subsets of central neurons. These lines provide a strong and specific marker of axons and expression is strong from mid-gestational stages, showing 100% expression in motor neurons that allows detailed visualisation of skeletal muscle innervation using confocal microscopy. We have successfully used such transgenic mice in the past.

Why can’t you use animals that are less sentient?
This project will use mice during ageing to complete work from a previous study. Mice are the lowest vertebrate group possible in this study and the availability of genetically altered mice will provide definitive data necessary to achieve the objectives for this study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

A number of check points for minimising animal suffering are included in the protocol design, including clear end points and shortest time necessary. The applicant has considerable experience in all the techniques used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The general experimental designs and methods of analysis of the results have been discussed with University's statistician. To ensure best practice and if unexpected adverse effects arise, advice from the "Home Office Animals in Science Regulatory Unit" will be sought.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The applicant regularly attends workshops organised by NC3Rs in order to stay informed.

114. Sprayed slow-release analgesic for application during abdominal surgery

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Vesicles, Hydrogel, Analgesic, Peritoneum, Abrasion

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main objective of this project is to investigate the safety and efficacy of a single-dose painkiller (analgesic) formulation for its use during abdominal surgery, avoiding significant side effects of commonly used analgesics.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Surgery on the abdomen is painful. It is usually treated by various painkillers (analgesics), which can cause secondary problems (drowsiness, constipation, poor mobility), leading to a slow recovery. Local painkillers can provide short-term pain control at wound sites but do

not target the area of surgery within the abdomen. There is a need for better strategies for controlling pain within the abdominal cavity. Therefore, we will develop a long-acting pain relief spray that remains active at the surgical site in the abdomen. Such a spray should be administered as a single dose directly onto the surgical site and provide continuous pain relief for 5 days.

What outputs do you think you will see at the end of this project?

Our spray analgesic will provide constant pain relief during the whole recovery period following abdominal surgery. This technology can be adapted to any open surgical procedure or site of trauma and adapted for the slow release of other drugs, i.e., chemotherapy. Outputs from the research will add to the general knowledge about alternative methods for providing safe and effective pain relief medication; this information will be published in academic journals to improve scientific knowledge.

Who or what will benefit from these outputs, and how?

The primary beneficiaries from the outputs will be patients undergoing laparoscopic surgery for benign and malignant abdominal conditions. Our sprayed formulation will provide constant pain relief during their hospital stay leading to quicker recovery, fewer complications, and faster return to normal function. Secondary beneficiaries will be healthcare providers. It is estimated that our pain relief medication will help reduce the length of time that patients spend in the hospital from 5 to 3 days, resulting in cost savings of ~£1,300/patient or ~£1.7billion/year to the NHS.

How will you look to maximise the outputs of this work?

We will disseminate the findings to relevant forums through presentations to surgical and pain associations in the UK and publish the results in peer-reviewed journals. The group will undertake various outreach activities to ensure that the general public is aware of the research. This will include presentations to “Pint of Science” and “Be Curious” events organised through the local research institution. To ensure lay people easily understand the relevance of the work, we will use modern forms of communication, such as Visual Abstracts. Engagement with public and patients will be central to the design and conduct of the research to ensure that it remains directly relevant to end-users.

Species and numbers of animals expected to be used

- Mice: Optimisation experiments will be performed on 40 C57BL/6 mice to determine the sample size for the definitive study. The final number of animals for the definitive study is unlikely to exceed 200 in total.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice are a good choice for animal experiments because they have many similarities to humans in terms of anatomy and physiological responses. Less sentient animals cannot

be used because they would not help us to assess the pain relief capabilities of the formulation.

Typically, what will be done to an animal used in your project?

The animals will go through a simulation of abdominal surgery. Animals will undergo laparotomy (opening of the abdomen) under general anaesthesia and a 1cm2 abrasion made to the peritoneum to simulate surgical trauma. Half the animals will have the analgesic formulation applied to the traumatised area; in the other half the area will be left untreated. The abdominal wound will be closed and the animal allowed to recover. Animals will be monitored to ensure their safe recovery and to assess their pain sensations with a validated scoring system. All animals will be euthanized at the end of the 5 day observation period to obtain tissues and fluid samples for further analysis.

A small number of animals in the optimisation experiments will undergo application of gel carrier alone (without painkiller) to confirm that application of the gel alone does not influence postoperative pain. This would be most unlikely given that the gel is a biologically inert material. Inclusion of a gel carrier arm has not been added to the main study as it is unlikely to add any meaningful information and would only serve to unnecessarily increase the sample size of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Possible adverse effects include the failure to provide pain reduction, a bacterial surgical site infection, wound infection and dehiscence, and organ dysfunction resulting from surgery. We will closely monitor for adverse effects and trained personnel will take immediate action to avoid unnecessary harm to the animals. A validated postoperative assessment scoring system will be used to grade the severity of complications and determine a humane end-point for euthanasia (described in the stop/go section). All the animals will be humanely sacrificed at day 5 to obtain different samples from fluids and organs for further analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The proposed methodology is of moderate severity because it involves abdominal surgery. We will require 40 mice for initial optimisation experiments to determine the sample size for a definitive experiment. It is not expected that the final number of animals for the definitive study will exceed 200 mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?
It is only possible to test the safety and efficacy of our formulation in a living biological model which experiences pain. We have previously assessed some inflammation (pain) markers associated with wound healing in the laboratory using cells. These experiments have shown promising results without any bystander toxicity. We need to verify that the results obtained are reproduced in a biological model.

Which non-animal alternatives did you consider for use in this project?

We have previously undertaken in vitro optimisation studies using human cells to detect different inflammation (pain) markers. There is nothing further we can do in vitro to advance our technology. We have considered the option of using less sentient animals, but these will not allow us to properly assess our primary end-point – pain reduction.

Why were they not suitable?

Human cell lines can only provide surrogate markers of pain control, i.e., reduced inflammatory mediators. While this can be considered a good indicator of pain reduction, it cannot be fully verified because pain is a complex sensation in biological systems. An animal model is now needed to understand the safety and efficacy of the formulation.

Reduction

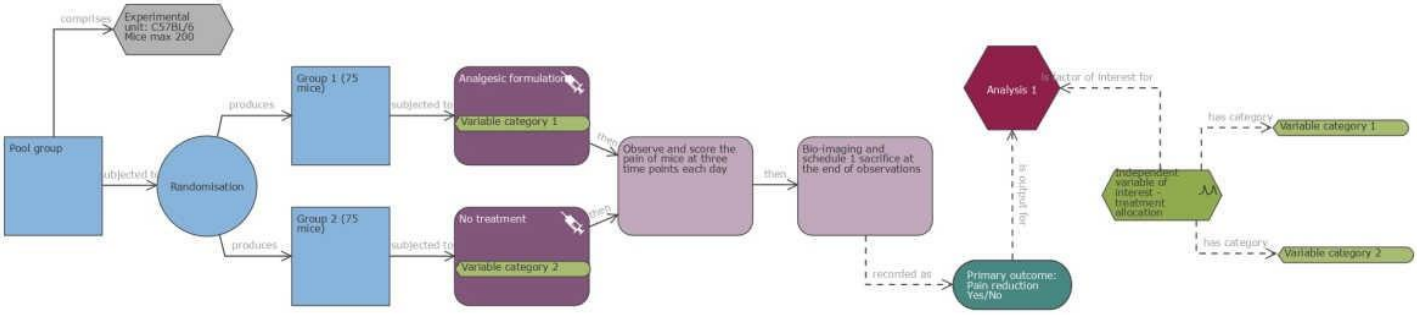
Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have discussed the design of our experiments with biostatisticians to obtain reliable and reproducible data with the fewest possible number of animals. We will first perform optimisation experiments in 40 animals, which will inform the sample size for a definitive study. Based on a 30% reduction in Grimace score on postoperative day 1 or 2 in favour of the intervention group we anticipate a total sample size of approx. 150 animals (75 intervention; 75 control) to demonstrate a statistical difference at 80 power and 5% significance level.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We utilised the NC3Rs experimental design assistant to guide the numbers needed to demonstrate the safety and efficacy of the novel sprayed analgesic formulation in an abrasion mouse model. We have adhered to the 3Rs principles, and up-to-date ARRIVE guidelines to design the experiment. The ideal study design to evaluate efficacy is a randomised controlled trial. In line with the 3Rs of animal research, there will be two groups, the analgesic formulation alone and no treatment, to keep the numbers of mice to a minimum.



What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Training for the model will be performed on approximately 6 schedule 1 mice. Optimisation studies using 40 mice (20 intervention group; 20 control group) will establish the required number of animals for the definitive study. This will include a small number of animals to confirm that the gel carrier does not influence postoperative pain scores. The ideal study design to evaluate efficacy is a randomised controlled trial. In line with the 3Rs of animal research, there will be two main groups, the analgesic formulation and no treatment, to keep the number of mice to a minimum. Randomisation & Blinding: Mice will be randomised using block randomisation through SealedEnvelopeTM at a 1:1 allocation ratio. All mice and samples will be labelled such that researchers assessing the effects of the treatment and analysing the results will be blinded.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice have been chosen for the experiment because they are ideal animal models for biomedical research and comparative medicine. They have many similarities to humans in terms of anatomy and physiology. We will use an abrasion model for the experiments adapted from Brodsky et al. and Kraemer et al. This model allows us to simulate the trauma of abdominal surgery without causing harm to vital organs. It is believed this model provides the least pain, suffering, distress, and lasting damage to the fewest number of animals, whilst still enabling us to adequately assess pain reduction associated with our formulation.

Brodsky, J. A., Brody, F. J., Endlich, B., Armstrong, D. A., Ponsky, J. L., & Hamilton, I. A. (2002). MCP-1 is highly expressed in peritoneum following midline laparotomy with peritoneal abrasion in a murine model. Surgical Endoscopy, 16(7), 1079–1082. doi:10.1007/s00464-001-8335-z

Kraemer, B., Wallwiener, C., Rajab, T. K., Brochhausen, C., Wallwiener, M., & Rothmund, R. (2014). Standardised Models for Inducing Experimental Peritoneal Adhesions in Female Rats. BioMed Research International, 2014, 1–8. doi:10.1155/2014/435056

Why can’t you use animals that are less sentient?

Less sentient animals would not help us assess the pain relief capabilities of our analgesic formulation due to their lack of nervous system. If the mice were terminally anaesthetised, we would not be able to measure the healing effects of the intervention at the required post-operative stage.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be reviewed regularly by the research team and staff from the Animal Facility to ensure animals do not experience excessive pain. A validated pain scoring system will be used - the Grimace Score. Oral analgesia (buprenorphine) will be given to animals, in both the intervention and control groups, with a Grimace Score of >/= to 3 out of 10 and the total daily analgesic requirement recorded. General animal well-being will be monitored using the validated Abdominal Surgery Post-operative Severity Assessment. At the first sign of a point of no return (>20 points on the scoring system), the animals will undergo schedule 1 killing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs & ARRIVE Guidelines and guidelines local to the research institution will be followed.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have reviewed the NC3Rs website regularly to ensure that our practice is up to date, for example, the recent change to the ARRIVE guideline recommendations (du Sert et al., 2020). We are also on the local animal housing mailing lists that distribute urgent updates that are reviewed regularly.

du Sert, N. P., Ahluwalia, A., Alam, S., Avey, M. T., Baker, M., Browne, W. J., … Würbel, H. (2020). Reporting animal research: Explanation and elaboration for the arrive guidelines 2.0. PLoS Biology (Vol. 18).

115. Novel brucellosis vaccine development

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brucellosis, Vaccine

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To evaluate the potential efficacy of novel advantageous vaccine candidates that could protect livestock against brucellosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brucellosis remains one of the world's most significant diseases of livestock, incurring a huge burden on both animal and farmer's welfare and a significant financial cost to the industry. Two of the three main causative bacterial species, Brucella abortus and B. melitensis are in the top 5 causes for livestock units lost for cattle, buffalo, camels, sheep and goats. Additionally, brucellosis is a significant disease in swine, largely caused by B. suis. Although there are three brucellosis vaccines in existence, they have considerable shortcomings. Despite these being available for decades, brucellosis is far from retreating and is a re-emerging disease across large swathes of the world. It is also one of the world's most significant zoonoses with an estimated annual incidence of between 5 and

12.5 million human cases. There is no human vaccine or internationally recognised vaccine for swine.

There are many problems with the current vaccines for cattle (B. abortus S19 and B. abortus RB51) and sheep & goats (B. melitensis 16M). These are live attenuated vaccines, but all possess residual virulence. Vaccination of pregnant animals frequently causes abortions, and this is a major cause of farmers choosing not to vaccinate. The vaccine strains are also pathogenic to humans. In addition to safety issues, there are additional costs as they must be cultured in specialist high containment laboratories. Also, during administration needlestick injuries frequently result in infection, which is compounded by the live vaccine strain's resistance to frontline antibiotics used to treat Brucella infection in humans. Two of the vaccines (B. melitensis 16M and B. abortus S19) generate positive results in the diagnostic tests used for brucellosis disease surveillance, making it very difficult to differentiate between infected and vaccinated animals. This leads to the slaughter of many healthy animals, which in turn affects uptake by farmers. This situation is a major impediment to disease control as the current vaccination regimens alone do not create sufficient pressure for disease eradication, which now relies on test & slaughter. Furthermore, the governing international organisation (the OIE) will not certify a country as officially free from brucellosis if vaccines have been used within the past three years. Under these conditions it is very difficult for brucellosis to be eradicated and one reason why it persists so abundantly in many areas of the world. Additionally, the B. melitensis 16M vaccine is unstable and will spontaneously change into a form that loses the major immunogenic component, so becoming less protective. The B. abortus RB51 vaccine is a mutant strain which has also lost this component and as a result is less effective. The current vaccine for sheep and goats is sufficiently problematic that AgResults (funded by the Gates Foundation) have funded a $30 million 'Brucellosis Vaccine Challenge Project' to improve upon it.

The basis for this project is the development of a brucellosis vaccine that is safe, protective, lacks cross-reactivity with diagnostic tests and has the commercial potential to lead to the production of an improved vaccine that can resolve many of the issues described above and provide an attractive option to facilitate the eradication of this disease.

What outputs do you think you will see at the end of this project?

Information on whether the vaccine candidates are immunogenic and protective in a mouse model will be the primary output.

This information will likely provide at least one scientific publication.

Who or what will benefit from these outputs, and how?

If the results for a vaccine are promising, it will be taken forward by our commercial partner for further testing in livestock within 24 months, which could give rise to the production of a commercially viable licenced vaccine within 10 years. This would provide benefits to the target livestock industry globally, such as improved animal welfare, increased production and improved wellbeing for farmers. With its potential to reduce the prevalence of brucellosis in livestock, this would also help reduce its huge annual incidence in humans. As this novel brucellosis vaccine concept has not been previously assessed, regardless of the outcome, the data produced will help inform ourselves and the scientific community of its application. This would help in the further rational development of brucellosis vaccines.

How will you look to maximise the outputs of this work?

Through our partnership with a global veterinary pharmaceutical company, with whom we have also been developing the vaccine production methodology to help ensure commercial viability, the outcome of this work has every chance of leading to a licensed vaccine. We aim to publish both successful and unsuccessful results in open-access peer reviewed journals. Results may provide information to allow us to modify the vaccine to improve the scientific outcome of follow up work.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have been selected here as a first line screen for vaccine immunogenicity and protective efficacy. Other animal models (such as rats, rabbits and guinea pigs) were evaluated, but mice remain the most relevant and standard small animal model for brucellosis research. A large body of scientific publications use the mouse models, which allow the data generated in this study to be more easily translated into potential observations in the target species (cows, sheep, and goats) for which this vaccine is being developed. This track record also enables virulent challenge studies to be conducted with knowledge of the outcomes and influencing factors to ensure severity is minimised to obtain the required data output, which is very reproducible in this model. As reviewed by Grillo et al. (2012), mice do not show clinical signs of suffering on challenge with standard doses of Brucella, which means that they are able to control the replication and progressively reduce the bacterial burden. Experimental challenge in the target species would lead to an increase in the potential for pain, suffering or distress because the model requires the challenge to be conducted during pregnancy using abortion (in the third trimester) as a readout. Therefore, initial screening in mice is the preferred option for new vaccines before committing to the experiments required in these target species.

Adult mice (>8 weeks old) will be used to ensure their immune system is mature. These will be sourced as Specific-Pathogen-Free (SPF) to reduce data variability due to other infections. Only females will be used to further reduce variability and allow group housing. The in-bred strain, BALB/c, have been selected as the most frequently used for brucellosis vaccine testing and have been recommended for this purpose (Grillo et al. 2012).

Typically, what will be done to an animal used in your project?

Animals will be injected (subcutaneously) with a vaccine, typically involving three separate immunisations 2-4 weeks apart. Blood samples will be taken (not exceeding 15% Total Blood Volume (TBV) within 28 days and up to 10% TBV per sampling) from superficial vessels prior to each immunisation for immunological assessment.

Subsequently animals will be euthanised, a blood sample taken by aortic incision or cardiac puncture during terminal anaesthesia and the spleen isolated for additional

assessment of immune responses (total duration ~50 days). Alternatively, four weeks after the last vaccination, animals will be challenged by injection with virulent Brucella spp. bacteria and euthanised to assess bacterial burden in the spleen, typically 2 weeks later (total duration ~80 days).

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects during the immunisation period may include mild transient discomfort or distress from the injections and blood sampling. The administered vaccine formulation may consequently induce an inflammatory response and localised swelling causing general discomfort, which may last a few days (equating to no more than moderate severity).

Apart from the mild transient discomfort of the injection, challenge with virulent Brucella spp. is not expected to cause adverse effects as the infection is noted to not cause any clinical signs in mice when using doses no greater than the large effective range of between 104 – 5x105 Colony Forming Units (Grillo et al. 2012).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild (25%)
Moderate (75%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are no alternatives to testing of brucellosis vaccines in vivo. There are presently no in vitro assays that can confidently predict vaccine efficacy and be accepted as strong evidence to allow investment in testing in the target livestock.

Which non-animal alternatives did you consider for use in this project?

Ex vivo primary cells Invertebrates
biomimetic tissue culture organoids

Why were they not suitable?

Ex vivo primary cells from animals cannot effectively mimic the generation of an immune response to immunisation or a response to challenge infection due to the complex interplay of many parts to the system in vivo.

Invertebrates lack an acquired immune system, which plays a key role in the protective immune response in the target species. Although insects such as the larvae of the wax moth show potential for studying pathogenesis of some infectious diseases, it is not yet clear that they can be used to effectively evaluate vaccine-induced immunity.

There has been some progress in the development of organoids which mimic individual elements of the immune system, such as the lymph node. Whilst these can potentially provide a surrogate for challenging animals (only after addition of cells/antibodies from vaccinated animals), they have so far been developed to mimic humans as the target population and we do not have a developed and validated equivalent model for our target livestock population.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Currently it is planned that one vaccine immunogenicity study will be conducted to assess one vaccine candidate against an earlier formulation tested in a previous study, probably requiring 5 groups of 10 mice (50 total). If deemed sufficiently immunogenic, a challenge study will be conducted to assess protective efficacy. This will likely involve a pilot experiment (probably one cage of 7 mice, each from a different treatment group) followed by the full study probably requiring 7 groups of 10 mice, due to extra control groups needed (77 total).

It is also a possibility that the immunogenicity study is repeated after modification of the vaccine if initial results did not indicate the presence of the required specific immune parameters (50 total).

Additional animals may be needed for contingency reasons (123).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design will be based on group sizes that should show significant differences so that experiments will not need to be repeated because results were inconclusive. To provide more statistical power by maximising the number of experimental units, the group housed mice will, where possible, be in cages containing animals representative of all the treatment groups. The number of vaccine formulations that were going to be tested has been reviewed and minimised to only what we deem as essential to answer our objective. Although we have never conducted a challenge with Brucella spp. before, a meta-analysis of the published literature has allowed us to be confident that when using the experimental parameters used by others, we can relatively confidently

anticipate the outcome in positive and negative control mice meaning only a small-scale pilot study will be needed. These data have also provided us with a good estimate of the likely variation to be expected so that a power analysis can be used to estimate the correct number of animals more accurately, which could otherwise be over-estimated. Statistical input for studies will be sought to ensure validity of data from the organisations bio-statisticians as well as using the NC3R's experimental design assistant. In-bred mice (BALB/c) will be used to minimise data variability and so reducing the number of animals needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will likely conduct a pilot experiment prior to the challenge to help ensure that the results are not compromised and are of the highest quality when the full study is conducted. This is to ensure that all practical hurdles are ironed out due to the need for stringent high biological containment work practices and to ensure the challenge inoculum is sufficiently virulent, due to potential for attenuation in vitro.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Adult mice will be used. These can be readily habituated to handling by humans to help minimise stress, including during invasive procedures. As a key role in this, we will follow the latest advancement in handling techniques and use non-aversive methods such as tunnelling. Female mice will be used which will allow animals to be group housed, allowing social interaction. The BALB/c strain of mice which will be used are more amenable to handling than others (e.g.C57BL/6 and DBA/2), which again reduces the likelihood for causing distress to the animal.

Mice do not show clinical signs of suffering on challenge with standard doses of virulent Brucella spp., as they are able to control the replication of and progressively reduce the bacterial burden. As the colonisation of the spleen is very reproducible even within a very large inoculum dose range, protective capacity of vaccines can be easily discerned by an accelerated reduction in bacterial burden, which can be observed as early as 2 weeks later.

Experimental challenge in the target species would lead to an increase in the potential for pain, suffering or distress due in part to the required longer periods of time for study outputs and the challenge conducted during pregnancy using abortion events (in the third trimester) to measure protective efficacy.

The subcutaneous injections of the vaccine and blood sampling conducted on the animals should only involve mild transient pain. Injection of the challenge infection will be

undertaken by the intraperitoneal route. Whilst other routes may be preferable from a refinement point of view, it is the recommended and standard method for Brucella challenge of mice. This is due to the ability to ensure 100% of mice are homogenously infected in the spleen, which would otherwise lead to more data variability and potentially the need to repeat experiments. Intravenous injection can also achieve this but is more prone to inoculation errors. Because of its established use, published data on the equivalent use of other routes are scarce and so the inability to conduct an appropriate meta-analysis for a statistical power analysis would also potentially lead to the use of more animals.

Why can't you use animals that are less sentient?

Mice provide well characterised models and immunological tools for such investigations and can provide the required experimental outputs without clinical disease. Species of lower sentience, such as invertebrates, are not yet validated for this work. A competent/mature immune system is required; therefore, fully developed mice are needed.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will follow the latest guidance on the strict single-use of needles, in accordance with the recommendations of the NCRs.

After mice receive immunisations they will be monitored more frequently, than the normal twice daily regimen, over the following 48hrs to help spot adverse effects.

Blood volumes will be minimised to only that required to carry out the laboratory tests (and in accordance with the NCRs guidance of not exceeding 15% Total Blood Volume (TBV) within 28 days and up to 10% TBV per sampling). This will allow small single-use lancets to be used to yield controlled volumes of blood which will be collected in proprietary capillary tubes of set volume. This use of 'micro-sampling' coupled with considerate handling, should minimise any harms caused.

To ensure unexpected adverse effects of the challenge infection are noticed as early as possible, a daily clinical scoring system will be used so that animals can be euthanised at an appropriate objective clinical endpoint. The use of a pilot challenge experiment will also minimise any unexpected harms.

All animals are group housed and provided with as much environmental enrichment (toys, shredding material, seeds etc.) as is possible under appropriate biological containment. Environmental enrichment is constantly re-assessed, in discussion with animal technicians, NACWOs and the NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance is obtained from NC3Rs, ARRIVE, IAT, LASA and the RSPCA. Publications and articles are also reviewed during the approval process prior to each individual study. Where specialist training is required, inter-institutional exchanges and training visits are organised.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will have regular contact with the NIO, NACWO and NVS through various forums. This includes during AWERB, pre-study and study wash-up meetings where suggestions for improvements can be implemented. The establishment has a Species Group Care and Use Committee where all PPLhs are invited to attend. Specialist topics are presented and refinements, such as environmental enrichment, are communicated and opportunities for implementation are discussed. By regularly accessing the various online resources accessible via the NC3Rs website, further advances can also be found. Staff often attend external symposia on laboratory animal welfare and feedback from these are reported back. By keeping abreast of current scientific literature on the disease model and the methods for measuring our study outputs, further refinements can be implemented.

116. Breeding genetically altered mice

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Breeding, Genetically Altered, CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats)

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Overall purpose: Breeding and maintenance of GA mice to support the drug delivery pipelines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This licence is dedicated to the breeding and maintenance of mice whose genome was modified through genome engineering techniques. Therefore, the main direct benefit of this licence is to supply healthy, well characterised (i.e., genotyping, phenotyping), genetically altered (GA) mice to support drug discovery pipelines.

In turn, these mice will contribute to a proven record of accomplishment in bringing novel and effective medicines to the market. Mice generated under this licence will enable us to continue our research efforts to the benefit of patients in the future. In some cases, it is necessary to alter the genome of mice to support drug development. That can be the case when, for instance, i) we need to understand a complex disease or test a complex hypothesis; ii) the drug being developed is made in part of antibodies (large molecules).

Understanding a complex disease:

Complex diseases such as diabetes or cancer are not completely understood. GA mice are instrumental in supporting drug development for such diseases because the modification of their gene helps scientists selectively test the relationship between a drug candidate and a molecule or cell in a model of the disease. Without these mice, it would be very difficult to isolate such molecular relationship from the rest of the microenvironment.

For instance, cells coming from the pancreas of GA mice were used to select some suitable drug candidates for diabetes. Once selected, these drug candidates were administered to GA mice missing specific receptors to confirm the involvement of the receptors and their susceptibility to molecular influencers in diabetes.

Cancer is a complex disease resulting from abnormal cell behaviour during the process of cell renewal. This leads to uncontrolled proliferation of cells, the stimulation of new blood vessels (angiogenesis) and the migration of tumour cells to distant sites within the body (invasion and metastasis). The immune system has the greatest potential for the specific destruction of tumours with no toxicity to normal tissue and for long-term memory that can prevent cancer recurrence. Immuno-oncology research has provided evidence that tumours are recognized by the immune system and that their development can be stopped or controlled long term through a process known as immunosurveillance.

The immune response to tumours is variable, which in some cases may be down to a poor recognition of the tumour' by the immune system. The aim of immuno-oncology drugs is to enhance tumour cell killing by increasing recognition and responses of the immune system to the tumour. Such drugs cannot be designed and developed using traditional mice because the immune system of the mice would interfere with the identification, optimization and testing of relevant large molecules. Using GA mice helps us ensure that the tumours and the environment mimic relevant aspects of the human immune system, assess therapy efficacy, dissect the impact of the tumour microenvironment, and evaluate mechanisms of drug resistance. This is for instance the case of mice belonging to the Pten or ODIn GA strains on this licence.

Generate large molecule therapies:

GA mice have already supported the development of many drugs and drug candidates. Examples of this would include the humanized mouse (ie, a mouse whose genome contains a section of a human gene) for the interleukin 13 (IL-13), which helped with the deeper understanding of some aspects of the skin inflammation. In turn, these mice contributed to supporting the development of monoclonal antibody drugs such as tralokinumab, for eczema.

Another example would be anti-IL 33 monoclonal antibodies, used to treat diseases such as asthma and chronic obstructive pulmonary disease (COPD). These antibodies are currently being trialled in people but beforehand, GA mice helped the generation and understanding of pathological pathways for these diseases.

What outputs do you think you will see at the end of this project?
Short-term: Production of high-quality GA mice or material for research in biomedical sciences.

Mid-term: New knowledge can emerge from the breeding activities: welfare/phenotype information, deeper understanding of fundamental physiological and pathological pathways, understanding of factors influencing the predictivity, replicability and reproducibility of in vivo models.

Long-term: The mice produced on this licence will be used under other PPLs (or equivalent authorities) to support the drug development pipelines. Consequently, new drugs for oncology, respiratory, cardiovascular, metabolic or renal pathologies are expected to be developed as a result from this licence. Similarly, new routes of administration, or refined drugs with less side effects can also be an output from this work in the long term.

Who or what will benefit from these outputs, and how?

Short-term & mid-term: The scientific community will be the main beneficiary because we are committed to sharing and publishing all scientific outputs of interest to the scientific community. Publication might need to be delayed until the IP is delivered/secured.

Mid-term: Publication of scientific outputs coming from the use of these mice across preclinical pipelines.

Long-term: Drug delivery for patients – see previous section.

How will you look to maximise the outputs of this work?

The knowledge gained through constant re-evaluating of our breeding strategies feeds directly into training courses that ran several times a year by the team on managing mouse colonies. This knowledge will also be disseminated across our global in vivo community as part of our commitment to our sustainability strategy.

All new lines have welfare information gathered and the archive is annotated with any relevant information so it can be passed on to future researchers. Any specific welfare issues or phenotype of interest to the community will be published as soon as possible without compromising IP work.

Species and numbers of animals expected to be used

- Mice: 40000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are needed for this project as it is a service licence to supply genetically altered mice to our research programmes. There is no need to age mice on this licence, but we will need mice at all other life stages for breeding.

Mice bred on this licence will be used to supply projects that have been through harm benefit analysis. We expect the majority of the mice produced on this PPL to be used in

the UK for work licenced by ASRU after AWERB scrutiny. More rarely, mice could be sent elsewhere for use, where licencing and Harm Benefit Analysis takes place under local legislation.

Whilst most of our animal research is undertaken at our own facilities, to supplement our internal capabilities and expertise, we outsource a proportion of our animal research to a variety of academic and commercial partners. We contractually require these organisations to comply with high ethical standards and we undertake a range of assurance and due diligence activities to ensure our expectations are being met.

Typically, what will be done to an animal used in your project?

Mice will be born, they will have an ear clip taken for identification and genotyping and then they will be socially housed in a cage with environmental enrichment. Mice of suitable genotype, age and sex will then be transferred to another licence/project, kept as stock for potential future breeding, or bred with other genetically altered or wild type mice. Any mice not moved on to other projects will be killed by a schedule one method or through a procedural route for the collection of tissues.

Sperm, eggs and embryos may also be harvested after killing by schedule one to ensure the backing up of the lines, prevention of genetic drift and minimise the number of animals bred but not used.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of mice on this licence will not experience any adverse effects. Thanks to the knowledge accumulated through the predecessor of this licence and the local expertise, we know that most of the lines bred on this licence are not prone to develop any adverse phenotype. For lines where adverse effects are unknown, new lines, or crossing certain combinations for the first time, mice will be carefully monitored. It is not the intention to keep mice with adverse effects on this licence, since for breeding it is preferable that all mice are healthy. Mice will only be kept if they are needed for breeding; the adverse effects are unavoidable (e.g. part of the phenotype, trait cannot be bred out or improved via veterinary/nursing care) and within the humane endpoints.

In cases where individual lines are associated with known adverse phenotype (not exceeding moderate severity), the breeding of such lines will be these will be and bred in the protocol of appropriate severity.

It is possible that some crosses will result in some genotypes being sub-viable or lethal. In these cases, mice of certain genotypes may not be born in expected ratios, or they may die suddenly soon after birth, mostly before weaning. Rarely, mice may die later in life. For lines where there is a known higher than expected mortality rate the expected rate and details will be justified in the protocol of appropriate severity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90% or more of mice on this licence will have a severity of mild or below.

10% or less of mice may have a moderate severity due to the appearance of phenotypes whilst still needed for breeding.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are committed to all aspects of the 3Rs, including the replacement of animal models by animal-free technologies where possible. The remit is this licence is limited to the production of genetically altered mice. These mice will then go and be used experimentally under other project licences (or equivalent authorities). No mice will undergo scientific procedures (other than those strictly related to breeding) under this licence. Therefore, the best way to tackle replacement is to support replacement strategies across the broader pipeline activities. Here are some examples of replacement strategies. Non-animal alternatives are used upstream of in vivo testing during drug discovery. This allows us to perform fewer studies which then have a higher chance of identifying a suitable new drug molecule. These non-animal alternatives include measurements of the likely efficacy of the agent on target cells and in vitro assays to determine potential metabolism and pharmacokinetics of compounds and, where appropriate, toxicity assessments in cell-based assays. More complex assay systems, such as co- culture assays and 3D tumour cell assays are used where the biology is more complex and cannot be replicated by cultures in 2D culture. In oncology, we are also further investigating the potential of tumour slice models to profile compounds where this may help answer specific scientific questions. Only compounds with good potency, efficacy and suitable predicted properties for in vivo testing are selected to be profiled in mouse models.

Cancer, respiratory and metabolic diseases have a complex pathophysiology with multiple components interacting to manifest the disease. Therapeutic agents target specific biochemical responses or physiological mechanisms that in vitro systems cannot replicate. Individual mechanisms can be probed in vitro, and we conduct extensive studies to characterise these as far as possible before conducting in vivo experiments. Activity in particular cell types cannot predict the likely in vivo activity given the complexity of issues such as bioavailability, metabolism and elaborate physiological interactions associated with pathological pathways such as tumour development, the tumour microenvironment and the interactions between the tumour and the immune system.

Whilst co-culture systems can address some of these questions, at present we are not able to fully reflect the complex interplay between cells in the microenvironment of the disease. Animals remain needed because no other system yet reflect the full complexity of in vivo biology. For example, the repertoire of interactions between immune cells, nerve cells, complex hormonal systems and organ- specific cell changes cannot be recreated outside of living animals. As such, there is still a need for using the whole animal, hence the need to breed them on this licence.

We continue to explore new in vitro models in our pursuit to reduce and replace the use of preclinical animal models. One rapidly evolving area is the field of microphysiological systems (MPS), which enable human-derived cells to be cultured on bioengineered chips, thereby more closely replicating tissue microenvironments, circulatory flow and cell–cell interactions. It is hoped that MPS will ultimately reduce or replace some safety experiments in animals in addition to enhancing translation, thereby replacing existing in vitro models.

Furthermore, regulatory authorities such as the FDA and EMA require compelling data packages to support the development of new medicines in humans. In vitro potency data are seldom sufficient to provide confidence of efficacy in man, and demonstration of activity (and mechanism) in animal models remains pivotal.

Which non-animal alternatives did you consider for use in this project?

The purpose of this licence is limited to providing a service supplying high quality, characterised mice for controlled and reproducible preclinical studies, where in vivo models remain required, and no animal-free alternative exists. There is no non-animal alternative to breeding. Non-animal alternatives, when they exist, are relevant to subsequent licences, not the present one. No mice will undergo scientific procedures (other than those strictly related to breeding) under this licence. However, here are examples of non-animal alternatives already in use, aiming at reducing the need for genetically altered mice.

Every project goes through intense scrutiny before the decision of using genetically altered animals are used. On this service licence, the reasoning underpinning the decision to breed GA mice will depend on the strain and its expected use.

Example of non-animal alternative for use instead of immunisation of GA mice for antibody generation.

Prior to deciding to conduct an in vivo campaign, we perform due diligence on all targets proposed for antibody generation. If there is precedence for success using in vitro antibody discovery technologies for the target or protein family, then we will not use the in vivo platform. There needs to be a strong rationale for generating in vivo derived antibodies over in vitro, and where we believe in vitro will work will then we always use that technology first and fall back to in vivo if it does not succeed, never parallel track them.

There are particular target types where in vitro technologies are poorly suited to antibody generation, e.g. complex membrane proteins such as G-protein coupled receptors and ion channels, where the target cannot be presented as a soluble protein to the in vitro libraries and success with these types of targets is almost non-existent.

When using in vitro technologies, the output antibodies are invariably of low affinity, and there may be complex biological assays linked to the mechanism of action that such low-affinity antibodies cannot be reliably measured, and there is an elevated risk that if we take forward for optimisation, we will have limited biological activity or wrong mechanisms of action (allosteric vs competitive inhibitors etc). Here it is necessary to use in vivo because we will get to proof of concept in man (e.g., a cancer patient) in a more expedient manner thus benefiting patients sooner.

Why were they not suitable?

There is no suitable alternative to animal breeding.

Non-animal alternatives are suitable for scientific experiments to an extent, as explained above. However, GA mice must be used at the point where a whole animal is necessary to study the complex and multiple interactions between its genome and its phenotype; or to generate specific antibodies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each breeding scheme is calculated based on the information from the strain, the genetic background, and the characteristics of the cohort required (age, genotype, sex). The numbers of animals required at each stage of the life of the colony (ie, maintenance, expansion, backing up) will be calculated to minimise the number of animals while safeguarding the quality of the colony over time.

The accuracy of the calculation is built on years of knowledge (predecessor from this Licence and expertise at the breeding centre), as well as the use of MCMS, a bespoke database originally created to support the recording of GA animal data.

Regular meetings between our teams will ensure that the requests for cohorts are timely and well defined. Lines of low use will only be bred when required and active mating will not be constantly maintained. Where possible, the line will be cryopreserved and removed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Breeding strategies are calculated considering several factors, including:

Strain information: fertility characteristics, complexity of the genetic construct and expected germline transmission. Binomial distribution statistics are used to assess viability of strains.

Characteristics of the experimental cohort required (genotype, sex, age, any phenotype where relevant; frequency of requirements).

Sample size calculations, determined at project level, in collaboration with the scientists.

The design of each experiment is discussed at the outset with members of the Scientific management team. The sample size and the justification for that are discussed, as well as how to generate the cohorts using the fewest mice possible. For example, if the cohort can be split into the batches that can be used more than 7 weeks apart, the breeding stock can be reduced by ~50%.

Regular meetings between our teams will ensure that the requests for cohorts are timely and well defined. Lines of low use will only be bred when required and active mating will

not be constantly maintained. Where the need for a line allows, the line will either be cryopreserved and removed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In cases where the viability or the phenotype of a line is unknown, a staged expansion breed will be carried out in the first instance to ascertain whether there are any unexpected welfare concerns.

For single allele breeds, tried and tested strategies can be used for the most efficient breeding. For more complex crosses, often several strategies are considered and assessed for efficiency in terms of timing, mouse numbers and welfare impact.

As part of initial characterisation of oncology models, cell lines and fragments determine whether transplantable models (e.g., models using tumour fragments) can be generated. This will reduce the requirement to specifically breed mice to support these experiments. Given the potential number of mice that are bred but not used during the generation of complex models, this has the potential to significantly reduce animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All aspects of the breeding protocols are refined in line with the 3Rs recommendations. For instance, the mice are housed in social groups, in environmentally enriched cages. The health status of the animal facility is tightly controlled through a stringent health monitoring programme, and all lines must be imported into the barrier of the facility through rederivation.

Care is taken to minimise disruption during daily checks of the cages, especially if young litters are present. Pups are checked for common health issues early and regularly, to prevent any inbreeding of an undesirable trait (e.g., malocclusion, alopecia). When required by the phenotype, weaning is done in coordination with genotyping, to avoid disrupting hierarchies and social groups later on.

All genotyping will be done on this licence using ear biopsy, which is also used as a method of identification. This should cause no more than minor and transient pain and prevent the need for any other procedure to be inflicted to the animals (except in <1% of cases where a second biopsy is needed).

Conventional breeding methods are used, and care is taken to ensure that the females are of appropriate weight/size.

Genetically altered mice will be bred in a way that causes the least harm to the animals. For example, if when carrying homozygous mutations, a mouse strain has a harmful phenotype, we will choose breeding techniques that minimise the number of pups born homozygous. It is not the scientific intention for any mice on this PPL to suffer from adverse effects.

Mice due to develop advert phenotypes will be moved on to PPL with the authority before the adverse effects become overt. In the case where these adverse effects are present before mice can be moved to another licence, or in breeding stock, specific justification will be detailed in the protocols.

Additionally, a large proportion of lines on this licence will be new or bred in specific combinations for the first time. In these cases, it is not possible to know what the adverse effects will be. Specific humane endpoints will be put in place based on an extrapolation of the symptoms in humans and predicted adverse effects in mice. For example, where humans have a neurological disorder with movement abnormalities, we might expect tremors or gait abnormalities in mice.

Why can’t you use animals that are less sentient?

Mice used on this licence must be of an age that is suitable for breeding; and their offspring need to be at an age suitable for shipping for use under other licences (usually, young adults).

Projects will be carried out on this licence when it is necessary to assess the gene function in a mammalian system. The ability to modify genomes in a complex way is more advanced in mice than in other species, although simple modifications are now possible across other species due to the advent of CRISPR/Cas9 technology. Additionally, and critically for genetic studies, there are a large variety of mouse inbred strains in which a genetic modification can be assessed in the context of a standardised genome. Such inbred strains are significantly rarer or not available for other species, including species traditionally considered as ‘less sentient’ such as zebrafish. Mice have a wealth of baseline data from which to draw comparisons with, both at a phenotype and genetic level.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Ear clipping is likely to be the only invasive procedure animals are subjected to during their life under this licence. Ear clipping will provide the biopsy tissue required for genotyping. The team performing these biopsies are highly experienced, and will carry the procedure quickly, minimising distress with excellent handling skills and skilful use of the ear notching device.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For terminal procedures routes and volumes for administration of substances are taken from LASA guidelines.

All procedures, including husbandry tasks, are carried out to strict standard operating procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PPL holder and managers working on this licence will attend national and international conferences focused on the 3Rs in animal science such as the 3Rs symposiums, NC3Rs, IAT, FELASA meetings, and meetings of the European College of Animal Welfare Science, Ethics and Law.

They will attend talks, give talks or run and/or take part in workshops focused on increasing reproducibility, reducing animal numbers and refining practices.

The PPL holder will also attend more specific disease-based conferences and undertake CPD through their employer's programmes to continue learning about the development of animal-free disease models.

Any near-miss or incident will be seen as an opportunity to improve, root causes will be identified, and any new refinement will be incorporated in working practices for the benefit of this PPL.

117. Understanding endogenous protective mechanisms in osteoarthritis; towards a new approach for disease management

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

osteoarthritis, disease-modifying drug, protective pathway

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to establish and utilise a mouse model of knee osteoarthritis (OA). The model will allow us to selectively knockout the gene encoding our protein of interest in the cartilage of adult mice in order to *define molecular and cellular pathways in joint tissues that protect against the development of OA*. This will help us to understand why some people suffer from symptomatic OA, whereas others do not, and will support our development of a new treatment for OA.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Osteoarthritis (OA) is a serious disease affecting 1 in 3 adults over the age of 45 in the UK. Pain and loss of mobility in joints (such as the knee) prevent people with OA from carrying out daily activities, which has a huge impact on quality of life. In addition, OA is associated with increased risk of heart disease, mental health problems and reduced life expectancy. There are no drugs disease-modifying drugs for OA and more than 160,000 joint replacements are performed each year in the UK to relieve pain and restore function. People with OA have identified a major need for treatments to reduce symptoms and delay joint replacement surgery. Previous research has developed our knowledge of how joint damage occurs in OA, but we don't know why some people develop symptomatic OA whilst others don't. Understanding the inherent molecular pathways that inhibit the OA disease process will pave the way for new treatments for this debilitating condition.

We have identified a protein that is made in joint tissues such as the cartilage, where it has protective effects and reduces inflammation. We are developing a drug for OA that is based on this protein and harnesses its beneficial activities. We have shown that our drug candidate can protect cartilage from damage and reduce pain in rodent models of OA. The focus of this project is to use a gene knockout mouse model to determine how the protein regulates molecular pathways joint tissues, e.g. following the type of injury that can progress to OA in humans. Informative studies on the early stages of OA development cannot be carried out with human tissues, due to a lack of availability of suitable samples.

The proposed work will support the development of our drug candidate, by providing information on its mechanism of action. Together with other ongoing work, where we are using tissue donated from joint replacement surgeries to explore pathways in established OA, this project will also help identify molecular markers to underpin the diagnosis and treatment of OA, including personalised medicine approaches.

What outputs do you think you will see at the end of this project?

The research outputs of this project will include:

A mouse model of osteoarthritis (OA) where the gene encoding our protein of interest is selectively knocked out in the cartilage of adult mice.

Data from our mouse model showing how our protein of interest influences the onset and progression of OA, both spontaneously and following surgical destabilisation of the knee joint. These will include imaging data and joint 'damage scores' to demonstrate whether OA develops more quickly and with greater severity in our model compared to controls, data on joint mobility and data on the expression of genes and proteins that are associated with pathways that promote or inhibit the onset and development of OA.

Insights into the mechanisms by which our protein of interest has protective effects in joint tissues and how our drug candidate harnesses these mechanisms in the treatment of OA.

We will publish our findings in open access peer-reviewed journals making them available to the OA- research community.

We will present our findings in the form or posters and oral presentations at conferences. The project will support our development of a disease-modifying treatment for OA.

Who or what will benefit from these outputs, and how?

These outputs have the potential to benefit patients with OA - a very common and debilitating condition - by improving our understanding of the disease process and, ultimately, by supporting the development of a new disease modifying treatment.

The outputs will also be of value to others who are conducting basic and clinical research in OA by providing new insights into the regulation of disease-associated mechanisms.

How will you look to maximise the outputs of this work?

We will maximise the outputs by:

Disseminating the outcomes of our work through conferences, seminars and publications, where we will publish the outcomes of both successful and unsuccessful approaches.

Continued collaboration with others in the OA field - e.g. by making our knock-out mouse model available to other researchers.

Working with our Faculty Media Relations team to disseminate outputs through the media.

Engagement with patients affected by OA and with clinicians to ensure that our work to develop a disease-modifying drug for OA is aligned with their priorities and needs.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will utilise mice as a model of human osteoarthritis.

Use of a mouse model will allow us to carry out genetic modification to generate a cartilage-specific gene knockout in order to specifically explore our protein of interest in the knee joint during the development of OA. The generation of the gene knockout will require a breeding programme, which will use pregnant mice, embryos and all life stages from birth to adult mice.

Cartilage-specific gene knockout will be stimulated in young adult mice at the point when they have a mature musculoskeletal system.

We will use these knockout mice to explore the spontaneous development of OA over a timeframe of up to 18 months.

We will also use the DMM (destabilisation of the medial meniscus) model of knee OA, where surgical destabilisation of the knee joint causes OA to develop over a few months. This model is used by many researchers in the OA field and is well accepted as providing informative data on disease-associated pathways and the effects of therapeutic

interventions. For example, we have previously tested our drug candidate in the DMM mouse model.

Typically, what will be done to an animal used in your project?

The generation of genetically modified mice will involve natural mating of animals. The mice will be kept in standard conditions for up to 15 months.

To induce cartilage-specific gene knockout, mice will be treated with tamoxifen. This will be administered either orally or by injection.

To induce OA, mice will undergo a precise surgical procedure (under anaesthetic) to destabilise the knee joint. Animals will be humanely killed at a series of endpoints after surgery (up to a maximum of 20-weeks) so that joint tissues can be examined for molecular and cellular changes.

Some mice will be kept for up to 18 months without joint destabilisation surgery and then humanely killed so that joint tissues can be examined for molecular and cellular changes.

Some mice will be treated by a series of injections (up to a maximum of 3 times per week) with our protein drug candidate.

As well as the endpoint examinations of knee joint tissues, the development of OA might also be examined using non-invasive imaging methods, such as x-ray and MRI (no more than once per month), and by observation of the animals' mobility (a maximum of once per week). Control mice, e.g. without gene knockout or with mock surgery, will be included for comparison in all elements of the project.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse effects are expected as a result of the breeding of genetically modified mice.

Short-term treatment with Tamoxifen can result in some weight loss, hair loss and signs of urinary tract infection; these effects will be short-lived.

Following joint destabilisation surgery, mice might experience some inflammation, discomfort and ultimately arthritis in their joint - i.e. a swollen joint and possibly limping. Our previous work in the DMM model has shown that, although we can see changes in the joint tissues at the endpoints of experiments, mice show very little sign of discomfort.

Injection with our drug candidate is not expected to have any adverse effects, based on our previous work.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding programme is a mild procedure. No animals are expected to experience adverse effects.

The effects of tamoxifen treatment may be mild or moderate; this will be minimised by optimising the dose and route of delivery. Most animals will experience some effect.

The effects of DMM surgery may be mild or moderate. All or most animals will be affected.

The spontaneous development of OA in our gene knockout mice may be mild or moderate. We do not yet know the extent to which OA will develop in these mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The onset and progression of OA in humans is very variable. We consider that this is due to differences in intrinsic protective pathways within the joint. We have identified a protein that is made in the cartilage and inhibits OA-associated processes. Defining the molecular mechanisms involved and how they influence joint structure and function will improve our understanding of OA and support our development of a new disease-modifying drug.

The use of a mouse model is essential to achieve our aim. Mice have a musculoskeletal system that is similar to humans and are well established as informative models of OA. Mice are also the ideal species for genetic modification. The generation of a cartilage-specific gene knockout for our protein of interest in young adult mice will allow us to specifically define the effects of this protein within the knee joint.

Mice mature much more rapidly than humans, so we will be able to look at the age-associated development of OA in our model over a relatively short timeframe (up to 18 months). In addition, surgical destabilisation of the knee joint in mice causes rapid onset of OA and is a very well accepted model of post-traumatic OA in humans.

In these mouse models we will be able to use non-invasive methods to assess changes in joint mobility and structure during the study timeframes. At the study endpoints we will also be able to quantify joint damage and determine the expression of genes and proteins implicated in OA. In the joint destabilisation model we will be able to gather data for very early time points (from 6 hours after surgery) through to a maximum of 20 weeks. Evaluation of precisely defined time points, from the point of onset and throughout the progression of OA, could not be achieved using human tissues.

Which non-animal alternatives did you consider for use in this project?

We have considered using knee tissue samples from people with late-stage, symptomatic OA that are collected during joint replacement surgery. We have already used these to explore how our protein of interest influences the expression of other proteins known to be associated with cartilage damage and how our drug candidate acts to suppress cartilage breakdown.

We have considered using tissue samples from people who have suffered knee injuries or who have early-stage OA, for this project. We have also considered the use of cell culture models of cartilage, which we have used previously to generate mechanistic data.

Why were they not suitable?

The proposed work requires a model system that provides an accurate representation of the whole knee joint and where we can carry out analyses at precisely defined time points that represent OA onset through to late-stage disease. Human clinical samples are not suitable because they would not allow us to carry out genetic manipulation. Furthermore: (1) the population of patients having knee replacement surgery for symptomatic OA is very variable, (2) there are no good diagnostic markers for early OA, so it is impossible to identify patients at specific stages of the disease, and (3) patients are seen by clinical teams at very variable times following joint injuries. Therefore, it is not possible to carry out an informative study using human samples.

Cell culture models could provide the option of genetic manipulation to knockout the protein encoding our gene of interest. However, OA is a disease of the whole joint and disease progression depends on the mechanical loading of the joint, which can only be achieved in a live animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated that up to 4000 mice will be involved in our breeding programme that will generate the genetically modified mice to be used for cartilage-specific knockout of our gene of interest. This is based on: (1) the number of experiments we plan to use these mice for, and (2) the conservative assumption that each litter of mice we breed will include one mouse with the correct genotype.

We have estimated that up to 1000 of the mice that we generate in our breeding programme will be treated with the drug Tamoxifen to stimulate cartilage-specific gene knockout. We will use up to 400 of these mice for our studies on the spontaneous development of OA. In addition, we estimate that up to 450 of the mice we breed will be used in the DMM surgical model of OA; this will include up to 50 mice as sham-operated controls. This is based on: (1) the different experimental time points we will use (in order to explore the effects of our protein of interest throughout the early stages of OA development), and (2) previous work by ourselves and collaborators using the DMM model, which suggests that each experimental group will need to include 10-12 mice in order to generate informative data. Approximately 50 control mice that have not been genetically modified will be used to generate baseline data in the DMM model of surgically-induced OA.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the outcomes of work in our own and collaborators labs and taken the advice of a statistician to reduce the number of mice being used in each experimental group. We will use pilot studies to further adjust group sizes as the study progresses.

By using both male and female mice in the spontaneous OA and DMM-induced OA studies we will reduce the numbers of genetically modified mice that we need to breed. Furthermore, generating data in both male and female animals is important with regard to the translation of our findings towards human clinical studies, where OA is common in both women and men.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continually review the outcomes of experiments and use our data to optimise animal numbers as the project progresses. For example, we will conduct pilot studies to optimise the protocol for tamoxifen induction of cartilage-specific gene knockout and to determine the group sizes required in the OA model studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use a genetically modified mouse model to allow selective knockout of a gene in the cartilage of young adult mice. This model will be used to explore the effects of the gene deletion on the onset and progression of knee osteoarthritis (OA). We will determine whether OA develops spontaneously in the knockout mice over time (up to 18 months); in this case we anticipate that any OA- like symptoms will be mild and slowly progressing.

We will also initiate OA by surgical destabilisation of the knee joint in the DMM (destabilisation of the medial meniscus) mouse model. This is a very well characterised model, which we have used previously. We have observed that whilst mice develop OA-like damage to their cartilage, they exhibit little or no evidence of discomfort/pain over the timeframe of our proposed experiments.

Why can’t you use animals that are less sentient?

OA is a complex disease that involves the whole joint and is influenced by factors including joint mechanics as well as cellular and molecular processes. In order to explore the onset and development of human OA we need to use a live animal model with a mature musculoskeletal system that is similar to an adult human. The adult mouse fulfils this requirement. In addition there are well-established methods for genetic modification and for surgical induction of OA in mice - both of which are essential for the proposed project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The major welfare cost to the mice in this study is the development of OA-like symptoms. Since the purpose of this project is to study OA in the mouse knee joint, this welfare cost cannot be changed.

With regard to the Tamoxifen induction of cartilage-specific gene knockout in our mouse model, we will carry out pilot studies to determine the least harmful way of administering Tamoxifen, whilst still ensuring effective knockout (determined by genotyping). We will preferably use an oral method of administration. Tamoxifen treatment can cause some weight loss and signs of general malaise such as loss of appetite, hunched posture and piloerection, but these are typically transient.

With regard to the DMM surgical model of OA, we will continually monitor our procedures for pre- and post-operative care to ensure that these are optimised. For example, using sterile techniques to prevent infection at surgical sites and making adjustments to food, bedding and enrichment and using post- operative analgesics if required. In addition we will carry out pilot studies and order our experiments so that the data we gather can be used to refine the numbers of animals being used at each stage, i.e. to ensure that all experiments are informative, but without using more animals than necessary.

As well as collecting data on joint damage and gene expression profiles at the end of each experiment, we will use non-invasive methods (such as imaging and observation of animals' mobility) during the course of each experiment so as to maximise the information we obtain, but without any additional welfare costs to the mice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use published documents recommended by NC3Rs to ensure that we are using the most refined approaches in all our experiments. With regard to DMM model of OA, we will regularly review the scientific literature for work by other researchers in the field to identify opportunities for refinement.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are registered with NC3Rs and subscribe to their monthly newsletters, which will keep us informed regarding advances in the 3Rs. We will utilise the NCRs Experimental Design Assistant as well as seeking guidance from our local NVS and NACWO to inform the implementation of any advances that can be applied to our project.

118. Immunisation against infectious diseases

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

vaccine, influenza, antibody, therapy, pandemic

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to study and develop vaccines and therapeutic antibodies against influenza and other emerging pathogens.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are no effective vaccines or therapeutics for influenza. Influenza epidemics have been causing up to 600,000 deaths annually and influenza pandemics cause a greater mortality. The current flu vaccines are based on prediction of which strains might be circulating in the coming years. On good years (in which the prediction is accurate) the effectiveness of the vaccine is ~70%, on bad years (like in 2013-2014 season) the effectiveness was only 10% due to a wrong prediction. Apart from influenza, as we learnt from the COVID-19 pandemic, it is important to study vaccine platform which could be used in the future as a pre-pandemic preparedness for emerging pathogens.

What outputs do you think you will see at the end of this project?

New vaccines against influenza and other emerging pathogens that are more “universal”. For instance, an influenza vaccine that would work against future strains without relying on prediction and therefore does not require annual update. Better understanding on the mechanism of protection mediated by vaccines against influenza and other emerging pathogens. We hope to eventually translate these vaccines for use in human.

Who or what will benefit from these outputs, and how?

We and the scientific community will be able to understand better on how vaccines against influenza and other emerging pathogens work, therefore able to design better vaccines in the future. This eventually will benefit the general populations when more effective vaccines are produced.

How will you look to maximise the outputs of this work?

We have established collaborations locally, within the UK and internationally in which we constantly share and discuss findings, experience and results from animal studies to help each other to improve the quality and outputs of research

Species and numbers of animals expected to be used

- Mice: 14,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We used adult mice because they are the lowest vertebrate group in the evolutionary tree for which the immune systems are well understood. Apart from that, we and other have extensively characterised influenza infection model in adult mice. Juvenile animals do not have a fully functional immune system therefore not a suitable model for our studies.

Typically, what will be done to an animal used in your project?

Typically, an animal will be immunised with a vaccine or a combination of vaccine (proteins, nucleic acid, viral vectors) and immune responses will be measured post immunisation in sera. Occasionally, immunised animal will be challenged with an infectious virus (eg. live influenza virus) and the protection of the vaccines against the infection will be studied. Adoptive transfer of sera, monoclonal antibodies, or cells will also be performed followed by challenge with an infectious virus. Occasionally, partial bone marrow deletion by irradiation or chemicals will be performed on mice to create bone marrow chimerea mice prior to immunisation. In certain experiments, in vivo live imaging (IVIS) will be used to study the biodistribution of vaccines/immunomodulators (tagged to bioluminescent proteins).

What are the expected impacts and/or adverse effects for the animals during your project?

(Protocol 2 Step 1) Mice undergone bone marrow ablation and rescue might experience transient weight loss (<15%) than don't typically last longer than 3 days.

(Protocol 2 Step 3) Mice that received transgene inducing or deleting agents might experience transient weight loss (<15%) and mind skin redness at the site of injection which typically improve within 24 hours.

(Protocol 2 Step 4) Mice receiving passive cells transfer might experience (extremely rare) embolism caused by clumping cells manifested as altered behaviour, hunching, laboured breathing and/or non- responsiveness.

(Protocol 2 Step 5) Mice receiving intranasal delivery of immunomodulators or vaccine might experience transient breathing difficulties that don't normally last longer than 30min, intramuscular injection might cause skin reddening at site of injection which normally improves within 24 hours. Mice that are immunised are expected to experience transient general malaise for up to 48 hours.

(Protocol 2 Step 6) In the influenza challenge model, unimmunised mice are expected to transiently lose weight over the course of 48 to 72h. Mice are monitored closely during this time and will be humanely killed if lost 20% of weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

70% Mild

15% Moderate

15% subthreshold

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The experiments described in this project license cannot be done using in vitro cell culture or isolated organs of animals as they often involve several cell types of the immune system and the complex interactions with each others. These interactions cannot be mimicked in vitro. In addition, the use of genetically modified mice allows us to study the effect of a single gene on the immune system, which cannot be studied in vitro. The mouse influenza challenge model and the immune responses have been well established and well understood.

Which non-animal alternatives did you consider for use in this project?

In vitro assays.

Why were they not suitable?

In vitro assays are not able to help us to answer most of the scientific questions as they cannot reliable mimic the multicellular environment and the complex immune system that determine the action of the vaccines or treatments (immunomodulators, monoclonal antibodies or sera).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our use of in vitro methods limits the numbers of animals required for the in vivo research. Prior to an in vivo experiment we consult the literature and try to minimise variables in the experimental design. Where necessary we seek advice from people who performed such experiments and experts in the relevant techniques who can advise us on the expected outcomes, unusual controls that may be required and adverse effect that they have encountered. Review of the previous experiments have confirmed that 6 animals are required to determine the effect of a vaccine or to compare multiple dose/type of vaccine. We run pilot experiments with limited size groups to determine intra and inter group variations and address simple questions before expanding our study further. After the pilot experiments, usually with groups of 3-4 mice, and if no adverse effects are detected, either additional repeats are performed with equally small group-size until the required statistical significance is achieved or larger group size are used based on the variation of data from the pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whenever appropriate, the NC3R’s EDA will be used to aid experimental design especially in determining the appropriate sample size and the ARRIVE guideline will be followed. We also perform in vitro screening experiments whenever possible and suitable to screen immunomodulators/monoclonal antibodies which allow us to narrow down the concentration range that is required to be tested in animals, therefore reducing the number of groups of mice. In experiment involving adoptive T cell transfer, we continuously improve tissue processing techniques to increase the yield of cells harvested, therefore less donor mice will be needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will ensure efficient breeding of colony and whenever available we will share data and resources (e.g. tissue) with other research groups. We will use refined statistical analysis and computer modelling (whenever appropriate), and regularly re-examining the findings

of previous studies al (systematic review) to help optimise the number of animals in subsequent experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using mice because mice are the lowest vertebrate group in the evolutionary tree for which they have a functional immune system that can be used to understand the immune responses in humans. As our background strains, we use both genetically altered and wild type mice for which much groundwork has been obtained and many genetically altered derivatives generated. This allows us to hone in on our specific area of interest with an understanding of the contextual settings.

Our understanding of the infectious is continuously increasing and we can anticipate much of the developments allowing us to identify variations at early time points. Typically, mice will be immunised with a vaccine (single or multiple doses, typically intramuscular but also sometimes via intranasal, intraperitoneal or intravenous route) and sera and/or organs (such as spleen and lymph nodes) will be harvested to measure the immune responses elicited by the vaccine. Occasionally, for influenza vaccine, immunised mice will be infected with a live influenza vaccine to study the protection efficacy. These are the most refined method as the various routes of administration are not expected to cause any suffering that’s beyond mild. From our past experience characterising the kinetics of the immune response, we are able to minimise the number of blood sampling steps such that blood is taken at the most informative time points post-immunisation and the blood sampling via tail vein is minimally invasive. The combinations of mouse strains and influenza virus strains/doses typically used are well characterised and recovery is expected in wild-type mice; although these infections will in most cases be symptomatic, adverse effects are typically transient. Infection resolution is expected, even in mice which exceed 15% weight loss, as discussed below. It is important to use a 20% weight loss limit since Influenza virus infected mice frequently lose 15% weight yet go on to make a full recovery; imposing a humane endpoint at 15% weight loss for influenza infection would mean that we might be less able to discriminate between mice developing an immune response that will clear the viral infection and those mice that are not protected.
Mice in which an effective immune response is mounted are not expected to exceed 20% weight loss. For genetically modified mice, breeding colonies will be managed in line with the best practice guidelines. Particular attention will be paid to genetic stability and good breeding performance. Data from breeding animals are readily available from the in house database and will be used to make decisions on future breeding animals and also to assist in maintaining a suitable colony size to ensure only those animals needed for experiments are produced.

Why can’t you use animals that are less sentient?

Mice are the lowest vertebrate group in the evolutionary tree with a fully functional immune system that can be used to study the immune responses in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be monitored regularly post procedures, and increased monitoring will be done when a new vaccine/adjuvant/treatment or procedures are administered. Analgesic will be used to minimise or remove pain post procedures accordingly. Cup or tunnel handling will be used when handling the mice to reduce stress imposed to the mice. Mice will be housed in group and in appropriate number to ensure that they have enough space to perform normal social behaviour.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to the LASA, PREPARE and ARRIVE guidelines for reporting these studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through frequent review of the NC3R in the UK and CAAT (Center for Alternatives to Animal Testing) I will keep informed about advances in the 3Rs and having access to the regional 3R’s manager and the Named Information Officers.

119. Analysis of Pain Pathways

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pain, Sensory Neurons, Nociception, Analgesia, Gene therapy

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to define mechanisms important in pain, particularly chronic pain in mouse models of human pain conditions. Importantly, all human analgesic drugs work well in mice. Although animal models have not always been useful in testing potential new human analgesics, there is a strong rationale for their use particularly in conjunction with human pain genetics which gives insights into potential targets that can be explored in mice.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The Global Burden of Disease Study 2016 found pain and pain-related diseases, particularly low back pain and migraine, are the leading causes of disability and disease burden globally. Low back pain and migraine are responsible for 57.6 million and 45.1 million years of life lost due to disability, respectively. This means the burden of pain conditions is higher than that due to depression, cancers, diabetes and Alzheimer’s

disease. In Europe alone, almost one in five individuals or 20% of the adult population report having moderate or severe chronic pain. This means there are 150 million people in Europe experiencing chronic pain. Chronic pain has been linked to numerous physical and mental conditions and contributes to high health care costs, early retirement and productivity lost. Clearly, there is a need to investigate the mechanisms that initiate and propagate chronic pain and to identify new analgesic targets to better treat the substantial number of people affected by the condition.

What outputs do you think you will see at the end of this project?

Our program of work is devoted to unraveling the cell and molecular mechanisms that contribute to different types of pain, to devise new approaches focusing on novel molecular targets that will be revealed by these studies.

Who or what will benefit from these outputs, and how?

As 7% of the population suffer from severe pain, the utility of identifying new therapeutic targets for pain is self-evident. There is a huge unmet clinical need for improved and targeted analgesia, as many chronic pain conditions are addressed with similar classes of centrally-acting drugs that do not differentiate between distinct diseases and classification of pain states. Our experimental approaches to define distinct cellular and molecular targets in different pain conditions is essential to providing candidate drug targets for more effective pain relief. Our experiments will define new analgesic targets within the lifetime of the licence. Although, drug development can require considerable time due to regulatory constraints, but the potential reward for pain relief remains very high.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work by having a range of relevant available mice for genetic studies and collaborations with pain groups around the world. These tools will allow us to assign particular subsets of neurons to precise functional roles in models of different pain syndromes, through electrophysiological and behavioural analyses. Our approach to exploit *in vivo* assays in animal models of chronic pain is fundamental to acquiring insight of the nervous system organisation for nociceptive processing – both at the molecular level that we can manipulate and at the whole system level that we can monitor. Moreover, the mice that we generate and characterise will be invaluable for use by other researchers and the Pharma industry to examine pain mechanisms. Composition of matter patents have been filed on analgesic targets that we have identified using mouse genetics.

The benefits that we will gain will be in the short term:

Provision of a set of research tools for pain studies of use to the whole world pain research community. The benefits that we will gain will be in the medium term: New insights into the cellular mechanisms that underpin different pain syndromes in rodents. The benefits in the long term will be: Identification of key genes that cause distinct pain syndromes and that present new targets for the development of therapeutic drugs.

Species and numbers of animals expected to be used

- Mice: 20900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used for this project as they represent the most appropriate genetically amenable species for this type of work; they are similar to humans genetically, and physiological systems for pain are largely similar and all forms of analgesia used in humans are also effective in mice. Many key physiological systems and structures involved in pain processing were originally identified in rodent and other models and validated in more recent human studies.

On top of this, decades of research have resulted in highly advanced and efficient techniques developed for investigating neuroscience questions in the mouse, such as optogenetic studies to control the activity of cells by light. Importantly, the mouse is highly amenable to genetic modification, allowing transgenic identification of specific cell types crucial to the fulfilment of the project.

Over several years of pain research, we have been able to establish protocols to minimise stress in rodents to ensure the best welfare of all animals and maximum scientific output from all studies requiring consistent animal handling. We have also developed new techniques to replace conscious animals with unconscious animals (e.g., in imaging experiments to assess cell activity) to reduce suffering.

Typically, what will be done to an animal used in your project?

The first two sections within this licence are for breeding and maintenance of the mice. The first section is a mild protocol where no harm should occur. The second is moderate, as some of the genetically altered animals may experience alterations to pain sensation that should be monitored closely for injuries or potential suffering.

The third section is mild, involving a range of behavioural tests for mutant mice, to establish whether they have loss or gain of pain. These produce data on the pain status of the mice. There are several sections described as moderate protocols that mimic human pain conditions. Use of these in animal models is necessary for understanding distinct mechanisms in different pain states that may be treated with different types of pain killers.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of our research involves procedures of mild severity using the majority of the animals. There are exceptions which we have identified as falling into the moderate classification for the protection of the animals. Expected adverse effects might include post-operative stress or discomfort, but these will be quickly identified, and measures taken to minimize suffering. In all these cases, or when unexpected clinical signs appear, we will consult our NACWO and NVS. At the end of each procedure, animals will be euthanized according to certified Schedule 1 procedure and tissues will be isolated for further studies.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All our protocols are conducted upon mice and consist of either sub-threshold mild or moderate procedures.

Our breeding and maintenance protocols consist of a mild protocol (90% of animals) where no harm should occur, and also a moderate breeding protocol (10% of animals, for animals that have some pathology).

The majority of our animals will be studied using mild protocols (90%) with a few taken to sub-threshold non-recovery imaging experiments directly (10%). These mice are studied under terminal anesthesia

We have several moderate protocols which mimic human chronic pain conditions and protocols involving induction of genes or application of gene therapy agents that require cautionary restrictions to protect the animal's welfare.

Inflammatory pain 20%
neuropathic pain 20%
cancer pain 20%
musculoskeletal pain 10%

What will happen to animals at the end of this project?

- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Pain is arguably the biggest clinical challenge of the age and is increasing with aging populations. The hope that human studies using functional imaging could be used to study human pain mechanisms has been heavily criticised after the demonstration that the so-called pain matrix is not directly related to pain perception, and only self-reporting of pain intensity from humans is a useful guide to drug efficacy. We apply many well-established protocols that have been refined over decades of use.

The use of animal models of acute and chronic pain conditions is fundamental to providing insight into molecular, cellular, and systems organisation of damage sensation that cannot be determined in humans. Such animal models offer the ability to produce fine-tuned characterisation of neurochemistry and anatomy, alongside the benefits of excellent temporal and spatial resolution with imaging and electrophysiological recordings of cellular activity. A very important finding from our recent studies has demonstrated that sensory neurons *in vivo* have properties that are lost when the neurons are excised and studied *in vitro*. This means that studies of sensory neurons in culture need to be interpreted with great caution, as the *in vivo* situation is so clearly different from culture conditions.

Which non-animal alternatives did you consider for use in this project?

Where appropriate we conduct in-depth genetic analysis of potential targets of interest prior to animal work using gene sequencing technologies and molecular and electrophysiological methodologies. Human genetic insights are also valuable.

In vitro and cell culture-based alternatives have been, and will be, used by us as replacements wherever possible (for example electrophysiological studies of channel function) to examine selected aspects of the responses we aim to more fully decipher *in vivo.*

Why were they not suitable?

Whilst we fully acknowledge the strengths of *in vitro* and cell culture-based alternatives and have reviewed their use, we are aware and appreciate their limitations. As valuable as these studies may be, they can never tell you which physiological systems are critical for pain perception – only behavioural studies can tell us this. The amount of information we can obtain from carefully designed *in vivo* studies is actually greater and more valuable in translating to clinical studies in its impact than *in vitro* studies that may superficially appear to be more attractive in terms of minimising animal use and discomfort.
The study of pain pathways thus requires the analysis of pain behaviour in animal models.

With our recent findings (PMID: 27847865), we demonstrate that sensory neurons *in vivo* have properties that are lost when the neurons are excised this finding unfortunately means that many *in vitro* studies designed to help with the 3Rs actually give us misleading data, re-inforcing the need for whole animal studies at the moment.

In a similar fashion, *in silico* techniques have no obvious utility when the fundamental mechanisms of pain pathways are so very poorly understood.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Appropriate experimental designs – unbiased and adequately powered studies – are applied in order to identify the minimum number of animals we need to use and identify the best technical approaches we can employ to answer the specific question being posed. We have extensive experience in animal pain behavioural studies and have found that for the paradigms described in protocols 3-8 we can obtain statistically meaningful data with groups of 6-10 animals (PMID: 32663221).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will optimise our breeding strategies to produce minimal numbers of animals. For example, we will breed homozygous floxed mice with homozygous floxed mice that

express one copy of a Cre- recombinase, so that all the progeny of the mating will either be experimental animals (i.e., genes will be deleted) or appropriate controls (i.e., floxed genes will be present but not deleted). It is important to emphasise that gene deletion studies are more reliable and reproducible than gene knock-down studies using antisense oligonucleotide or siRNA approaches (PMIDs:22531176, 22188729, 18669863, 16850455, 15621361).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In several of our protocols, the cumulative severity is low enough that the same mouse can be maintained for continued use on different days, for measuring thermal and mechanical hyperalgesia. This action reduces by half the number of necessary mice. Group sizes in all other studies will be in accord with power analysis applied to previously generated data or published findings from our own or other groups (PMIDs: 33823138, 33693512, 31911151, 30638309, 35233469, 29394316). Wherever it is possible we will also exploit contralateral limbs as controls in order to reduce the numbers of animals required still further; the possibility of exploiting such controls is another area in which future reduction in numbers may be achieved. This may not always be possible, however, but efforts will be made in all initial investigations to secure the validity of internal control samples. We also use the help of on-line tools such as the ARRIVE guidelines form: a guideline basis for the determination of experimental design at https://arriveguidelines.org/.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen to focus particularly on transgenic mice. This decision has been made as it will provide us with the potential to explore the role of specific genes in the response we identify, through the use of mutant and transgenic mouse models. It is possible to generate transgenic mice much more easily than other rodents.

Animal suffering will be limited in our studies by our strict monitoring of animals with regards to severity limits of associated protocols. Our use of protocols has been carefully designed to minimise trauma and suffering. We have chosen a range of models to cover different types of pain conditions as it is clear from previous research that there is not one common pathway for all types of pain. The number of different models allows us to look specifically at a type of pain and reach our objectives efficiently and by using as few animals as possible.

Neuropathic and bone cancer pain models involving surgery or strong chemicals are currently the only way to model neuropathic and bone cancer pain states in animals, and we will endeavour to review our methods along with the current literature to ensure that we are causing the least amount of suffering to the animals, in order to reach our objectives.

With all models used, we will minimise suffering by administering pain relief where possible. The animals will be culled immediately after the last time point of testing or as soon as social behaviour, grooming, weight loss/gain and/or wound healing indicate the animal is suffering to a level noted in the licence.

Why can't you use animals that are less sentient?

Mice will be used for this protocol as they represent the most appropriate species for this type of work; they are very similar to humans as in their genetic and physiological systems for pain are largely similar with all types of analgesia known to work in humans also being effective in mice. Many key physiological systems and structures involved in pain processing were originally identified in rodent and other models and validated in more recent human studies. On top of this, decades of research have resulted in highly advanced and efficient techniques developed for investigating neuroscience questions in the mouse. Importantly, the mouse is highly amenable to genetic modification, crucial to the fulfilment of the project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely examine the scientific literature for advances in procedures. The majority of these also produce refinements in the experience for the animal and betterment of its welfare. A relaxed healthy animal produces far better outcomes for our research. Over many years of pain research, we have been able to establish protocols to minimise stress in rodents to ensure the best welfare of all animals and maximum scientific output from all studies requiring consistent animal handling. We have also developed new techniques to replace conscious animals with unconscious animals (e.g., in imaging experiments to assess cell activity) to reduce suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We consult trusted sources e.g., Handbook of laboratory animal management and welfare' by Wolfensohn and Lloyd (2003), The Laboratory Animal Science Association (https://www.lasa.co.uk) alongside the NVS.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Alongside regular scientific publications, we receive regular updates regarding the interesting advances in the 3Rs from our biological services team. Most of our researchers are registered with the NC3R's website (https://nc3rs.org.uk) for the latest developments in the field.

120. Understanding the link between stress-induced peripheral dysfunction and development of mental illnesses

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Stress, Gastrointestinal tract, Neuropsychiatric disorders, Neurotransmitter, Brain function

Animal types	Life stages
Mice	adult, juvenile
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main aim is to better understand how exposure to negative environmental factors, especially psychosocial stress, and peripheral pathologies can engage the central nervous system and lead to development of mental health disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neuropsychiatric conditions present a major burden for the sufferer and for the society. Depression and schizophrenia affect up to 27% of people during their lifetime. Attention deficit hyperactivity disorder (ADHD) affects up to 3.3 million children in the EU. Neurodegenerative disease such as Parkinson’s and Alzheimer disease affect a growing number of people with population ageing. An even larger number of individuals suffer from psychosomatic conditions, likely associated with stress and depressive symptoms, such as irritable bowel syndromes (IBS). Treatments for these conditions are often only partially

effective, and their mechanism of action poorly understood, with unpleasant long- term side effects.

Environmental factors modulated by stress, diet, metabolism acting on our gastro-intestinal systems can strongly interact with our central nervous system and contribute to the development of neuropsychiatric disorders. A highway of nerves runs from our brain to our digestive system, and messages flow in both directions between the two. This bidirectional regulation has not sufficiently been considered in relation to our understanding on the physiopathology and treatment of mental disorders. Indeed, environmental factors, including psychological stress, can cause major dysfunction in our gastrointestinal tract which in turn, via activation of a number of neural, endocrine, and immune pathways, has ability to change brain neuronal activity, central receptor sensitivity, cognition, response to stress, risk of drug abuse, and pain perception (nociception).

The project intends to explore mechanisms by which our gastrointestinal tract can react to environmental factors such as stress, diet and metabolism to transmit important changes in brain neurotransmission processes involved in neuropsychiatric disorders and to examine if this could have therapeutic implications.

What outputs do you think you will see at the end of this project?

The data obtained will be disseminated among the international scientific community through publications and presentations. The data generated will help to better understand gastrointestinal mechanisms modulated by stress and contributing to the development of neuropsychiatric disorders. Our data can also reveal new information about the role of diet and gut microflora on brain function, particularly on cognition and nociception. They may encourage the general public to modify their diet (for example with pre/probiotic compounds) to benefit their mental health. This may have a significant positive impact on public health in the sense of managing debilitating problems such as cognitive decline and visceral pain, which are extremely common. Cognitive decline is now a major health problem with our ageing population. The study would also provide more insights in our general understanding of the regulation of brain function by the intestinal tract and may demonstrate that manipulating diet and metabolism may improve the effectiveness of psychotropic drugs. Our strong long-standing connection with the industrial word, through project collaboration, will also contribute to the discovery of new product or new food formulation that can alleviate dysfunctions of the gut-brain connections and improve therapeutics.

Who or what will benefit from these outputs, and how?

During the course of the project we will ensure that our data will be disseminated through the scientific community by writing scientific publications and presenting our results to scientific conferences, which, in turn, will build up and establish connections and collaborations with other scientists and stakeholders.

Both scientific and clinical investigators should find our data of interest. We will also ensure that our publications will be accessible to the general public. This can be done through our University network (e.g. University Research repository) and/or educational and charity organisations.

How will you look to maximise the outputs of this work?

Collaboration with other Universities and with industrial partners will be a priority. During the previous project we have built up important collaboration on project looking at the

effect of selective diet on cognitive function and brain neurotransmission. In addition, our previous collaboration with industry has also contributed to demonstrate potential therapeutic effects of some products for psychosomatic and inflammatory gut disorders. It is our intention to pursue these collaborations.

During the course of the project we will ensure that our data will be disseminated through the scientific community by writing scientific publications and presenting our results to relevant scientific conferences, including our "negative" results, when we have not been able to verify our hypothesis.

Species and numbers of animals expected to be used

- Mice: 1250
- Rats: 950

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To investigate brain circuitry at the molecular levels involved in complex behaviour, we need animal models. The use of peripheral tissues from patients or volunteers, such as blood, has limited value. Some of the limitations have been overcome by using postmortem brain samples from human subjects; however, their availability is scarce and is often associated with confounding variables.

Animal research has made an enormous contribution to human health and welfare. Rats and mice have been the leading model organisms used in biomedical and behavioural research. Our experiments will be carried out on small rodents (rats or mice) which are the most suitable species for the proposed studies: 1) they are most convenient lab animals as they are small, easy to house and maintain, adapt well to new environment and reproduce quickly; 2) most cost effective species; 3) almost genetically identical in the same sex as they are mostly inbred to ensure more uniform results; 4) share virtually the same set of genes as humans which enables investigation of functional mechanisms, both at the molecular and behavioural levels. Exposing rodents to acute or prolonged stress has proven to be useful in understanding the molecular mechanisms underlying affective-like disorders. Such research cannot be carried out on living organisms with a too substantial genetic distance with humans as it requires investigation on functional mechanisms, both at the molecular and behavioural levels, which would be too different. Rats and mice are the animals the lowest in evolution on which such type of research can be carried out. Although other animals, such zebrafish, fruit flies and roundworms, can also be used, they won’t be suitable in this type of research as the organisation of their central nervous and digestive system is too different from human being.

Typically, what will be done to an animal used in your project?

Animals may be subjected to a specific diet or to a specific drug administered in the food or via the drinking water or via injection or gavage.

Animals may be subjected to some psychological and social stress tests such as the acute or chronic restrained test or the social defeat test (SDT). In the restrained test, animals are immobilised for a short period (1-2 hrs) no more than once a day for 1-10 days. In the SDT, tested animals are repeatedly subjected to bouts of social defeat by a more socially dominant cage mate for short periods (2-5 min) no more than once a day for 1-10 days.

Animals may be subjected to some non-regulated behavioural procedures, not expected to induce any significant stress, which will test whether a specific treatment or condition has not induced any behavioural change (e.g. open field tests, sucrose preference tests, motor function tests, cognition tests.

Animal may be anaesthetised for a short period for implantation of a subcutaneous device used for chronic treatment.

Animals may be administered chemicals that can induce intestinal irritation.

Animals will be terminally anaesthetised and will undergo some surgery for brain and intestinal investigations.

What are the expected impacts and/or adverse effects for the animals during your project?

Stress can induce mild weight loss (around 10%), social defeat tests can occasionally cause bite scars that typically resolve in a matter of hours. Stress can induce anxiety and depression-like behaviour that can be assessed using specific (non-regulated) test, like the open field or the sucrose preference tests.

Most of the treatment administered will not normally cause more effects than minor discomfort, for example skin irritation at the site of injection.

Some chemicals can cause intestinal discomfort that can induce weight loss and gastrointestinal pain and dysfunction, including diarrhoea occasionally with some small amount of blood in the stools. These symptoms are mainly observed during the treatment period (maximum 7 days) and often progressively attenuate after the cessation of the treatment. Animals are carefully monitored to make sure these symptoms do not worsen.

Short anaesthesia should only induce minor discomfort during the recovery period.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expected the severity to be mild for 80-90% of all our animals (rats and mice) and moderate for 10- 20% of them.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animal models is crucial for the determination of long-term effects of treatments. The determination of the neuronal changes induced by psychotropic medication and metabolic factors requires the presence of neurones in an intact brain. Neurons to be examined are within a particular brain structure which is regulated by the different inputs from other brain regions. The entire central nervous system is required for such study. Whenever possible we propose to use in vitro techniques. However, in in vitro conditions cells are not in their natural environment and are dissociated from neuronal connections. It is precisely these various inputs which are of particular interest in our studies.

Which non-animal alternatives did you consider for use in this project?

There is very little animal alternative for use in this project. Whenever possible we will consider using tissue culture from immortalised cell lines to perform some of our experiments on protein expression and release of mediators. However, this can be only limited to some investigation aiming to better understand intracellular pathways, while most of our experiments require the integrity of the tissues in an entire body .

However, whenever possible we propose to use brain slices taken from wild-type and transgenic animals killed by Schedule 1 to investigate the effect of drugs in vitro on brain cell electrical activity.

The use of peripheral tissues, such as blood, or from postmortem brain or intestinal samples from patients or volunteers could also be considered.

Likewise, we intend to perform in vitro neurotransmitter release experiments using brain slices or synaptosomes wherever possible, although similar limitations apply for this technique.

Why were they not suitable?

The determination of the neuronal changes induced by drugs requires the presence of neurons in an intact brain. Using tissue culture from immortalized cells can be only limited to some investigations as our experiments require the integrity of the tissues in the entire body.

Cells within slices are not in their natural environment and are dissociated from neuronal connections with other brain structures. Neurones to be examined are within a particular brain structure which is regulated by the different inputs from other brain regions. The entire central nervous system is required for such study. Whenever possible we propose to use in vitro techniques. However, in in vitro conditions cells are not in their natural environment and are dissociated from neuronal connections. It is precisely these various inputs which are of particular interest in our studies. In addition, the natural spontaneous activity of some neurones may be lost within a slice preparation; this requires additional manipulation of the preparation (eg adding an excitatory substance in perfusion medium) which may impair the validity of the data.

Availability of post-mortem brain tissue is scarce and is often associated with confounding variables. The use of tissue culture to investigate consequence of stress on brain activity is limited.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A large number of animals will be used for protocol involving terminal anaesthesia only.

Numbers are calculated to meet the requirement for statistical power. For pilot studies and trial experiments, numbers are estimated from our previous experience, the number of primary and secondary objectives and investigators involved in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will follow step by step the approach provided by Experimental Design Assistant to design our various protocols. We will perform the power analysis to calculate the number of animals needed for each experiment to ensure minimum number of animals will be used with acceptable statistical power.

Our protocols are internally reviewed by experimented scientists using an online submission system.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animal numbers will be minimised by optimising our experimental design. We use specific statistical analysis to identify the optimum least number of animals required under each protocol and this will be constantly reviewed.

Animal numbers will be minimised by optimising our experimental design. We use statistical power analysis tools such as G*Power-specific statistical analysis to identify the optimum least number of animals required under each protocol without compromising statistical power, and this will be constantly reviewed.
The number of animals estimated for use under each protocol will be calculated as the minimum number needed to meet the objectives and will be reviewed throughout the duration of this programme. In general group sizes of 5-6 are appropriate for electrophysiological and microdialysis studies and group of 4-6 are appropriate for ex vivo experiments and 6-10 for behavioural experiments.

We will optimise our surgical methodology and minimise the loss of animals by employing best practice at all stages following discussion with our NVS, for example by using good surgical technique, the use of suitable short acting anaesthetics, minimal surgery time, thermoregulation, aseptic procedures and appropriate postoperative care and analgesia.

We will also provide sufficient training to all investigators to ensure they can perform competently and consistently to avoid repeating experiments or needing more animals.

Wherever possible, in vitro studies will be used to obtain data.

Whenever possible, negative results will be disseminated to avoid other groups repeating the same experiments in order to reduce animal use.

We will use appropriate controls to prevent false results: for example use drug vehicles, inactive drug of similar chemical structure, and pharmacological blockade to confirm specificity of action. Rather than repeating controls, we will use "rolling controls" for each similar set of experiments spread over a period of time. We will optimise our surgical methodology and minimise the loss of animals by employing best practice at all stages following discussion with our NVS, for example use of short acting anaesthetics, minimal surgery time, thermoregulation, aseptic procedures and appropriate postoperative care and analgesia.

When appropriate we will design pilot experiments (2-3 animals) before embarking on full-scale studies, and carefully check literature updates to avoid replication of experiments already published. Wherever possible, in vitro studies using tissue culture sources will be used to obtain data that would otherwise be achieved using animal tissue sources, for example to estimate the affinity profile of a drug at specific target proteins.

The protocols used in all animal studies will be constantly reviewed for improvements in terms of minimising trauma and careful monitoring of the animals' condition by the personal licence holders and NACWO.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will carry our experiments on rodent (mice or rats) models.
To achieve our objectives, it is necessary to model or investigate complete neural pathways of the brain and this is not yet possible using in vitro models or cell cultures. To minimise animal suffering, our in vivo measurements of neurotransmitter function and neuronal electrical activity will predominantly utilise anaesthetised, non-recovery preparations rather than recovery preparations.

Why can't you use animals that are less sentient?

Our experiments will be carried out on small rodents (rats or mice) for the reasons we stated in the "Project Harms" section above. Rats and mice are the least complex species in which such studies can be successfully undertaken. Although other animals, such zebrafish, fruit flies and roundworms, can also be used, they won't be suitable in this type

of research as the organisation of their central nervous and digestive system is too different from human being, and therefore their functions of brain and digestive system and behaviour, as well as the underlying mechanisms, are different from humans. It would have little translational potential if these less sentient animals were used. As indicated above, our in vivo measurements of neurotransmitter function and neuronal electrical activity, which ends up each of our 5 protocols will only utilise anaesthetised, non-recovery preparations.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The principle of refinement is to minimise pain and suffering and improve welfare of animals. We will apply the following rules:
Routine health monitoring using a score-sheet to detect and intervene early in signs of ill health. The frequency of monitoring will be increased in the small number of instances when the likely incidence of adverse effects is uncertain (eg. novel drugs, previously unstudied lesion sites – see below).

Use of literature and other databases to aid selection of drugs and treatment regimens that produce optimal pharmacological effects and minimal adverse effects. Drug-induced adverse effects will be detrimental to the experiments and drugs with this potential will be avoided.

Use of literature and other databases to aid selection of neurotoxin and lesion sites which do not alter the animals ability to perform normal behaviours (movement, eating and drinking, cleaning etc.) and avoid impairment of sight, hearing or smell. To maximise the value of the experimental outcome and minimise the probability of adverse effects, neurotoxins will be selected on the basis of high chemical specificity.

Use of pilot experiments (2-3 animals) before embarking on full-scale studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will particularly follow advices from the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines which are intended to improve the reporting of research using animals – maximising information published and minimising unnecessary studies. The guideline, originally published in 2010, is constantly revised (last version 2020: Percie du Sert N et al. (2020). Reporting animal research: Explanation and elaboration for the ARRIVE guidelines 2.0. PLoS Biol 18(7))

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will utilise on-line resources including those provided by the NC3Rs, (https://nc3rs.org.uk/who-we- are/3rs which includes a resource library specifically for this purpose, https://nc3rs.org.uk/3rs- resources). By subscribing to NC3Rs newsletters, we will also get the latest updates directly.

We will also regularly attend to Training and Information Forum and are following up information provided by the ASPEL website.

121. Normal Blood Products

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Diagnostics, Plasma, Serum, Fibrinogen, Blood Products

Animal types	Life stages
Goats	adult
Sheep	adult
Alpacas	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Sheep, goat and alpaca blood donations will be taken and the:

blood products used in production of diagnostic kits

blood cells will be used to produce recombinantantibodies

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to have access to various blood proteins, cells, plasma, serum and whole blood that are used in manufacture and development of diagnostic kits. Recombinant antibodies can also be produced using extracted blood cells.

What outputs do you think you will see at the end of this project?

Expected outputs are that sera, plasma, blood or PBLs/ PBMCs are supplied as specified by the customer. Blood products have a wide range of uses and demands can fluctuate depending on customer requirements. Examples are:

Plasma supply to one of our customers is expected to be 300L over the 5 years of the project to meet production demands of a diagnostic kit

Creation of naive sheep and alpaca antibody libraries that will enable future antibody production without the constant requirement for animal use.

To supply whole blood for blood agar plates for diagnostic microbiology.

Who or what will benefit from these outputs, and how?

There is a continuing commercial demand for normal animal sera, plasma and blood, as reagents in immunoassays and other clinical assays. The majority of this is used to extract clotting factors for use as critical reagents in clinical chemistry assays, such as fibrinogen which is used directly in diagnostic tests for the monitoring of blood clotting function in patients taking oral anticoagulant drugs. Wherever in the world clinical microbiological investigations are carried out, the characteristic appearance of bacterial colonies on agar plates, supplemented with sheep blood is a universally accepted and recognised first stage of the isolation and identification process.

Whole animal blood can be used to test mechanical devices such as mechanical hearts as it provides a more real to life comparison than with artificial blood.

PBL and/or PBMCs from non-immunised animals are increasingly used to develop naive antibody libraries. These are extracted from the blood of donor animals.

How will you look to maximise the outputs of this work?

Use of larger animals such as sheep aim to maximise the outputs of this work by producing larger volumes from minimal numbers of animals. The production of blood products will be to demand to fulfill requirements without the need to produce excess product. Blood products usually have a very long shelf life which maximises the length of use without the need to replace products.

Dissemination of new processes and products throughout the company and our customer base will maximise the outputs as this will lead to better use of blood products in diagnostic kit manufacture and for better production of recombinant antibodies for use in diagnostic kits and therapeutics.

Species and numbers of animals expected to be used

- Goats: 5

- Sheep: 250
- Camelids: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Sheep, goats and alpacas are large animals and enable larger volumes of blood to be collected at any given donation. This leads to the requirement for lower numbers of animals to obtain a given volume of blood.

Adult animals are used as they are mature and better adapted to regular blood donation.

Sheep and goats, with their contractile spleens can adapt to regular bleeding, with no effect on their health.

Alpacas produce nanobodies and can have advantages over other large animal antibodies when used in therapeutic and diagnostic applications. Peripheral blood lymphocytes taken from healthy adult non-immunised animal blood can be used to create naive nanobody libraries by phage display thus reducing the number of animals required to produce nanobodies.

Typically, what will be done to an animal used in your project?

Typically, an animal will have a set volume of blood collected, correlating to its size and species. This will involve insertion of a needle into a vein and collection of blood into a blood bag, comparable to blood donations by humans. The duration of the procedures is a single donation but this may be repeated as permitted in the licence

What are the expected impacts and/or adverse effects for the animals during your project?

Blood removal may cause bruising/haemorrhage/haematoma at the collection site. From many years' experience the likely incidence is very low.

Less than 1% incidence of systemic reactions, e.g. anaphylactic shock, is expected or anaemia. During the previous 5 years of the licence no systemic reactions have been observed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Animals for blood donations only would be expected to have 100% mild severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Normal animal blood products can only be obtained from the species corresponding to individual clients' requirements.

Whole animal blood can be used to test mechanical devices such as mechanical hearts as it provides a more real to life comparison than with artificial blood. Blood cells for extraction of DNA to create naive recombinant antibody libraries require animal source for initial material.

Which non-animal alternatives did you consider for use in this project?

Customers requirements indicate animal sources of blood products.

Synthetic blood or blood products have been considered for some of the applications but they often do not mimic the characteristics of natural blood and it's products e.g. plasma and serum.

Why were they not suitable?

Synthetic blood or blood products have been considered for some of the applications but they often do not mimic the characteristics of natural blood and it's products e.g. plasma and serum.

No substitute for animal blood cells to extract DNA from to create recombinant antibody libraries. Once library is created, the requirement for animal products is removed leading to a long-term replacement for animal-based antibody production.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of sheep and goats have been estimated based on usage in previous years. About 250 sheep and 5 goats.

Alpaca normal blood products is a new product and is not expected to have a big demand initially. It is primarily for creation of naive antibody libraries, so single blood donation from each animal would be sufficient for each new library.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Normal animal blood products can only be obtained from the species corresponding to individual clients' requirements.

The required volumes of the blood and blood products, and hence the animal numbers required, depend greatly on their application. The animal numbers required will depend on the reviewed demand of the client.

Animals are sufficiently rested between donation events to allow a single animal to complete many donations throughout the life of this license, thus reducing the number of animals required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Larger sheep are selected for production and are better suited to our environment. Larger animals are able to donate larger blood volumes thus reducing their number of uses, and reducing the number of animals required.

For blood cells for recombinant antibody production, smaller volumes of blood are required to extract the cells, thus the number of animals required is reduced.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Large animals provide the most effective and economical source of blood products. They may be bled regularly with no ill effects. Large animals provide larger volume of antiserum at each blood donation to minimise the number of animals required to meet the necessary requirements.

Minimal rest period ensure the animals recover fully before another donation is collected. Having larger animals allows less frequent collections.

Total traceability and quality of our product is essential to the customer for their required use for the benefit of human health. The re-use of an animal which is continually under veterinary supervision is essential and this historical health screening ensures a product of the highest standard.

The use of animals such as sheep, goats and alpacas permits the husbandry of animals under high standards of farming conditions; with grazing in fields in the summer and indoor housing with feed supplements in winter. Their useful life is generally longer than commercially farmed animals. All animals are under the day-to-day care of an animal welfare officer and are visited frequently by NVS.

Why can’t you use animals that are less sentient?

Less sentient animals are unable to produce large volumes of blood donations to fulfill the requirements.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Use of animal conveyor system for handling, turning and weighing of animals: used for routine husbandry (e.g. dagging, foot trimming) and blood sampling. Safe efficient and calm system for both animals and handlers. Use of the same systems for routine husbandry and procedures allows animals to acclimatise over extended period of time before procedures begin.

Advances in animal welfare, care, husbandry, feeding, accommodation, and routine prophylactic treatment such as worming and vaccination ensure the animals are kept in a healthy condition for the prodedure.

Extensive daily monitoring of animals undertaking procedures. The animals will be restrained for bleeding which is planned and set up ready in advance which reduces the procedure time allowing the animal to return to its flock/herd quickly keeping the associated stress to a minimum.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Continuous improvements for procedures and training for operators undertaking procedures to maintain a high level of performance and minimise effects.

The Home Office Supplementary Guidance (HOSG) on projects for the removal of blood in accordance with the BVA/FRAME/RSPCA/UFAW Joint Working Group recommendations (2000).
NC3Rs: Experimental Design Assistant

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Subscription to the NC3Rs e-newsletter to keep up to date with the latest 3Rs developments. These monthly updates focus on funding opportunities, 3Rs events and publications.

Regular local and corporate animal welfare committees discuss 3Rs routinely with specific projects across the global organisation designed to implementing the 3Rs.

This establishment has the facility to browse a large and diverse range of publications via their parent company e.g. Journal of Visualised Experiments, Journal of Immunological methods.

122. The tumour microenvironment in cancer growth, metastasis and response to therapy

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Tumour microenvironment, Therapy, Biomarkers, mRNA splicing

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to study how cancerous cells communicate with normal cells inside tumours and how this causes cancerous tumours to grow and spread around the body.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer remains one of the leading causes of death world-wide, with one in three people dying of cancer in the UK each year. Although treatments have improved for some cancers, many still lack effective treatments and more research is needed before further improvements in survival will be seen.

Cancers that form solid tumours are the most common type. The spread of cancerous cells from these tumours around the body in advanced cancer, known as metastasis, is particularly hard to treat and is the predominant cause of death in cancer patients. The growth and spread of cancerous cells are dependent on a network of supportive signals. These are generated by the cancerous cell's interactions with normal cells recruited into the tumour from the surrounding tissue and the circulation. This supportive network is called the tumour microenvironment.

This project will study how the tumour microenvironment contributes to the growth and spread of cancerous cells from solid tumours and use this knowledge to identify new ways of diagnosing and treating cancer.

What outputs do you think you will see at the end of this project?

The potential outputs from the research outlined in this project are firstly to gain new knowledge concerning the role of the tumour microenvironment (TME), the cellular environment that surrounds cancer cells and is vital for their growth, in cancer biology. In particular this project will increase our understanding of the role of differential expression of gene variants within the TME and their impact on fundamental cancer biology. This project will also use information derived from these studies to identify new molecular process within the TME. Secondly this project aims to exploit this knowledge to improve existing cancer therapy by increasing our understanding of how this impacts on the TME and how it contributes to their effectiveness. Thirdly we will use the information gained to identify new therapies for targeted patient groups.

In addition to increasing the knowledge base surrounding the TME in cancer biology, we would expect this project to develop intellectual property that could be protected and further developed to provide novel therapies and prognostic and predictive biomarkers for the treatment of cancer. Information and knowledge generated during this project will form outputs including peer reviewed primary research articles and reviews articles, and presentations at workshops and meetings nationally and internationally.

Who or what will benefit from these outputs, and how?

We would expect the scientific community to be the primary, most immediate beneficiary of outputs from this project. In the longer term, we would expect out outputs to support improvements in cancer treatment through improved prognostic and therapeutic options for cancer patients.

How will you look to maximise the outputs of this work?

Results will be presented at national/international conferences and workshops, published in relevant journals and posted on the university's website, so that this information is made available to other scientists and clinicians with an interest in tumour biology within academia, research institutes, the pharmaceutical industry, NGOs and the public at large. We will also contribute to review articles and outreach activities in conjunction with local and national charities to make our research findings accessible.

Species and numbers of animals expected to be used

- Mice: 3300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

As cancer is a systemic disease that impacts on the whole body, we need a model system that resembles human disease as closely as possible that allows us to study the impact of cancer growth and spread through the whole organism. This project will use mice as they are the least sentient animal whose physiology most closely resembles human disease. Mice allow us to study cancer across multiple parts of the body during cancer growth, metastasis and response to therapy. In the majority of protocols, we will be using adult mice in our studies. Occasionally juvenile mice may be used where we wish to activate specific genetic markers that will label the tumour microenvironment to aid our studies in cancer when the mice become adults.

Typically, what will be done to an animal used in your project?

In the majority of protocols (approximately 80%) mice will have cancer cells injected under the skin to grow tumours. These typically grow to a sufficiently large size to study in the laboratory by 4 - 5 weeks. During this time, we may treat mice with drugs to understand how the microenvironment within the tumour controls growth. We may also give localised radiotherapy to replicate human cancer treatment. Less commonly we may implant pieces of human tumour under the skin through a small incision.

These take longer to grow, sometimes as long as six months. Tumours grown under the skin do not spread very often and do not always closely resemble human tumours that occur elsewhere in the body. Where we wish to study cancer spread or need the tumour to better represent human tumours, we may inject the cells into different sites in the body. For example, we may inject cells into muscle or we may inject cells into a vein so they spread to other parts of the body. Less occasionally, we may need to inject cells into internal organs, for example into the liver to replicate the spread of colon or breast cancer, to better reflect human disease. When we cannot see the tumours to measure growth, we will label the cancer cells with a gene from the firefly that causes them to emit light. Mice will be briefly anesthetised so we can measure the amount of light being made to monitor tumour growth. Alternatively, we may use ultrasound to detect and measure tumours.

What are the expected impacts and/or adverse effects for the animals during your project?

When tumours are grown under the skin, mice usually show normal behaviour providing the tumour is less than 1 cm in diameter and it is positioned so it does not interfere with mobility, e.g., on the back. Occasionally the skin over the tumour may redden and scab, which can irritate the mouse. If this occurs, it usually happens near the end of the tumour growth period and mice are killed if this does not heal within 48 hours
Mice that have cancer cells implanted through a small incision in the skin or into an organ in their body usually recover quickly from the procedure, are generally able to move and feed within an hour and heal completely within a week to two weeks. To aid recovery mice are given pain relief and antibiotics. Mice are closely monitored and killed if recovery is not proceeding normally.

Mice often experience weight loss when tumours are growing in internal organs and this is monitored closely. Behaviour may also change and mice can become more withdrawn. These adverse effects are minimised through experimental design, particularly the use of methods for imaging and detecting tumour growth within the mice allowing the protocol to be ended before these impact noticeably on animal health and behaviour.

In the majority of cases, the drugs administered will not have a noticeable impact on animal health or behaviour. Some chemotherapeutic agents and radiotherapy can cause weight loss, as they do in human cancer treatments. These effects are closely monitored and doses that may give rise to noticeable weight loss or changes in behaviour are avoided unless there is a high likelihood these will have a significant impact on tumour growth. In most cases, treatment starts when tumours are detectable, typically within one to three weeks after the protocol starts and continue to the end of the protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For mice with tumours growing under the skin, the majority (approximately 80%) will experience mild levels of discomfort or harm and the remaining mice no more than moderate levels of discomfort and lasting harm. Mice experiencing moderate levels of severity may increase when mice are treated with anti-cancer agents, particularly chemo and radiotherapy to approximately 50 - 60%.

A greater proportion of mice on protocols that include surgery or that lead to the development of metastasis will experience moderate levels of severity, and this could be as high as 80% of animals.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer is a disease of the whole body and is regulated by complex interactions between the cancer cells and normal tissue cells recruited into the tumour, called the tumour microenvironment, that aid its growth and subsequent spread to other organs in the body. These interactions also control response to therapy.

This project aims to understand how these interactions control cancer growth, spread and response to therapy and then use this information to improve the use of existing therapies and to develop new ones. In order to achieve this, we need to use a model system that reflects human disease and response to therapy as closely as possible. Mice represent the

closest and least sentient animals that can accurately mimic the systemic nature of cancer and the tumour microenvironment so the aims of this project can be met.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of isolated human cancer cells, the use of human cancer cells and normal tissue cells in co-cultures, including in three-dimensional culture, and cultured human tumour tissue as alternatives.

Why were they not suitable?

Although models of cancer using cells and tissues grown in lab culture are certainly useful, and we do use these extensively in the lab, they can only model limited aspects of cancer growth, spread and response to therapy. None are able to reflect the systemic, or whole-body nature of cancer, and lack perfusion with blood vessels and drainage by the lymphatic system that are important considerations if an accurate model of cancer is needed. These models also lack the complexity and variability seen within cancers growing in living mammals that have a direct impact on cancer biology and response to therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice have been estimated based on my previous experience as a Personal Project License (PPL) holder. This Project will support a similar number of investigators to my previous PPLs (approximately seven) conducting a commensurate number of protocols over five years (average three per year). Most investigators conduct pilot experiments using a small number of mice before moving on to protocols designed to test hypotheses (e.g., comparing different cancer cell’s ability to metastasise or response to therapy) using approximately 50 mice on average across three protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to reduce the number of mice used in this Project we have consulted the NC3Rs Experimental Design Assistant where applicable. We have also incorporated additional imaging methodologies like ultrasound that will allow us to monitor tumour growth within mice over time, reducing the number of mice needed for some experiments, in addition to using non-invasive imaging like luciferase activity (light production by cancer cells). Where transgenic mice have activatable genes within them to study cancer biology, these also activate expression of a fluorescent protein at the same time, allowing us to see our experiment is working in live mice, reducing the number of mice needed for optimisation of gene activation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will optimise the number of mice used by carefully controlling breeding of mice on this Project. Mice will be genotyped immediately after weaning and those not needed for protocols or further breeding will be killed. We also combine more than one female with each male reducing the number of mice used for breeding. Where possible, we will purchase mice from commercial breeders rather than breeding in house.

As I have held more than one PPL, I can draw on previous experience in planning experiments and protocols. This means we can accurately estimate the numbers of mice needed and in some cases, we do not need to conduct pilot experiments. We also use mathematical modelling to more accurately estimate group sizes. This can reduce the numbers of mice in one arm of a study when making comparisons between treatments.

Where we cannot draw on previous experience or modelling with confidence, we conduct pilot experiments with small numbers of animals. This includes optimising the doses, timing of new treatments or new methods of implanting cancer cells to study tumour growth or metastasis. These allow us to estimate the minimum number of animals for use in protocols to test our hypotheses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice and several different models of cancer growth and metastasis during this project. The reason for using multiple models and methods is to ensure we use the most refined approach that will lead to the least pain distress and lasting harm in order to meet our objectives. Cancer is a disease that proceeds through several stages before it causes death. By using different models and methods we can study these separately. For example, if we are most interested in growth at the primary site and early stages of cancer, tumours can often be grown under the skin to replicate this, where tumour growth causes minimal pain and distress and frequently do not spread to other sites. If this method will not allow us to meet our objectives, tumours may be implanted into more physiological sites, for example the muscle for sarcomas. In these models we minimise pain and distress by increasing monitoring of mice and ending protocols when tumours have smaller volumes than with tumours grown under the skin.

Where tumours need to be grown in physiological sites in internal organs, we will avoid making a surgical incision where possible by injecting through the skin into the organ directly, guided by ultrasound imaging if needed. On advice from the Vet, antibiotics and analgesia will be used peri and post operatively and mice will be carefully monitored. Growth of tumours in internal organs will be followed using non-invasive imaging techniques like bioluminescence, fluorescence and ultrasound. This allows us to stop the

protocol when the tumours are large enough to analyse, but not so big they lead to more than moderate levels of pain, distress and lasting harm.

We can often study growth of tumour cells at the most common sites of metastatic spread without having to grow a primary tumour and then wait for cells to spread elsewhere. For example, sarcoma normally spreads to the lung and by injecting cells into the tail vein we can get cells into the lung without needing to establish a primary tumour. For colorectal and breast cancer metastasis we can use ultrasound to inject cells into the liver, the common site of spread. As before we can monitor growth using non-invasive imaging techniques like bioluminescence, fluorescence and ultrasound.

Less frequently we may need to study how cells spread from the primary tumour to the secondary sites. In this case we can sometimes establish the first tumour as described earlier and use non- invasive imaging techniques like bioluminescence, fluorescence and ultrasound to detect spread to the secondary site. In some instances, the growth of cells at the secondary site can be very slow. In this case we may need to remove the initial tumour to allow the metastases to get big enough to study. To ensure mice experience no more than moderate degrees of suffering, pain and lasting harm, this method is limited to tumour grown at sites where they can be removed easily, or treated with localised radiotherapy to slow their growth, like under the skin. Again, if these are removed surgically, antibiotics and analgesia will be used peri and postoperatively and mice will be carefully monitored.

By using these approaches, we can generate tumours that are large enough to study and meet our objectives.

Why can’t you use animals that are less sentient?

Although less sentient animal models can be used to understand some fundamental aspects of cancer, for example zebra fish, the microenvironment within these models lacks the complexity seen in human disease in terms of stromal, or normal recruited cells. The least sentient animal suitable for our studies is the mouse. As a mammalian model, mouse tumour biology is a close approximation of human disease and the pattern of spread of cancer within mice often matches human cancer. As the cancers we are interested in are adult diseases we will also study them in adult mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In addition to increasing monitoring, we frequently use pre and post-operative analgesia and antibiotics to ensure recovery from surgery is rapid and as pain free as possible. We also refine surgical techniques through training and practice, reducing the incision sizes and sometimes remove the need for surgery all together where injections guided by ultrasound can be used. We also carefully consider what is needed to achieve our objectives so that welfare costs to the animals are minimised e.g., tumours are not grown longer or larger than is absolutely necessary, imaging methods are developed for models of metastasis to identify end points.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to the guidance published by the NC3Rs we also consult literature published by the Laboratory Animal Science Association (LASA), the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines and subject specific guidance e.g. Refining

procedures for the administration of substances, Morton DB et al, 2001, Laboratory Animals "Guidelines for the welfare and use of animals in cancer research, Workman P et al, 2010, Br J Cancer and more recent publications including "Endpoint Matrix: a Conceptual Tool to Promote Consideration of the Multiple Dimensions of Humane Endpoints, Ashall V and Millar K, ALTEX. 2014" that encourage planning for unexpected harms during procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am registered with the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), am in contact with the NC3Rs regional programme manager based at our university. I also attend conferences and workshops organised by the NC3Rs and I encourage Personal Individual Licensees working on my Project Licenses to do the same. This enables us to keep up to date with the majority of advancements related to our research. We also regularly consult the published literature and attend workshops and conferences related to our specific field of research where information regarding new methods and procedures that lead to improvements in the 3Rs can be exchanged. If training is needed this is obtained through the staff within our animal unit or colleagues within our field of study. We regularly implement 3Rs improvements where they will not adversely affect our ability to achieve our objectives. This has included changes in the way we handle mice e.g., cupping or using tubes rather than their tails to pick them up, not using needles repeatedly and avoiding surgery to implant cells through improved methods or ultrasound to guide injections.

123. Studying glial cell regulation of central nervous system formation, function and dysfunction

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

neuron, oligodendrocyte, zebrafish

Animal types	Life stages
Zebra fish (Danio rerio)	pregnant, adult, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The goal of this project is to use zebrafish as a model organism to better understand the mechanisms by which glial cells (support cells for nerve cells) regulate how the central nervous system is formed, how it functions, and how it can change to adapt or repair after damage. This work will help understand diseases of the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We only have a limited understanding of the complex mechanisms that underlie the formation and function of our nervous system. This limits our ability to prevent or manage the effects of developmental, cognitive and degenerative disorders, which represent major societal burdens. Part of the reason for our limited understanding of the nervous system

lies in the vast complexity of the brain. The nervous system consists of an incredibly complex network of nerve cells (neurons), which are connected in a specific manner to form functional circuits. The formation and function of these circuits is orchestrated by intricate interactions between all cells that constitute the brain. About half of our brain cells are neurons, the electrically active and primary computing units that drive communication across our nervous system. The other half of our brain cells are support cells for neurons for which we use the umbrella term "glia" cells. There are different types of glial cells with different functions, from providing nutrition to neurons, allowing our neurons to talk to our immune system and our blood vessels. We are particularly interested in studying the functions of a glial cell type called oligodendrocytes. Oligodendrocytes are traditionally known to be the myelin producing cells of the central nervous system in all vertebrates. Myelin serves as an insulating coating around neuronal connections to enable proper signal transmission between neurons - just like the electrical insulation of a cable. Humans that don't form proper myelin or where their myelin is lost or damaged, as it is the case in neurodevelopmental and neuroinflammatory/degenerative disorders, suffer from severe neurological dysfunction. It therefore important to understand how oligodendrocytes make their myelin to help device strategies to improve these processes when they are faulty. In addition, there are large populations of tissue resident oligodendrocytes within the brain lifelong which do not form any myelin. The role of this cell population for brain function is almost entirely unclear, but recent evidence suggests that these cells have important roles for nervous system formation over and above their traditional role of making myelin. We use the relatively simple zebrafish as model system to discover the diversity of oligodendrocyte functions in shaping how the brain is formed, how it functions, how it is disrupted in disease, and how we might develop strategies to overcome dysfunction of the nervous system. The zebrafish is a vertebrate with many similarities to humans, including the presence of neurons and oligodendrocytes. Zebrafish also have an array of experimental advantages for studying nervous system formation and function in an intact living animal without the need of surgical intervention, allowing us to study the roles of neurons and oligodendrocytes and their various interactions with an accuracy difficult to obtain in other animals.

What outputs do you think you will see at the end of this project?

The work of this project will teach us how nerve cells (neurons) and nerve supporting cells (glial cells) of the brain interact to ensure normal nervous system formation, health, and function. We will also learn how neurons and glial cells respond to disruption to the nervous system, and how dysfunctional glial cells affect assembly and function of the nervous system when we create animals that model specific aspects of human diseases. Our ability to study zebrafish that model human disease also allows us to carry out discovery projects that aim to identify new targets as well as strategies to treat disease, be they manipulations to genes or drugs. We will publish our findings that describe our new insights in scientific journals, all of which will be open access to the public. In addition, we have generated and will continue to generate genetically altered zebrafish to share with researchers around the world. We will prepare press releases and social media-based outputs to convey the findings of our work to the public in a digestible manner. Our long-term goal is to help find treatments for disorders of the human nervous system, including neurodevelopmental disorders, disorders affecting cognition and mental health, and neurodegenerative diseases.

Who or what will benefit from these outputs, and how?

Numerous groups will benefit from the outputs of our studies. The scientific community directly involved in studying mechanisms of brain development and disease will benefit from new knowledge that can be integrated into our growing understanding of the nervous

system. Young scientists at early career stages will benefit from the training that they will receive by doing cutting-edge research to foster the next generation of excellent scientist in biomedicine in the UK. Pharmaceutical companies may benefit from our research by identification of new targets in our research that are of relevance to human disease. Therefore, we hope that patient groups, families, carers, and the wider community will ultimately benefit from our work, through the development of strategies to cure nervous system dysfunction. During the course of the project the general public will benefit from knowing that progress is being made in tackling major areas of unmet need in human health.

How will you look to maximise the outputs of this work?

We maximise the output of our work by collaborating widely with groups who have diverse expertise in technology or the use of different model systems. We collaborate with academic research groups that have complementary expertise (e.g. geneticists, systems neuroscientists) to help increase the impact of our work. We make our findings publicly available through open access publications, and by deposition of our work on pre-print servers prior to publication. In addition, we present our work widely at local, national, and international meetings, and through various media outlets.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 46,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All experiments will be carried out with zebrafish as model organism. Developmental, neuropsychiatric, and degenerative diseases of the nervous system represent a major burden to society, and there are currently very few treatments for diseases of the brain because we still lack understanding of the fundamental principles that govern its formation and function. This is in part due to the complexity of the brain and in part due to the difficulty of observing key biological events in real time in most animal models. Zebrafish help overcome many of these challenges. Zebrafish are vertebrates that exhibit remarkable conservation in terms of their molecular and cellular makeup with humans meaning that they often have shared mechanisms related to diseases and respond to gene and drug-based manipulations in similar ways. Importantly, the function of oligodendrocytes in zebrafish is highly conserved when compared with their roles in higher mammals, which allows us to use this model to understand oligodendroglial regulation of CNS function and dysfunction.

We primarily study young developing zebrafish in the laboratory because they develop quickly and are relatively simple, yet building a functional nervous system within a week when they also have oligodendrocytes as they communicate with surrounding neurons. At the same time, young zebrafish are very small in size (only about 0.5cm long) and thus optically translucent so that one can send light easily throughout the animal without need to any surgical intervention. These features, together with our ability to create genetically altered animals, and to treat young zebrafish with drug like compounds, means that we

can directly see into the brain and observe oligodendrocyte development, brain function and even brain pathology as it occurs over time. This then allows us to investigate how experimental manipulations, for example drug treatments, genetic and optical manipulations affect such processes in real time. Thus, the use of zebrafish allows us to gain insights into oligodendroglial control of the central nervous system that are difficult to achieve using other systems and to identify mechanisms underlying disease at an unprecedented scale.

Typically, what will be done to an animal used in your project?

The majority of animals that will be used in our project will be genetically altered zebrafish that have fluorescent proteins in cells or tissues of interest that allow us to track biological events in real time using a range of cutting-edge microscope and camera systems. Many of the animals that we use in our project will have further genetic alterations that change the function of specific genes of interest, e.g. a gene that can change the physiology of a cell using, for example, optogenetics to activate specific cells using light, or a gene associated with a human disease. In some cases, animals will be treated with small molecule compounds applied to the water to activate specific genes, to alter the state of a cell, or to induce the selective death of specific cells. Imaging experiments under different microscopes are always non-invasive and will typically be carried out under anaesthesia. Do do imaging, animals are typically embedded in a small drop of agarose to hold the animal in position while under anaesthesia.

In some cases when we need to directly assess CNS activity, animals may be embedded in agarose in the presence of neuromuscular junction blockers. In other cases when we need to assess behavioural outputs, imaging will be carried out without anaesthesia or neuromuscular junction blocker and the agarose is removed from the tail to allow free movement of the animal, or to monitor the animal as it is freely swimming.

What are the expected impacts and/or adverse effects for the animals during your project?

Due to the small size and rapid development of young zebrafish, we can carry out all our experiments in largely non-invasive manners, and typically with no signs of adverse effects on the animal. The vast majority of experiments will be non-invasive imaging carried out under anesthesia. These procedures may be repeated. However, we did in the past not observe accumulated impacts from repeated imaging as the animals recover fully from this non-invasive procedure.

In some cases, non-invasive imaging will have to be carried out on immobilised animals without anesthesia to assess nerve cell function and aspects of animal behaviour. These procedures may be slightly uncomfortable to the animal, similar to a human experiencing an MRI scan, but do not have any lasting adverse effects from on the animal. Sometimes, animals are restrained in the presence of neuromuscular junction blockers to prevent them from moving whilst under high-resolution microscopes. Again, these are acute non-invasive procedures where the animal will not experience any pain, but we cannot exclude a discomfort from being restrained.

We are, however, also interested in understanding diseases of the human nervous system, and so we have created models of certain aspects of human diseases using zebrafish. These include systems to ablate cells of the nervous system, or the alteration of gene function that changes function and the physiology of nervous system cells. In some cases, such animals can exhibit adverse effects including disrupted development, sensory

function or motor outputs. In the vast majority of cases, we study such animals at very early larval stages when they are about 0.5cm long and 0.1cm wide. Even though young zebrafish can exhibit sensory-motor functions which we study, they are at these stages not yet well developed so that it is not possible to measure adverse effects in great detail, which is different to rodents.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do not study animals that exhibit severe adverse effects.

We occasionally study animals that exhibit moderate adverse effects, due to their genetic alterations, and because very few of our experimental protocols elicit adverse effects of their own. As our genetic alterations and experimental manipulations principally affect cells of the nervous system, moderate effects may manifest in altered neural circuit formation, such as impaired motor outputs leading to altered swimming behaviour. We would only study animals experiencing moderate adverse effects for short periods of time and only when scientifically necessary. We expect that less than 2% of all the animals that we will use during our project would experience this level of effect.

We also study animals that exhibit mild adverse effects. Such effects could be caused by the administration of anaesthesia, or mild stress due to being restrained during microscopy. We expect that up to 10% of the animals that we will use might experience this level.

Our experience to date indicates that the vast majority (>90%) of animals will not exhibit evidence of experiencing an adverse effect that is measurable. Most animals that we use are for breeding and maintenance reasons, and carry genetic alterations to visualise different cells of the nervous system with fluorescent markers. These alterations do typically not show any adverse effects due to their genetic alteration and are indistinguishable from wildtypes.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The formation and function of neural circuits in the vertebrate central nervous system is incredibly complex. Brain development, function, and healthy maintenance involves intricate interactions between neurons, between neurons and glial cells and between these cells and our immune system and cardiovascular system. Many of these cellular interactions are not yet possible to study without animal models, because they are so hard to recreate in a dish. The consequences of damage or disruption to the nervous system

also triggers very complex cellular responses and interactions that cannot easily be reconstituted without animal models. Therefore, to be able to understand how neurons and glial cells interact to construct the nervous system, we need animal models to see how these cells are influenced by the immune system and vasculature in disease. However, in using zebrafish, we make use of arguably the simplest vertebrate model in which the complexity of the nervous system can be directly interrogated.

Which non-animal alternatives did you consider for use in this project?

Certain aspects of neuron and glial cell development, and even certain aspects of myelin formation by oligodendrocytes can be studied without using animals, by studying cells grown in the dish. I have spent my PhD research studying oligodendrocyte cell biology in culture dishes and have gained many insights from this work. Moreover, we continue to work closely with colleagues who use non-animal models. However, this current project aims to use the simple zebrafish model to begin to study the complexity of brain formation, function, and disease as it occurs in the natural setting. At present there are no other suitable non-animal alternatives to do so. We considered using cell culture techniques that now allow mini-brain-like "organoids" in the dish and are hopeful that in years to come technologies will become so refined that we they can be used to study neuron and glial cell interactions and neural circuit function. Such cell culture systems may even allow us to model certain aspects of disease in the dish, and we look forward to incorporating such models into our work.

Why were they not suitable?

Brain organoids are beginning to show great promise as an experimental tool for neuroscience, but have not yet been established to the point where they have all of the neurons and glial cell types that would be required to be able to probe the mechanisms of nervous system formation and function.
Furthermore, brain organoids have not yet been developed where they can function under physiological conditions with a vascular system, the full complement of immune cells, that are known to influence nervous system formation, plasticity, and repair.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

We have calculated the number of animals that we are likely to use based on our use of zebrafish as a model system over the past 5 years. One of the major advantages of using zebrafish as an animal model is that many distinct genetically altered lines of zebrafish can be maintained by single laboratories, and that the system can be used for large-scale discovery projects that are not feasible using mammalian models. Therefore, we plan to use a large number of animals through our project. Of the animals we project to use, that majority are for breeding and maintenance purposes. We have calculated the projected number of fish, based on our previous and projected use of approximately 250 tanks of zebrafish per week, in which we keep an average of 20 fish. We refresh stocks once per year, meaning that we will use 5 separate generations of each stock over the course of the

project, giving a total of 25,000 animals. We maintain >50 genetically distinct lines of fish, many used by several users, and we constantly monitor our stocks to ensure that we are not maintaining lines that are not in use.

In very few cases, animals will need to be maintained for breeding purposes where they may exhibit moderate adverse effects, which will be kept under protocol 2. We anticipate this to affect less than 2% of all animals used for breeding under protocol 1 and therefore project a maximum number of 500 animals here.

The third protocol projects the use of up to 6,000 zebrafish for the generation of new genetically altered animals. This number largely reflects the new ability to target gene function at scale using new tools, including "CRISPR-cas9" gene editing. We can now assess the effect of changing gene function in animals very soon after injecting reagents that can edit the genome. In the past, if we were interested in a gene's function, we would have to edit the genome and grow animals up to sexual maturity, maintain them through subsequent generations, and test if they affected a biological process of interest. Now we can look for the effects of disrupting gene function within days of such "editing". Although the number of animals we are likely to use may increase, the length of time that animals need to be maintained will be greatly reduced, representing an experimental refinement. The ability to target gene function directly means also that we can quickly assess how individual genes affect many different biological functions. For example, we can see how editing different genes affects different cell types or disease states because we can directly edit genes in animals with fluorescent reporters in their neurons, glial cells, immune cells, cardiovascular system etc. Testing the effects of 30 genes over the course of this project in up to 5 assays using up to 20 animals per assay will require 3,000 animals. We will also generate stable mutant lines from genes that exhibit particularly important functions when assessed by acute gene editing, and expect to generate up to 10 such lines, with current estimations that we need to grow up 50 animals to successfully do so (500 in total). In addition, we are currently generating animals in which gene function is disrupted in a cell-type specific manner. At present we need to screen through many animals to find suitable ones for in depth study, thus meaning we require about 200 animals per new line we establish. We anticipate establishing another 10 such lines over the course of the project. meaning that we will need 2000 animals for generation of cell-type specific mutants. In addition, we will continue to establish further new transgenic reporter and effector lines for which we need up to 15 animals per line. Thus, we estimate that we may use a total of up to 6,000 animals for the generation of new genetically altered animals.

In addition to the animals that we will study directly after their gene editing, we predict using a further 15,000 animals in our experimental analyses. This is driven in large part due to the ability to carry out in vivo imaging using transgenic reporter and effector animals. This enables us to have all experimental procedures being non-invasive, meaning that we directly observe and measure the intact living animal. However, it also means that a new animal is required for each cell type to be measured and/or manipulated because each individual animal can only bear a very limited number of transgenic reporters of effector (usually no more than two). Although we anticipate that many of our studies will be carried out at embryonic stages (5 days after egg fertilisation and under) before zebrafish are considered sentient enough to require legislative protection, we have established assays that do require analysis at protected stages after 5 days post fertilisation. For example, these include transgenic models in which we can ablate oligodendrocytes, i.e. cause demyelination, which we study after 5 days of age because myelin only forms in significant amounts during these later developmental stages. Similarly, studying neural circuit maturation and function requires analysis over 5 dpf as these are the stages when

zebrafish begin to feed and swim freely. Analyses of circuit function, and in particular the analysis of animal behaviour can we highly variable, so that we may need up to 50 animals per condition to obtain scientifically robust measurements. Therefore, we predict using up to a further 15,000 for other experiments, based on our current use. We carry out very careful calculations to define how many animals are needed to find statistically meaningful effects in our experiments and will continue to do so for new studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The principal step that we take in our experimental design is to determine what questions we can address using zebrafish at unprotected stages. The use of zebrafish at unprotected stages greatly reduces the number of animals on experimental protocols, and we will continue to pursue this strategy. However, the modelling of disease and the analysis of some aspects of neural circuit maturation are not possible to carry out at unprotected stages, nor are breeding and maintenance protocols, nor the generation of new stocks of genetically altered lines. However, we can assess the efficiency of transgenesis and gene editing at unprotected stages, which reduces the number of animals taken on to protocols. Another important way in which we can reduce animal number is through live imaging of individual animals over time. Through time-course or time-lapse imaging, we can gain a wealth of information about the dynamic nature of biological events from single animals that would otherwise require multiple animals being assessed at many different time-points.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to work to optimise the efficiency of transgenesis and gene editing, particularly cell- type specific gene editing, which we hope will reduce the number of animals that we use in our work. We will also work closely with our aquarium staff who are implementing trials that aim to adapt husbandry procedures to ensure more reliable sex ratios in our breeding stocks. Skewed sex ratios are prevalent in zebrafish stocks and definitive protocols to balance male and female generation have not yet been established. This would help reduce the number of animals that we need to use to generate sufficient breeding stocks for our experiments. In many cases, we will also be able to carry out pilot experiments on zebrafish that can be shared by other users who have the authority to do so.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use zebrafish to study neuron-glial interactions during nervous system formation, function, disruption and repair. We use zebrafish due to the ease with which one can

generate and maintain genetically altered animals with fluorescent reporters that allow direct visualisation of molecules and cells of the nervous system in embryonic and larval stages without the need of invasive procedures, and typically without any evidence of adverse effects. We also use zebrafish because of the ease of gene editing and manipulation of cell function. Again, the ability to carry out transgenic manipulations and gene editing on newly fertilised eggs means that their efficiency and any potential adverse effects can be observed prior to their development to ages that are protected. This is an important refinement that reduces animal numbers used and helps reduce any potential suffering the animal might experience, were it not possible to do so.

Our principal experimental methods involve live imaging zebrafish, and we can do so at different scales. We can carry out high-resolution screens of many animals to quickly assess how gene or compound function affect biological processes of interest, and in a manner that shows no signs of causing distress to the animal. In contrast we can also carry out extensive in-depth imaging over time of individual animals, either of the structure or function of their nervous system in a healthy or disease context. Time-lapse, time-course, of individual animals is a refinement, because we can gather enormous amounts of information from single animals. Such analyses provide insight into dynamic processes impossible to gain in other systems that would require the use of multiple animals if using other models.

We continue to pursue any innovations in husbandry practices, and when trialled and deemed successful, will be applied to our protected stocks, and may significantly reduce numbers of animals used for breeding and maintenance throughout the project.

Why can’t you use animals that are less sentient?

Oligodendrocytes are a vertebrate specific elaboration. Therefore, zebrafish are the simplest standard model in which they can be studied. Zebrafish also have an early onset of oligodendrocyte development and neural circuit formation and so are arguably less sentient than mammals by the time they have developed similar properties. We make every effort to study animals at the earliest stages at which we can address the questions that underpin the aim of our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Very few of our experimental protocols cause significant harm to animals and are already well refined. The main source of potential adverse effects to animals comes from the generation of new genetically altered animals where all possible effects on the animal are not possible to predict. However, as noted throughout, we can assess how new genetic alterations affect animals at unprotected stages and we carefully monitor animals following the introduction of new genetic alterations. We have also implemented a cutting-edge stock management database that will allow us to better track and monitor survival rates and any effects seen across all of our stocks.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines issued by the National Centre for the 3Rs, and will follow the recently published guidelines put together by a group of zebrafish researchers in collaboration with animal welfare experts at the Federation of European Laboratory Animal Science Associations (FELASA).

In addition, we continue to refine practice across all experimental approaches as innovations and advances are published in the literature.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

My group and I follow NC3Rs on social media, and stay informed about relevant innovations through our proactive bioresearch and veterinary services at the establishment. We will implement appropriate advances through discussions with our local vets and named animal care and welfare officer. In addition, we plan to propose research proposals to NC3R to actively contribute to the goals of NC3R in biomedical research.

124. In Vivo Imaging and Studies in Cancer Disease Models

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Imaging, Diagnosis, Therapy

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate
Rats	pregnant, adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim ofthis project?

This project aims to develop in vivo imaging methods and agents to improve diagnosis and treatment of cancer. A variety of novel imaging technologies, combinations thereof and therapies will be assessed for utility in cancer management.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
In the UK, more than 367, 000 patients are diagnosed with cancer each year. Further

improvement in the management of cancer patients requires: early detection of small tumours and metastases (cancer spread), informed treatment selection, outcome prediction, and monitoring of treatmentoutcome.

Imaging techniques can non-invasively detect disease and measure response to treatment.

The project will allow us to develop novel imaging techniques and devices that will help to better diagnose, understand and quantify the severity of cancer development and also improve current interventional procedures for the treatment of cancer. As a consequence, we aim to more efficiently treat patients with cancer and help to assess how patients respond to treatment (thus avoiding debilitating and expensive treatments in patients who will not benefit). This knowledge is important and valuable as it will help us in identifying patients that are at high risk of cancer spread and provide the appropriate treatment to patients based on more quantitative and objective measures.

Ultimately this work aims to improve cancer treatment by early detection and improve monitoring of cancer spread over time.

What outputs do you think you will see at the end of this project?

This programme will develop the requisite: new imaging contrast agents and improved chemistry for their synthesis, and the imaging instrumentation and methodology, for application in cancer.

In the context of this licence, a contrast agent is any administered substance which permits differentiation of structures or fluids within the body, (generally detectable by imaging devices), for the purposes of identification, diagnosis and monitoring of disease evolution or response to treatment.

We will develop contrast agents for molecular imaging of processes that hitherto could not be imaged, develop improved agents so that known processes can be imaged better and develop new chemical methods for synthesis of the agents so that they can be produce more simply and cheaply. These new technologies will undergo a “bench to bedside” translational process in which small animal imaging is a key component to validate the targeting principle employed, predict efficacy, and provide information required by the regulatory agencies to allow assessment of the methods in humans. The new agents must be validated, demonstrating that the images truly reflect the process in question and its response to treatment.

We will develop new imaging instrumentation to combine modalities synergistically, potentially compensating for inadequacies of individual modalities and exploiting their complimentary advantages.

Who or what will benefit from these outputs, and how? Short-term:
Better animal model development: The use of pre-clinical imaging allows us to monitor and evaluate tumour model development particularly in deep seated organs such as ovaries, lungs or brain to help us understand tumour evolution prior to appearance of significant clinical symptoms. Thus, we may then study our novel contrast agents at earlier points in the disease evolution, and thereby achieve our scientific aims at earlier humane endpoints. In addition, better understanding of molecular processes during tumorigenesis (e.g. blood vessel development, regions of dead vs living tissue within tumour masses, up-regulation or down-regulation of receptor expression during disease progression and it's

consequences for targeted treatments, tumour cell spread, impact of treatments/therapy) and dissemination of this data, will increase our basic knowledge as a scientific community.

Less animals used: Repeated imaging provides us with the capability to image an individual animal much like a human during its disease progression and treatment. By using this technology or indeed using multiple imaging technologies, we can obtain far more data per animal than would otherwise be possible using traditional scientific experimental designs.

Evaluation for progression towards human clinical trials: The immediate benefits of research under this licence would be to allow us to make an informed decision whether to test a new contrast agent or therapy in humans, or return to cell studies or chemical laboratory for further modification. The same is true for the evaluation/development of novel instrumentation, computational methods and combinational imaging modalities to asses their suitability for progression to human clinical trials/studies.

Medium/Longer term:

Chemistry & manufacturing: By developing and evaluating better contrast agents, the quality of imaging data will be improved (e.g. improving affinity for target) and give better detectability of smaller amounts of disease. For example, in the field of radiochemistry (for diagnosis and/or treatment), by making radiosynthesis and purification of agents simpler and more robust will lead to shorter production times. In turn, this will result in wider availability to more hospitals without the need for costly cyclotron, radiochemistry equipment and radiochemical expertise in situ. Thus with more widely available contrast agents, more patients will benefit from the technology available.

Therapeutic delivery and monitoring: In addition, imaging also has the potential to non-invasively evaluate therapeutic efficacy in patients, providing rapid feedback on therapeutic or interventional effectiveness.

Novel instrumentation, computational methods and the combination of imaging modalities will benefit both patients and health services through improved diagnosis and clinical decision making.This has already been demonstrated through development of PET/CT and SPECT/CT which are now in routine practice. Clinical MR/PET and MR/SPECT are on the horizon and will extend application of these principles while reducing radiation doses to patients through avoidance of CT scanning. The immediate benefit that the experiments will provide is the basis for authorised translation of these techniques into clinical use.

Whether directly by the development of new imaging technologies/contrast agents, or indirectly by use of imaging as a tool in basic biomedical research, better quality and wider availability and applications of imaging technologies will lead to better clinical decision making and better quality of life for patients, reduced drug development costs, and reduced costs for health services. The beneficiaries will be patients, health services and pharmaceutical companies.

How will you look to maximise the outputs of this work?
We will closely collaborate with academic, clinical and industrial partners to ensure that the developed imaging probes can be tested in human trials and ultimately be commercialised to ensure widespread clinical use of the developed probes for patient benefit.

Similarly, we will closely collaborate with industrial partners to develop prototype software and hardware that can be subsequently shared with other academic centres for wide spread clinical testing.

We will also disseminate the results of this work at conferences and workshops and publish in peer reviewed national and internal scientific journals. In addition, we will organise internal workshops where we will share our results, unsuccessful approaches and provide hands on training for internal and external academics interested in this work. Other means of dissemination will include public engagement events such as talks at the Pint of Science initiative or active participation in the summer festival of the Royal Society.

Species and numbers of animals expected to be used

- Mice: 8000
- Rats: 1750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are the mammalian species of lowest neurological sensitivity that provide the necessary size compatible with the scale of resolution or movement associated with the techniques being studied. Resolution of the whole body imaging techniques is of the order of 0.5 – 1mm. Distribution within smaller animals will be beyond these limits.

We will generally use young adults for our studies. Older mice may be used, particularly if these are genetically modified strains which develop cancer spontaneously as the animal ages. Animals may be allowed to age within limits, if we are studying the impact of therapy/surgery on tumour re-occurrence.

Typically, what will be done to an animal used in your project?
Generally, over a period of 2 - 3months:

Induction of tumour or implantation of cells/tissues in genetically altered animals/wildtype animals (may take 2 - 6 weeks for establishment) or use of a transgenic spontaneous cancer model (may take weeks or up to 6 months for this model to be established).

Injection of contrast agent generally under anaesthetic (typically by intra-venous injection; anaesthesia may not always necessary); in some cases, an additional molecular or cellular agent may be administered, e.g. an inhibitor of the specific process, to modify the biodistribution of the contrast agent. This could be administered via a variety of routes, ranging from intra-peritoneal to possibly through food/water.
Imaging by PET/CT, SPECT/CT, MRI, Optical or other imaging modality, under general anaesthetic.

Less frequently, mice may be housed singly in cages with a grid floor post- step 2 or 3, to collect radioactive faeces/urine for no longer than 3 consecutive days to obtain more complete information regarding the fate/stability of the radioactive contrast agent (e.g. a long-lived antibody).

In some cases both steps 2 and 3 may be repeated to obtain time dependent data or to image different stages of the induced/spontaneous disease or disease response to therapy. Therapy can be radio/chemo/biological therapy.

The final imaging session will be under terminal anaesthetic and will generally be followed by tissue explantation for further data extractions e.g. radioactivity measurement to provide additional quantitative biodistribution and dosimetry data and/or histology.

Rarely, animals may undergo surgical removal of the primary tumour, if the aim of the imaging experiment is to assess the efficacy of the surgery (without optical enhancement) and the re-occurrence of the tumour over time.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect to observe adverse events in the different tumour model induction, development and also during therapy.

Almost all tumour induction models (bar spontaneous tumour development) would be done under general anaesthesia. This would include, administration of cells via intravenous injection or administration post surgical exposure of target tissue/organ. However painkillers given before, during and after any surgery to reduce pain and discomfort.

A superficial tumour may not cause any adverse events but dependent on its growth, the skin surface could redden due to inflammation or become thin and breakdown.

Generally, we expect to see changes in animal well being as tumours progress or metastasise: possible weight loss, hunched posture, ruffled coat and subdued behaviour. Specific cancer models will be prone to particular known adverse effects, e.g. lung tumours would be expected to affect breathing, ovarian cancer is known to lead to visible distension of the abdomen, bone cancer may lead to less weight applied to affected limb or brain tumours may cause head tilting or seizures. All such adverse events will have humane endpoints to prevent animal experiencing clinical signs exceeding Moderate severity limits.

Administration/application of certain therapeutic strategies are known to lead to adverse events. Some chemotherapeutics and radiotherapy regimes are known to cause changes in well being as described above or development of diarrhoea as known to occur in human patients.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals under this licence are expected to experience a Moderate Severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We require the use of animals because:

Data generated from this body of work may be used to inform whether to go forward to human clinical applications. Regulatory agencies require animal data to demonstrate safety and efficacy before molecular imaging agents or therapeutics (that can be validated through imaging) can enter human trials.

To validate the mode of action new/improved molecular imaging agents, experiments are required that cannot be conducted in humans for ethical and scientific reasons.

Bio-distribution in whole organisms (i.e. tracking the injected agents route/ accumulation and excretion through the body), with intact biological barriers and excretion mechanisms, is key to clinical use.

Most aspects of cancer can only be studied in live animals because there are complex interactions between different body systems, which cannot be truly replicated in anything other than an intact animal.

Which non-animal alternatives did you consider for use in this project?

In some limited cases, absolute replacement using humans is a possibility, e.g. when contrast agents that are already used in humans are evaluated for clinical utility and uptake mechanisms. If this is feasible and allowed by the regulatory agencies we will do so.

Prior to all in vivo work, human and animal cell- and tissue-based methods will be used as relative replacements to answer as many research questions as possible and build solid hypothesis to be subsequently tested in vivo. This includes:

experiments in the laboratory, designed to determine target-binding efficiency, agent toxicity to cells, agent stability in cultured cells/tissues/serum;

Within our School we are working on developing the chick chorioallantoic membrane (CAM) as an alternative, high-throughput method for the development of novel cancer imaging agents. The CAM is a highly vascularised extra-embryonic membrane of the chick embryo. The CAM can be accessed easily with minimal invasion to the embryo, enabling the growth of cultured cancer cell and patient-derived xenografts, complete with a co-opted vascular system. This may serve as a replacement for some animal experiments in the future.

'Phantoms' are objects used as substitute or mimic for human tissues to ensure that systems and methods for imaging the human body are operating correctly. So 'Phantom' experiments will be to demonstrate function and capability of the new instruments prior to further testing in live animal settings.

Any new/improved molecular imaging agents or instruments, which are found by such experiments to be unlikely to succeed in animal or later human trials will be eliminated at this stage.

All alternatives are limited in the amount and quality of data they can provide.

Why were they not suitable?

Alternatives are not suitable because such non-living animal/human alternatives cannot replace the complexities of the interactions of these probes in whole body systems or with realistic models of cancer.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The preclinical teams within our School have worked for more than 12 years on similar projects using tumour models. Therefore, based on our extensive experience using such tumours, we estimate this number based on previous experience.

We also have new grants which have been award following peer review and we have factored in the types of experiments and animals proposed therein to account for future work over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As we have access to our archived imaging data from the past 12 years, it is possible to re- examination/re-evaluation this imaging data. By doing so, we may be able to avoid starting from scratch and running a pilot experiment, thereby reducing animal numbers.

Our researchers are able to access online tools such as the NC3Rs Experimental Design Assistant during experimental design but all experimental protocols are also assessed by a number of colleagues (group leaders, myself/imaging scientist, other collaborative scientists, NTCO, NACWO) from inception to final approval.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our animal unit has implemented a new Mouse Colony Management system which is leading to efficient breeding management of colonies through better and clearer data generation.

Imaging to determine tracer distribution rather than conventional ex vivo organ counting is a major contributor to reduction. It allows repeated time-dependent measurements on the same animal as animals are only killed at the last time-point; for example, if a study

involves six time-points, the animal numbers are reduced to one sixth. Since each animal serves as its own control, the data are statistically also more robust, which in turn leads to further reduction as smaller cohort sizes are required (because inter-animal variability no longer needs to be considered at the experimental design stage). Moreover, not only contrast agent distribution in vivo, but potential time-dependent and unexpected re-distribution can be detected through serial imaging. All these attributes contribute to a greatly improved benefit: cost ratio (benefit=data quality/quantity, cost=animal numbers/procedures).

Using imaging technologies and pilot studies allow us to use far few animals in determining the best experimental design to develop.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Species: Mice and rats are the species of lowest neurophysiological sensitivity that provide the necessary size compatible with the scale of resolution or movement associated with the techniques being studied. Resolution of the whole body imaging techniques is of the order of 0.5 - 1 mm. Distribution within smaller animals will be beyond these limits.

Pilot studies are small experimental groups which help us to decide quickly how best to design a statistically and scientifically valid experiment. Thereby helping develop better larger study design and reduce possible suffering. Generally, inhalation anaesthesia will be used to minimise any transient pain or distress and where possible, used for blood sampling, contrast injection, weighing and combined with imaging techniques where it is mainly used for restraint. In addition, there would be full and complete recovery between periods of anaesthesia and/or food withdrawal; rehydrating of animals during long imaging sessions; monitoring of respiration and/or cardiac function and maintaining body temperature during imaging. These steps/measures will optimise the animal's welfare whilst undergoing these procedures. By the very nature of the work involved in this project animals will develop cancer and may undergo therapy. Therefore, careful monitoring will occur throughout the life- span of an animal undergoing these procedures and appropriate interventions will be made to control, reduce or prevent adverse events.

Prior to development of 'orthotopic' tumour models (placing the tumour in the organ where it would naturally develop , e.g. lung cancer), we will assess the tumour growth in a sub-cutaneous (under the skin) model first. By doing so, we would also be able to ensure that the contrast agent being used can truly target the tumour tissue and is useful to study further. Sub-cutaneous tumour models are less likely to cause adverse events to the animal and allow easier visual monitoring of the tumour. Only agents which are likely to be successful will be tested further in tumour models where the tumour develops in it's preferred organ. However, generally adverse events are more likely to be seen in the animal, e.g. a lung tumour could eventually interfere with breathing and is more difficult to

monitor as it grows.

Pain relief will be administered as required, (always in association with surgical procedures) and under veterinary direction. Animals will be humanely killed at the end of the experiment or before then, if the humane endpoint is reached and tissues used for further examination.

Why can't you use animals that are less sentient?

Studies in less sentient animals cannot be used to replicate the complexity of tumour development, metastasis and therapy which could be applied directly to humans.

It is not possible to study tumour development or response to therapy in animals which have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

It is a part of PPL conditions and our ethical understanding that we let animals only develop tumours to a level of burden required to answer the specific research questions of each individual experiment, for example:

if initial in vivo experiments are performed to investigate the uptake of a new contrast agents in early disease, the answers can be obtained by the presence of relatively small tumours without the need of advance disease or clinical signs; the use of repeated imaging in disease progression and treatment experiments where we then can quantify tumour burden by imaging and obtain statistically better data (repeated imaging reduces suffering by reducing the required animal cohort sizes). In fact, imaging will help us in many cases to better assess the overall disease burden in our animals. Once an individual experimental goal is reached the animals will be culled regardless of whether the endpoint has been reached.

We always use objective animal monitoring to allow us to develop better practices regarding better identifying animal discomfort, pain or distress but which also allows us to bring an imaging session forward and cull the animals prior to it reaching a humane end-point.
We always induce tumour model establishement under general anaesthesia and administer analgesia prior to and post any surgical intervention under NVS guidance.

Inhalation anaesthesia will be used wherever possible to minimise transient pain and distress, e.g. during imaging. In addition, full recovery between periods of anaesthesia, rehydration during long imaging sessions, respiration/cardiac function monitoring, body temperature monitoring/maintenance will be conducive to animal wellbeing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow established published guidelines to ensure experiments are conducted in the most refined way. These includes:

The Responsibility in the use of animals in bioscience research produced by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

The Home Office Guidance on the Operation of the Animals (Scientific Procedures) Act 1986.

Accepted limits of volumes and frequencies when administrating compounds and anaesthesia (Appendix 1a in Action Plan section).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project? We will stay informed by updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) website and seminars on the 3Rs organised within and outside of our institution.

Additionally, we have direct support and contact with an NC3R's regional Programme Manager who supports the application of the 3Rs within our institution and is a member of the Policy and Outreach Group. This includes providing expert advice and coordinating the sharing of best practice.

I am the Chair of our Campus AWERB and therefore have access to the latest developments, advancements and information relevant to this project.

125. Understanding fundamental aspects of thymus development and function

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Thymus, T cells, Immunity, Stromal Cells

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to improve our understanding of the basic cellular and molecular mechanisms that control T cell development within the thymus.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The thymus is a unique organ situated in the upper chest that supports the development and export of mature T cells. T cells are a highly specialised type of immune cell that provide immune protection against infections such as bacteria and viruses, and additionally protect against cancer formation. The importance of the thymus to the generation of protective immunity is illustrated in individuals that lack normal thymus function and T cell development, with such individuals possessing a significantly enhanced risk of developing potentially life-threatening diseases. Despite the essential requirement for normal thymus function in generating effective T cell-driven immune protection, the basic mechanisms that control i) the development of the thymus and ii) how it is uniquely

able to support the development of functional T cells remains incomplete. In this programme of work, we aim to undertake fundamental, exploratory research that is targeted at increasing our basic understanding of the cells and molecules that play key roles in thymus development and function. This programme of basic exploratory research is anticipated to contribute to our knowledge base of how T cell development is regulated and may therefore ultimately provide a platform for the subsequent long-term development of therapeutic strategies targeted at manipulating the thymus and T cell immunity when this is dysfunctional.

What outputs do you think you will see at the end of this project?

Work performed under this licence will:

Generate basic science data that will enhance our fundamental understanding of the cellular and molecular mechanisms controlling thymus function and T cell development.

Provide a platform for the identification of new pathways and targets that may inform follow-on studies that are targeted towards the development of translational approaches to manipulate and enhance thymus function.

Generate scientific findings that will be communicated to the wider public and scientific community through presentation at scientific meetings, public engagement activities and publication in high impact peer-reviewed scientific articles.

Who or what will benefit from these outputs, and how?

The outputs from this will be of interest to a wide range of individuals and groups interested in understanding thymus function, and exploring the potential for manipulation of thymus tissues in order to enhance T cell development and output. It is anticipated that the immediate beneficiaries of this research will include basic research scientists within the field of biomedical research interested in T cell biology and the impact of perturbed T cell development on immune protection. At a local level, interactions with both clinical and non-clinical colleagues will ensure discussion and distribution of data and findings from the project. Wider academic beneficiaries will be engaged through sharing of information through attending and presenting data at national and international meetings. Results from the project will be published in free-to-access scientific publications.

Importantly, this basic science project sits at the discovery end of the translational pathway. However, it is essential that such exploratory projects are undertaken if we are to identify novel targets and thereby make new advances in the potential for manipulating the immune system for therapeutic benefit.
Therefore, although outputs from the project may be of interest to the clinical community in the short term, the likely potential for any outputs to directly inform future therapeutic approaches should be viewed in the long term. In addition to individual beneficiaries, the ultimate potential long-term goal to translate research findings into methods to manipulate immune function in humans may have socio- economic impacts due to the health and wellbeing implications of poor immune function.

How will you look to maximise the outputs of this work?

In order to maximise outputs from this work, we will continue to maintain existing and develop new collaborations with clinical and non-clinical colleagues at both national and international levels. Such collaborative interactions are anticipated to enhance sharing of

both knowledge and materials that will provide added value to both this programme of work and others. Outputs from this programme of work will be shared with the scientific community through communications of results and technical approaches at meetings and conferences e.g. by both oral and written presentation. Such dissemination of work will raise the profile of work and allow sharing of data outputs that will enhance knowledge exchange and support development of our projects via feedback from experts in the field. In addition, we will continue to publish our results in high-impact journals. Importantly, in line with the requirements of our funding bodies published results will be in open-access scientific journals in order to make our research as accessible as possible. We also aim to publish negative results where these will provide important data that may inform other studies or prevent replication of experiments elsewhere. In order to communicate outputs with wider audiences we will continue to use additional platforms, including social media e.g. Twitter to maximise exposure of results and publications. Where possible we will also engage with the wider public through public engagement events in order to communicate our work to wider audiences.

Species and numbers of animals expected to be used

- Mice: 18,400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The immune system is formed by a network of cells and inter-connected organs that are spread throughout the body. In this programme of work we aim to look at how the thymus supports development of T cells and how these are exported into the peripheral circulation in order to provide protective immunity. In particular, we aim to study thymus development and maintenance throughout the life- course and investigate the pathways that endow the thymus with its unique ability to support T cell development. In order to investigate these aims, we will use mice in this project. The mouse represents the lowest order of placental mammal that possesses an immune system of similar make-up and function that can be used to effectively model the human immune system, including the thymus. In addition, mice represent the primary species that possess a wide range of naturally occurring and induced genetic defects that allow us to study the role of specific cells and molecules in thymus biology. As this project seeks to explore how the thymus initially develops and is subsequently maintained we will use mice at multiple stages of the life-course including fetal, neonatal and adult.

Typically, what will be done to an animal used in your project?

This project licence will support the breeding and maintenance of mice that possess alterations in specified genes (herein termed genetically-altered). The use of genetically-altered mice will underpin experiments aimed at exploring the role of specific genes or cells of interest in thymus function. In order to do this, we will breed genetically-altered mice that have altered expression of defined genes. At various stages of life, mice will be humanely killed and cells/tissues will be isolated for direct post- mortem analysis without any additional procedures being performed on animals. Such experiments will allow us to experimentally examine whether thymus function and T cell development is perturbed

where expression of the gene of interest is altered.

Where the above experiments reveal a disruption in thymus development or function, we will perform further investigations to explore how the gene of interest is exerting an influence on thymus biology. These experiments will involve animals experiencing one of the following approaches:

Animals will receive an injection, typically this will be a single injection, although in some cases may involve up to 6 injections separated by at least 24 hours over a maximum period of 2 weeks. Mice will then be humanely killed at a later time point for analysis of tissues post-mortem. The majority of animals will undergo a peripheral injection (for example into the tail vein), but some will receive an injection directly into the thymus; this is a surgical approach that will be performed under general anaesthesia. Thymus injection will only ever be performed on a single occasion.

Animals will be transplanted with donor thymus tissue placed under the kidney capsule on one side of the animal. This involves a short surgical procedure and will be performed under general anaesthesia. Animals will be subsequently humanely killed at a later time point and tissues will be analyzed post mortem.

What are the expected impacts and/or adverse effects for the animals during your project?

Brief stress due to temporary handling of mice and discomfort due to needle insertion required for the delivery of cells OR substances (typically labelling agents or proteins/peptides) by injection into peripheral sites.

Recovery from general anaesthesia following EITHER a single injection into the thymus (intrathymic injection) or surgical transplantation of thymus tissue under the kidney capsule.

It is not anticipated that any genetic alterations in mice used in this project will have downstream adverse effects. In addition, in animals undergoing thymus injection or tissue transplantation we do not anticipate any adverse effects arising from the grafted tissue. Transplanted tissue will be genetically matched to the host to avoid rejection or additional complications of transplant. Animals are expected to make a full recovery following injection or transplantation of cells/tissues and are expected to exhibit normal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The upper severity of an estimated 80% of animals will be mild. This encompasses the breeding and maintenance of genetically-altered animals, followed by post-mortem analysis of cells/tissues, and also animals undergoing a single mild intervention involving an injection of cells OR substances (typically labelling agents or proteins/peptides) into peripheral sites.

It is estimated that 20% of animals will experience an upper severity of moderate. This includes animals undergoing surgical approaches involving general anaesthesia, encompassing EITHER a single intrathymic injection OR transplantation of thymus tissue under the kidney capsule.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The analysis of T cell development and thymus function relies on the coordinated activity of many cell types and molecular signals that require the use of whole animal models to investigate in detail. For example, the thymus does not contain haematopoietic (blood) stem cells that develop into T cells.
Rather, blood stem cells are located in the marrow of skeletal bones and migrate from these distant sites in the body through the bloodstream in order to colonise the thymus. Importantly, this is a continual process meaning that the study of T cell development relies on an interconnected system of skeletal and circulatory blood vessels with the thymus. Following development in the thymus, a critical step is the export of T cells into the peripheral circulation in order to provide effective immune responses.

Similar to thymus colonisation, in order to study this critical step it is necessary for the thymus to be fully connected to an intact circulatory system. At present no *in vitro* experimental systems exist that can effectively model this complex, interconnected network of the circulatory and skeletal systems with the thymus.

Which non-animal alternatives did you consider for use in this project?

We routinely use in vitro (in a dish) models in our research, including cell and thymic organ culture systems. These approaches include thymus organ culture systems. These models help to reduce the need to perform experiments in whole animals, and provide a key system where we are able to validate experiments in vitro e.g. screening and testing the ability of particular molecular pathways to influence thymus function before these are explored in animal models. Isolated thymus tissues will be placed in in vitro culture where they can be maintained for up to 10 days and are able to replicate a normal programme of thymus and T cell development, at least for a limited short term period of time. Using this system, it is possible to test the role of defined molecular pathways in thymus function by introducing agents that can either stimulate or inhibit pathways of interest. In addition, using in vitro ‘tissue engineering’ approaches in these thymus culture systems (similar to organoid models), we are able to isolate defined cellular components from the thymus and mix them back together where the cells are able to spontaneously reassemble back into a mini thymus in a dish. This model provides a useful in vitro replacement model where we are able to create a ‘designer’ thymus in a dish. Using such systems we can track the development and function of cells within the thymus.

However, current limitations to such in vitro models, such as lack of a connected blood supply and therefore absence of immature T cell recruitment from the bone marrow, currently place limitations on the use of such models as a complete replacement for whole animal models. A further current limitation to the use of non-animal models for thymus research remains the lack of information regarding stem cell populations that are capable of

generating functional thymus tissues. Although our previous work, and that of other research groups, have sought to identify stem cell populations that can form complete thymus tissues, as yet no specific markers have been identified that allow for the isolation and propagation of such cells in vitro, thereby precluding their use in alternatives to animal models.

Why were they not suitable?

The thymus contains a unique three-dimensional network of cells that support the development of T cells. At present, attempts to use cell culture models to recapitulate normal thymus structure and function, in particular use of 2D cell culture models has met with limited success. The lack of specific markers to isolate stem cells from thymus tissues in order to attempt generate thymus tissues has also hampered efforts to replace animal models. Recent efforts have also been made to utilise organoid systems to study aspects of thymus biology, although as yet the effectiveness of such systems remains limited and have failed to model normal thymus development and function. Critically, the need for a fully integrated immune system that communicates and directs the migration of immune cells through a system of blood vessels is essential for the study of the thymus and T cell development. As such alternative models to study thymus function currently remain limited. However, we will continue to study the scientific literature for any emerging models that may facilitate reduction and replacement of animal models, and will continue to utilise and refine our current use of non-animal models such as thymus organ culture systems wherever possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This programme of work is a continuation of work performed under our previous project licence. We have therefore estimated our numbers based on our experience of animal husbandry and use of animals using identical protocols and procedures over the last 5 years of our previous project licence. Numbers of animals are therefore based on previous Home Office data returns for the use of animal numbers, in-house data from pilot studies and ongoing/published studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase we use power calculations (e.g. using G* Power software) to estimate the predicted group sizes necessary to determine statistically significant results. In order to reduce animal use, we routinely use robust approaches to ensure standardisation of experiments in order to make them directly comparable for example where an individual scientist repeats an experiment across different days, or where experiments are performed by more than one individual. We adopt standard experimental approaches within our research group to ensure reproducibility via the use of shared experimental techniques and regular lab meetings to ensure that all research lab

members are performing experiments in exactly the same way. We also perform regular calibration of our scientific instruments again in order to reduce the need to repeat any experiments due to variability in the acquisition and recording of results.

Wherever possible we use control animals from the same litter as experimental mice in order to both reduce unnecessary animal breeding and to reduce the potential for any observations occurring as a consequence of differences in genetic and/or age-related factors. Where undertaking a new series of experiments we will perform pilot experiments coupled with power calculations to estimate the number of animals that we need to breed, maintain and subsequently use in experiments. We will also make use of NC3Rs resources for 'Experimental Design and Reporting' (https://nc3rs.org.uk/experimental-design-and-reporting) to support our studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to optimise our use of animals, we will use a combination of approaches:

Efficient animal breeding and husbandry. Mouse colonies will be maintained at a size necessary to generate animals required for robust experimentation. Wherever possible, we will use litter-mates as control mice in order to optimise maximum use of animals generated under this licence.

Pilot studies. These will be undertaken whenever we commence a new series of experiments or use new reagents etc. Outputs from such experiments will allow us to accurately plan animal breeding and subsequent experiments for example through the use of power calculations.

Sharing of materials. We undertake regular team research meetings at the start of every week where we discuss experimental plans. Here we are able to maximise use of every animal by combining experiments and sharing tissues/cells taken from each animal.

Archiving materials. We regularly archive cells and tissues by freezing and storing materials. Such archived tissues provide a valuable resource for future experiments, for example gene expression and microscopy analysis of cells/tissues. Using such approaches we are able to maximise use of tissues and reduce the need to breed additional animals.

As described above, we will make use of NC3Rs Experimental Design and Reporting Resources to guide our studies, and will ensure experimental design and conduct is performed and reported in line with the ARRIVE 2.0 and PREPARE guidelines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm

to the animals.

This programme of work will be underpinned by the breeding and maintenance of genetically-altered mice in order to explore the cells and molecules that control thymus development and function.

Injection of cell or substances

Where we have identified candidate pathways for examination of cellular and molecular pathways, we may need to inject cells or reagents in order to activate or block identified pathways in whole animals. Through such experiments we will examine the impact of pathway manipulation in thymus function and T cells development. We will administer either cells or substances via the least invasive route possible. In all cases, we will ensure to minimise any adverse effects through use of minimum possible needle size and number of injections.

In a small number of experiments, we may need to deliver cells or substances directly to the thymus (intra-thymic injection) in order to avoid introduced materials ending up at the wrong site or influencing other cells/organs if they were to be delivered for example by intra-venous injection via a peripheral vein. We have refined the technical approach to conducting intrathymic injection to ensure the surgery is less invasive by reducing the size of the skin incision to the minimum possible size and removing the need to perform a thoracotomy (incision between the ribs) or incision through the breastbone.

Tissue transplantation

In a small number of experiments, we will perform transplantation of thymus tissues under the kidney capsule of adult mice. Here, we will isolate thymus from embryonic genetically altered mice and transplant it under the kidney capsule of an adult host mouse. Importantly, due to the highly vascularized nature of the kidney, the transplanted thymus becomes fully connected to the host circulatory system and is able to operate as a 'normal' thymus over an extended period of time. Using this system, we are able manipulate thymus tissues in vitro (for example remove or add a particular cell type in the thymus) prior to transplantation. Essentially this allows us to create a 'designer thymus' in vitro. We can then transplant the donor thymus tissue into a whole animal model in order to study its development and function. This approach allows us to reduce the number of complex genetically- altered mice that need to be bred due to our ability to generate manipulated thymus tissues in vitro. In all experiments, tissue transplantation is performed solely under the capsule of a single kidney.

Importantly this refinement helps to mitigate any risk of perturbed kidney function, due to the unoperated kidney being able to provide sufficient function in the very rare event that surgery compromises function of the operated kidney. We continue to seek to refine such approaches, for example we have previously sought to identify less invasive sites for tissue transplantation, such as under the skin of the ear.
However, this has so far met with limited success and reproducibility for thymus transplantation potentially as a result of the degree of blood flow at the site of transplantation. However, we will continue to explore opportunities to refine this approach wherever possible. Following surgery, mice will be placed in warming chambers and closely monitored post-surgery to ensure that mice display appropriate recovery and behaviour, with animals subsequently being maintained for the minimum possible amount of time to achieve experimental objectives.

Why can't you use animals that are less sentient?

In this project we will use mice as an experimental model. The mouse is the species of choice as it supports the production of embryos at carefully staged points of development. Embryonic mice will be used as a source of cells and tissues (including thymus) to perform in vitro organ culture experiments that allow us to both reduce and inform our work in mice at later stages of life. The mouse replicates the mammalian placental pattern of human development over a gestation period of 21 days and provides the closest model that replicates the development, maintenance and loss of thymus function with increasing age. The mouse is also the only species that provides a wide range of natural and induced mutants with defined genetic alterations that allow the study of target molecules crucial to the function of the immune system. A large body of published data has been generated characterising the immune system in murine models, and the vast majority of knowledge regarding thymus development and function is solely based on the use of murine models since the first formal description of the critical role of the thymus in T cell development in the 1960s using mice as an experimental model. Importantly, the use of species that are less sentient remains limited. For example, Drosophila fly models do not possess an equivalent of the lymphoid lineage, including T cells nor do they possess a thymus which is evolutionarily restricted to jawed vertebrates. While fish models e.g. zebrafish possess a thymus, notable differences preclude their use as a model to fully replace the use of mouse models, particularly in regard to studying thymus biology in relation to bone marrow transplantation due to these animals lacking bone marrow haematopoiesis with blood cell development taking place in the kidney of adult fish. Although this project will use embryonic models wherever possible, we will however need to extend use of animals to adult stages in order to track postnatal stages of thymus development and maintenance that include critical stage specific roles for the thymus in T cell production.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our research group has played a significant role in refining approaches to study thymus development and function in mouse models that have helped to reduce the number of animals used in in vivo studies. For example, we have played a major role in developing novel in vitro models for the study and manipulation of thymus tissues. Such approaches have been widely adopted within the international research field and have provided an important model to validate candidate cellular/molecular pathways without the need to use complex in vivo models.

Collaborative work by our research group has additionally sought to refine approaches for the ectopic engraftment of lymphoid tissues in murine models. In this approach, we have sought to refine methods for applying the least invasive surgical approach to transplant lymphoid tissues into adult host mice. We will continue to seek to refine in vivo surgical approaches and continue to ensure that only the most robust and reproducible, yet least invasive approaches are used and this will continuously be assessed on an experiment by experiment basis.

We will always aim to keep our experiments to the minimum possible duration to meet our experimental end-points, and will always use the fewest possible interventions (e.g. injections) that are needed. Best practice in animal husbandry e.g. handling and enrichment will also be adhered to.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experiments will be planned, conducted and reported in line with the PREPARE (planning) and ARRIVE (reporting) guidelines. We will also make use of the NC3Rs Resource hub e.g. 'Breeding and colony management' and 'Experimental Design' to inform our approaches. LASA guidelines will be adhered to and used where appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to make good use of NC3Rs resources both through the NC3Rs website, and also at a local level via communications and activities driven by the local 3Rs Focus Group e.g. regular distribution of the NC3Rs newsletter. We will seek to engage with relevant seminars, conferences and webinars where available, and will maintain contact with NACWOs, and the NVS where necessary. As described elsewhere, we will also continue to review the scientific literature to ensure that we are able to identify and potentially adopt any new approaches and/or models that may supplement or replace our current animal models.

126. Cancer Drug Discovery

Cancer Drug Discovery

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Immunology, Therapy, Immuno-oncology, Oncology

Animal types	Life stages
Mice	adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our Company's overall aim is to provide a suite of advanced, mode-of-action models that will allow pharmaceutical and biotechnology industries to test novel and existing drug candidates for use in the field of oncology and immuno oncology. In vivo models are combined with advanced in vitro assays that allow us to study the effects of drug candidates.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
This project aims to accelerate drug discovery in oncology and immuno-oncology at a time

when there are exciting developments in the field of cancer therapy and immunology. Although cancer therapies are improving there are still significant gaps in treatments available.The short-term benefits from this project will be that our expertise in immunology and drug development will be available to clients lacking our level of expertise, thereby facilitating the evaluation (chiefly efficacy and mechanism of action (M-o-A), but with some safety data also obtained) of potential new products, improving the go/no- go decision making process. The long-term benefits of our work in this area, collaborating with a range of organisations, are therefore expected to be: a) new and improved drug regimes for a range of cancers; b) better clinical management of cancer and c) societal benefits from lower disease burden and greater productivity.

What outputs do you think you will see at the end of this project?

We provide a suite of advanced, mode-of-action models that will allow the pharmaceutical and biotechnology industries to test novel and existing drug candidates for use in many conditions where the immune system plays a role. Information from studies performed are used to make decisions about the progression of drug candidates to clinical trials.

Who or what will benefit from these outputs, and how?

In the short term, these outputs will assist the pharmaceutical and biotechnology industries in making key decisions about their drug discovery pipelines and whether to progress a drug candidate towards clinical trial. In the long term, this benefits patients as it prevents exposure to ineffective therapeutic agents and also facilitates the development of novel drug candidates that may have substantial clinical benefits.

How will you look to maximise the outputs of this work?

As work is performed solely on a commercial basis, for biotech and pharmaceutical clients, output will be subject to client confidentiality and therefore collaborative opportunities will be limited and at the discretion of the client, however, some of our previous clients have published our data in peer reviewed journals and presented at Scientific conferences. As dissemination of information may not be feasible, we will maximise the usefulness of the output through high quality experimental design and review of proposed experiments for scientific merit before proceeding with any work.

Species and numbers of animals expected to be used

- Mice: 6550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to replicate human disease, we shall predominantly use adult mice, with an intact, mature immune system in this project, but may also use other stages if required. The role of the immune system and the mechanisms of disease in these models closely mimic a lot of the aspects observed in the human disease. Therefore, use of these animals for drug development is directly relevant for the clinical treatment of humans.

Typically, what will be done to an animal used in your project?

It is envisaged that many of the genetically-modified animals will be humanely killed to provide cells and tissues for use in the laboratory and will undergo no further experimentation. Where experimentation is conducted, procedures include assessment of cancer models (where tumours are induced in healthy animals), dose finding procedures and the analysis of the process by which healthy cells are transformed into cancer cells (compound-driven carcinogenesis). All animals will be humanely culled at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that have received a subcutaneous cancer cell transfer will experience tumour growth, this will normally be in the flank and should induce minimal direct adverse effects. However, to replicate the effects of human cancer, listed models may lead to clinical signs including tumour ulceration, which is normally not accompanied by bleeding, exudation, or infection. Animals will be closely monitored throughout for signs of distress and culled humanely if they exceed the predefined limits.

Tumour location, onset of ulceration, bleeding, exudation, and other animal welfare observations will be recorded in detail and may allow further refinement of the models. If the study goals are achievable prior to reaching the tumour size endpoint, this will be reflected in earlier termination. This option will be agreed with the client at the study design stage, with consideration given as to the best way to gain all necessary data from each experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of the animals used will experience mild (60 %) to moderate (40 %) effects. Direct effects from tumour growth should be mild, with other animals experiencing mild discomfort following administration of treatment.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?
Importantly, many of our assays are performed in the laboratory, rather than in animals. These often use human cells and allows us to test how different cells respond to potential drugs. However, once we have defined the most likely candidate drugs, we must understand whether these can in fact help to promote the immune response seen in cancer, ultimately reducing tumour size and improving long term prognosis.

Which non-animal alternatives did you consider for use in this project?

We routinely perform in vitro assays using human cells in order to test drug candidates on cells of the immune system. The majority of our work is conducted using these in vitro assays, however, animal studies are often required downstream of this in order to test drug efficacy in a living system prior to clinical trials in humans.

Why were they not suitable?

In vitro assays are very useful at measuring the effect of drug candidates on particular cell populations and complex assays can be designed to model a lot of the processes that occur in the body. However, in vitro systems currently cannot model all of the aspects involved in cancer that occur in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is the maximum number of animals predicted. As a CRO it is difficult to accurately calculate the exact number on animals that will be used as this largely relies upon client requirements and demand. Whilst we offer in vivo models as a service, these experiments are ordinarily only performed as a small part of a larger package of work that is primarily focused on in vitro models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our emphasis as a company is to use data-rich in vitro methods so that clients can select the best compound(s) before moving forward to in vivo models. This means that drugs that are unlikely to be effective are screened out at an early, in vitro stage. We have almost 5 years ' experience with these models and as part of establishing these models, we optimised the models so that we could use as few animals as possible but still obtain sufficient relevant information.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
Our advanced in vitro assays allow us to advise our clients on which of their test compounds are most likely to be effective in in vivo studies. This saves time and money and, most importantly, reduces the numbers of animals required for studies.

In addition, pilot/initial studies will be performed using the least invasive protocols and only using drug candidates that have been proven to be effective in in vitro experiments. We will also apply statistical procedures to determine that we are using sufficient but not excessive numbers of animals per group for the optimum scientific design.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our objective is to provide advanced, mode-of-action models that will allow the pharmaceutical and biotechnology industries to test novel and existing drug candidates for use in cancer. In vivo models are combined with advanced in vitro assays that allow us to study the effects of the test drugs on tumour growth during the development of cancer.

Many of the genetically-modified mice used within this project will be humanely killed to provide cells and tissues for use in the laboratory and will undergo no further experimentation. Beyond our breeding program, the majority of the WT and GM animals used will experience mild to moderate effects. These include administration of inflammatory agents to provoke an immune response.

In some experiments we will also need to induce tumour growth so that we can further study the immune response in a cancer model, or to analyse the effect of treatment upon tumour growth. We now have experience with several of these models and animals will be closely monitored throughout to minimise pain and suffering.

Why can’t you use animals that are less sentient?
Many of our clients begin their programs of work using isolated cells from rodents from which sufficient quantities of desired cell types expressing a target of interest can be obtained in sufficient quantities for moderate throughput, data rich in vitro screening assays. Those successful "Hit" compounds can then be further progressed to rodent in vivo models to ensure continuity of species used. Rodent models are extremely well-characterised and validated for studying the progression of cancer and for evaluating the efficacy of new therapeutics. They also have the most extensively characterised immune systems, which is relevant for understanding the role immune cells play in the progression of cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
Where necessary, animals will receive appropriate anaesthesia during the procedure and analgesia following surgery. In some experiments animals are at risk of infection. These animals will be kept in a barrier environment and receive appropriate antibiotics. All animals are monitored regularly and any that show signs of ill health receive prompt veterinary intervention. If significant ill health is evident, the animals are humanely culled. Any further refinements that can be implemented over the course of this projects will be put in place following consultation with the Named Animal Care and Welfare Officer (NACWO) and Named Veterinary Surgeon (NVS).

Subcutaneous tumours will be monitored twice weekly by caliper measurement, with those animals reaching 15mm diameter being culled to minimise any adverse effects. Tumour

location, onset of ulceration, bleeding, exudation, and other animal welfare observations will be recorded in detail and may allow further refinement of the models.

The vast majority of animals that receive intraperitoneal, or intravenous, administration of neoplastic cells will not show any clinical signs of tumour growth. Animals will be closely monitored and any showing any adverse effects will be humanely culled.

In terms of general handling, as advised by our establishment we have adopted non-aversive handling methods where feasible and update our practices according to recommendations.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to following the PREPARE guidelines and the best practice procedures recommended by the NC3Rs, regular literature searched will be performed to ensure that the models used are the most refined for each purpose.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

In addition to communications and seminars from the University Veterinary Services, we will routinely access the resources on the NC3Rs website (https://www.nc3rs.org.uk/) and subscribe to the NC3Rs newsletter in order to keep up to date with current developments.

127. Characterising mechanisms involved in Gastrointestinal diseases

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Immune System, Metabolism, Blood vessel development, Gastrointestinal disease

Animal types	Life stages
Zebra fish (Danio rerio)	embryo, juvenile, neonate, adult, pregnant
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to identify cell populations and mechanisms involved at key stages of gastrointestinal disease progression. We will develop and assess new treatments to stabilise, or reduce gastro- intestinal disease progression and also novel diagnostic tools.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Gastrointestinal diseases, such as inflammatory bowel disease, affect 449 patients per 100,000 people in the UK. Patients with inflammatory bowel disease experience abdominal pain, severe diarrhoea, fatigue, weight loss and malnutrition. In more serious cases surgery is required to remove the affected bowel area.

Approximately 33% of patients do not respond at all to limited current therapy offered and a further 50% lose response over time. Persistent inflammation in the gut can lead to cancer. Colorectal cancer is the third most common cancer in the UK, with only 53% of patient with colorectal cancer surviving for more than 10 years.

Gastrointestinal diseases are classed as multi-factorial diseases. This is because there are many factors and cell populations that initiate and cause progression of gastrointestinal disease to advanced stages. However, the mechanisms that drive gastrointestinal disease are not fully known. Neither are the associated mechanisms and cell populations involved in the lack of response or resistance to current therapy.

It is important to be able to continue to identify these mechanisms. Using this new knowledge, we can develop appropriate therapy to reduce, stabilise and reverse gastrointestinal disease. Collection of samples at key stages will enable us to develop biomarkers to identify disease stage, and predict outcome and response to therapy.

What outputs do you think you will see at the end of this project?

Using mice and zebrafish to model aspects of gastrointestinal disease (including the use of syngeneic models and genetic modified animals) we will have gained the following knowledge at the end of this project:

Improved knowledge of how different aspects of the immune system and other cell types (such as microbiota or stromal cells) and factors are involved in aberrant biological processes, which drive intestinal diseases.

Improved knowledge on how diet can influence initiation and progression of gastrointestinal disease.

Improved knowledge of the different cell types of the gut respond to low oxygen and nutrient levels in normal and pathological states within the gut.

Identify mechanisms of resistance to current therapies used in gastrointestinal disease.

Developed new treatments (including therapeutic antibodies) to reduce, stabilise or reverse gastrointestinal disease.

Developed biomarkers (including diagnostic antibodies) to identify disease stage, and predict outcome and response to therapy.

This information will be shared with the scientific community through publications, conferences and online data portals.

Who or what will benefit from these outputs, and how?

Patients with gastrointestinal diseases, clinicians and academic researchers will benefit from the outputs of this project.

Ultimately, the results of this research will enable improved diagnostics for patients and also inform which treatments are most appropriate in gastrointestinal disease. This project will enable us to have a better understanding of the mechanisms and involvement of cell types that hallmark different disease states, enabling improved drug targeting in patients.

How will you look to maximise the outputs of this work?

This information will be shared with the scientific community through meetings, publications (including unsuccessful approaches involving animals) and conferences. In addition, we hold in regular person meetings and invite collaborators from diverse scientific backgrounds to attend and exchange knowledge and experiences. These improve the outputs of our projects.

Species and numbers of animals expected to be used

- Mice: 5000
- Zebra fish (Danio rerio): 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures. Explain why you are using these types of animals and your choice of life stages.

Zebrafish: We will be using zebrafish as the lowest organism in which gut, vasculature, metabolism, immune development is well studied. Some of the cell types involved in these processes in humans have not been identified in mice; for example, those involved in gut formation. Zebrafish need to be at the age that they can bred and produce healthy offspring. Studies on development and factors involved in gastrointestinal disease would be conducted up to the stage of young fish, when the immune system is functional.

Mice: We will be using mice to model the complex interaction between cell types and regulation of processes that occur in humans and generate clinically relevant information. Mice need to be at the age that they can bred and produce healthy offspring. Successful modelling of gastrointestinal disease and evaluation of therapy is dependent on the use of young adult mice. Juveniles, neonates and pregnant females are used in cases where early deletion of a gene is required, based on the expression profile of that gene.

Typically, what will be done to an animal used in your project?

In Zebrafish: Genetically altered zebrafish may be bred and given an injection of a gene inducing or deleting agent to modify its genetic status. The administration of these drugs will be typically for a time ranging 72h.

Embryos are given an injection of a gene inducing or deleting agent to modify its genetic status once.

Fish may be injected with cells once, continuously exposed to microbiome, or exposed to substances to evoke elements of gastrointestinal disease stages. The administration of these substances can be continuous in water or food for eight weeks.

Fish may be continuously exposed to therapeutic microbiome or substances in water or food for eight weeks to modify the process which is being studied.

Developing embryos or fish may be exposed to substances and imaging to visualise changes in during key developmental and disease stages.

Samples will be collected at key development or disease stages to assess changes (e.g. for ex vivo assessments).

In mice: Genetically altered mice may be bred and given an injection of a gene inducing or deleting agent to modify its genetic status. The administration of these drugs will be typically daily for one week.

Mice may be given a substance or cells (such as immune cells or microbiota) to modify the process which is being studied. Administration of substances or cell types/microbiota to initiate gastrointestinal disease. The administration of these substances typically being repeated cycles of daily treatments for one week, followed by rest period until stage of gastrointestinal disease is reached.

Administration of substances or cells to modify gastrointestinal disease progression as a single or combination of treatments.

Imaging or endoscopy may take place to identify changes that occur at key disease stages.

Typically, samples will be collected at key disease stages to develop biomarkers or therapeutic antibodies and to assess changes in gastrointestinal disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Zebrafish may develop abnormally, display small signs of internal bleeding, signs of redness to indicate inflammation, become lethargic, may fail to maintain weight, have signs of diarrhoea, or become constipated.

Mice with gastrointestinal diseases will be expected to develop diarrhoea and experience slow weight loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Zebrafish: Subthreshold (10%), Mild (40%) and moderate (50%)

Mice: Subthreshold (40%), Mild (26%) and moderate (34%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal disease models, in combination with imaging, will allow us to study closely the cellular mechanisms of initiation and progression of gastrointestinal disease. We will also be able to assess the effectiveness of the new diagnostics and therapies. These can be translated to the clinical setting.

The animal models of gastrointestinal disease mimic aspects of the complex processes and interactions between cell types that lead to the disease, or cause progression of the disease. Some of these processes involving immune cells and other cell types can be studied in lower organisms such as zebrafish.

Which non-animal alternatives did you consider for use in this project?

Access to material and results from patients with gastrointestinal disease in the clinic and previous animal experiments are available and will reduce the number of animal experiments required. Collectively, this material and data can be interrogated using computational approaches to aid finding new links to processes and mechanisms driving gastrointestinal disease progression.

We can model certain basic processes in the laboratory setting. Cell culture will be used throughout this project to provide key information on gene function and mechanisms of cell adaptation to specific stresses in culture. We can model basic outcomes following exposure to new therapies (such as reduce rate of disease progression).

Why were they not suitable?

At present, the use of non-animal methods does not allow us to answer all of our scientific questions. Non-animal models cannot fully recapitulate the 3D nature of the gut tissue architecture and the many different cell types interacting with each other, the exposure to microbiome, fluctuations in blood delivery of oxygen and nutrients and how these collectively influence response to therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous studies have shown what number of animals are required for each study and conditions investigated with appropriate numbers of animals and controls in the experimental design. Data on the numbers of animals required for breeding and maintaining a productive colony is also available from our archive of animal database.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We regularly cross-reference our experimental design, where appropriate with online tools such as the NC3Rs Experimental Design Assistant. We also use statistical design models to aid confirmation of appropriate numbers of animals to be used.

Computational analysis of non-animal model data, previous animal experimental data and information from pilot animal studies also aids the selection of appropriate targets and experimental design to improve the quality of data obtained at the end of the experiment but using the least number of animals. An example of this is incorporating imaging points into our design. Use of imaging increases the output from each animal, creating a better picture of the changes that occur at key disease progression stages without the need to kill animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Well planned, efficient breeding calculations are carried out to ensure that only those animals needed for colony maintenance and experimental studies are produced. An animal database gives us the most recent data to enable these calculations to be carried out.

The use of imaging techniques allows for more information to be gathered from each individual animal.

Harvesting of extra tissues and appropriate sample collections at the end of the experiment and banking them allows for future use and negates the need for animals in these cases.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals lacking a functional aspect of the immune system will be used to investigate which part of the immune system initiates and cause progression of gastrointestinal disease.

We will use animals with or without a genetic change because we can directly study the mechanisms involved in specific processes in disease progression, for instance blood vessel development or metabolism changes, response to microbiota presence. Use of genetic modifications enables targeting specific key pathways/mechanisms that is impossible to replace by an alternative method, e.g. due to current lack of appropriate specific inhibitors and avoids animals being subjected to multiple administration of substances. Animals used for breeding will only undergo methods that are natural and suitable to maintain the genetic status of the strain.

Pilot studies are always conducted using the fewest number of animals to establish the profile and outcome following modifications or exposure to novel substances/cell types.

Imaging provides important insights into disease progression, enabling us to visualise stages of disease (e.g. extent of inflammation and damage to gut lining) and real time changes inside the gut without dependency on changes in animal health and behaviour.

Why can’t you use animals that are less sentient?

The experiments proposed are being conducted in the least sentient possible animal system.

Zebrafish: In this project, we will be using zebrafish, being the lowest organism in which gut, vasculature, metabolism, immune development is well studied during the first five days where animals do not feel pain. Zebrafish lay their eggs externally and therefore we can easily collect embryos without harming the breeding females.

Embryos and free-feeding fish are required to study developmental stages and aspects of disease initiation. The majority of experiments will terminate before the free-feeding stage is reached. Only zebrafish models required for observing modulation of the immune system will end after eight weeks.

Through the use of zebrafish, we can learn and identify new cell types and methods involved in developmental stages and also in controlled initiation of disease states. Some of these cell types are not found in mice but are in human; for example, those involved in gut formation.

Mice: Juveniles, neonates and pregnant females are used in cases where early deletion of a gene is required, based on the expression profile of that gene.

The adult mouse model is relevant to our studies because they enable us to address our studies into complex processes involving multiple cell types that promote gastrointestinal disease initiation and progression. The mouse model is appropriate to study gastrointestinal disease due to the need to study the different functions of the immune system that are not present in the zebrafish.

Initiating gastrointestinal disease in animals, exposure to cells (immune, microbiome) and substances (diagnostic, therapeutic) are being conducted in mice at an appropriate age, using well studied mechanisms and models of gastrointestinal disease.

The mouse model is most widely used and accepted animal system for these types of studies. In addition, the information provide at this animal stage and disease models translates into the clinical setting.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experimental designs are based on previous recorded and pilot experimental observations and outcomes. This ensures appropriate use of procedures and routes to minimise welfare costs for animals. We provide appropriate pain management following any procedures.

We regularly monitor animals for changes in their health, for example measure their weight change and their behaviour.

Observations during experiments are documented to allow control measures such as increased monitoring or treatments to reverse, reduce or prevent further harms to the animals.

We always conduct pilot studies to check that measures and experimental designs will minimise welfare costs for animals when necessary for novel substances/cell types.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The design of experimental procedure will be compared with best practices guidance in order to ensure the most refined methodology is used, such as: local AWERB guidelines, those outlined on NC3Rs (e.g. ARRIVE guidelines), Guidance on Animal Testing and Research from the Home Office, LASA and RSPCA guidelines, PREPARE guidelines and published guidelines on gastrointestinal disease models.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review publications (including those relating to the 3Rs) and attend conferences, discuss with other experienced groups, Named Animal Welfare Officer, hold in vivo meetings to ensure that we constantly implement advances in techniques and non-animal alternatives. We also check experimental needs and designs with information on websites, such as Home office, the NC3Rs, LASA and RSPCAs.

128. Studying how signalling proteins control development and regeneration in zebrafish

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Embryogenesis, Organ function, Wound healing, Regeneration, Growth factor signalling

Animal types	Life stages
Zebra fish (Danio rerio)	adult, neonate, juvenile, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to understand how two families of growth factors, namely Wnt and Shh, controls fundamental cell behaviours, namely proliferation, differentiation, and migration during complex tissue formation in the early embryo. In addition, we want to understand the roles played by these signalling systems during wound healing and regenerative processes in the fin, heart, and brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We still do not understand how growth factors regulate fundamental processes like organ formation and wound healing. We envisage that this programme of work will lead to an improved understanding of the genetic and cellular processes involved in cell proliferation, differentiation, and migration leading to organ formation and tissue repair. This is important

because we will then understand the beneficial functions of growth factor signalling during embryogenesis and regeneration.

Zebrafish have a remarkable capability to heal and regenerate many tissues, specifically the fin, heart, and brain after injury. We will decipher these signalling mechanisms to identify mechanisms and treatments that could be used to promote wound healing in humans.

What outputs do you think you will see at the end of this project?

We envisage that over the 5 years of the programme, we will learn new knowledge of the genetic and cellular processes regulated by the growth factor signals Wnt and Shh, leading to organ formation in embryogenesis and wound healing. We envisage three key outputs during the project:

Identification of mechanisms regulating cell proliferation, differentiation and migration guided by Wnt and Shh signalling in embryogenesis

Identification of essential proteins regulating these signalling cascades controlling fundamental decisions in regeneration

Identifications of genes and pharmaceutically active compounds influencing signalling process

The primary way we will communicate our findings is through peer-reviewed publications in specialist and generalist journals. We will also present information orally at scientific conferences and to the general public through public engagement talks.

Who or what will benefit from these outputs, and how?

Human health. Although this research project is generally in the area of basic biology, it has the potential to impact human health. Over 70% of all human genes have at least one zebrafish equivalent (ortholog), making our work potentially relevant in the vertebrate lineage. The evolutionary conserved Wnt and Shh signalling pathways regulate both the maintenance and differentiation of all cells in the body, including stem cells. Growth factor signalling is activated within minutes after tissue damage and fulfils a vital role for protection in cell survival. Signalling is a prerequisite for tissue repair from zebrafish to humans: For example, when the heart muscle is damaged, a functional heart will regenerate, provided that Wnt and Shh signalling is active at the time of damage. However, if it is not active the result is an incorrectly functional heart with scarring. In mammals, including humans, blockage of Wnt and Shh signalling delays wound healing and leads to insufficient wound closure.

Developmental biology. Our insights into how the signalling behaviour of individual cells is regulated in a tissue context in the living vertebrate organism will advance our understanding of the mechanistic basis of cell-cell communication. In contrast to passive diffusion, controlled dissemination of signalling molecules will open up a new field to control of signalling range in a growing tissue. The far-reaching importance of this finding is already apparent as these were recently discussed in a chapter of the latest edition of Scott Gilbert's 'Developmental Biology' textbook for pupils and students.
Signalling biology. Our results will provide insights into the relationship of signalling in individual cells. This will advance the field since most of our knowledge of signalling comes from the analysis of simple in vitro systems or invertebrate model organisms. Wnt

and Shh signalling regulate the progression of tumours, and it has been shown that 95% of patients with colon cancer have a massively increased production of these growth factors in the tumour tissue. Also, growth factor signalling is strongly down-regulated in Alzheimer's diseased brains leading to neuronal death. Advanced systems allowing more direct insights into cellular signalling by studying growth factor trafficking in a living vertebrate animal are currently limited. Our experiments will serve as a novel basis for manipulating signalling in diseased tissues.

Cell biology. In recent years, due to live-cell imaging, evidence is mounting that the cytoskeleton is highly dynamic and controls many processes beyond cell shape changes. The proposed analysis of cell protrusion formation in zebrafish embryos will yield valuable insights into this fascinating field of cytoskeletal dynamics, also contributing a novel perspective on the regulation of these processes by signalling cascades.

Quantitative biology. New quantitative approaches for describing molecular relationships from sub- cellular imaging are critical for developing the field of cell and developmental biology. Throughout the proposed study, we will develop and refine tools to quantify signalling molecule concentration in a tissue required to activate the signalling cascade.

Zebrafish biology. This work will further develop the early zebrafish embryo as a model system, particularly highlighting the benefits of the cells of the embryonic ring as a source tissue for various signalling molecules that is well suited for studying the cellular signalling process in vivo.

In summary, insights into the mechanisms underlying the regulation of signalling gained during this project will increase our knowledge of two of the most important signalling cascades, Shh and Wnt, acting in all multicellular organisms – from worm to human. In addition, we will substantiate our fundamental understanding of growth factor signalling during development and regeneration as a short- term goal. Therefore, we will make our results available to the scientific community through research publications and conference contributions. In the long-term, we envisage the development of drugs to tackle the cell-protective function and the injury repair process based on the knowledge generated in this project. Furthermore, our acquired knowledge on Wnt and Shh trafficking might help identify drug targets for neurodegenerative diseases and cancer.

How will you look to maximise the outputs of this work?

Wherever possible, we will share knowledge and experience in our peer-reviewed publications and will utilise the skills and expertise of colleagues at our institution and colleagues nationally and internationally to generate high-quality studies with the most meaningful data. Wherever possible, we will implement new and thoroughly developed methodologies to stay current with our procedures. This includes attending NC3Rs seminars, workshops and conferences.

Negative results will be submitted for publication or uploaded to preprint servers, where appropriate.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 28000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this programme of work, zebrafish are used as a model organism to understand growth factor signalling during development and diseases in vertebrates.

Genetics will play a major part in this project. Zebrafish have a similar genetic structure to humans and share over 70 per cent of genes with humans; over 80 per cent of genes known to be associated with human disease have a zebrafish counterpart. The zebrafish genome has been fully sequenced to a very high quality. This enables us to create mutations in these disease-related genes and study their function.

To study the growth of the vertebrate embryo, the zebrafish is an excellent model as light triggers mating in zebrafish. Then the zebrafish produce hundreds of offspring at weekly intervals leading to a great supply of eggs with an identical genotype. Zebrafish eggs are fertilised and develop outside the mother's body. This allows us to study developmental processes in a non-invasive way. In addition, the zebrafish embryo/larvae grow at an extremely fast rate allowing to study processes of cell proliferation, differentiation and tissue growth. In this work programme, the distribution and function of growth factors in a tissue will be investigated and the zebrafish embryo/larvae is nearly transparent makes it ideal to study growth factor signalling in an intact tissue by high-resolution microscopy. To complement our studies, we will also use the adult zebrafish to study growth factor function in wound healing and regeneration. As a vertebrate, the zebrafish has the same major organs and tissues as humans. Their muscle, blood, heart and brain share many features with human systems. Of specific importance to this project, zebrafish have the unique ability to repair nearly all organs - including the heart, brain and fins. For example, if a part of these organs is removed zebrafish can grow it back in a matter of days or weeks. In this project, we will work to find out the genes involved in this process to see if this will help us to develop ways of repairing damaged organs in humans.

Typically, what will be done to an animal used in your project?

Most adult animals (95%) will be kept and bred to study growth factor signalling in the embryo/larvae.

In particular, we will study the distribution and function of growth factors in the zebrafish embryo/larvae pre-independent feeding (5days post-fertilization or younger, pre-ASPA). We will use the translucent embryo/larvae to visualise the spread and the function of growth factors by various microscopy techniques.

A few adult animals (5%) will be used to study similar processes such as cell proliferation and differentiation guided by growth factors during wound healing and regeneration. Some animals will undergo surgical procedures, most taking around 15 minutes to complete, although some could be a little longer (~60 mins) and some very short (~10 mins).
To study the process of wound healing, we will remove parts of the fin tissue under anaesthetic and study wound healing, and the formation of the regeneration bud.

As a myocardial infarction/heart attack model, the fish will have a localised area of damage created on the ventricle of the heart under anaesthetic. The animal is returned to its tank and monitored for 14 days to assess the regenerative capacity of the heart.

To study neuronal regeneration, we will treat zebrafish with chemical compounds generating synaptic fragmentation and synaptic loss as observed in the Alzheimer's diseased brains in humans.

After the procedure, animals will be used for non-invasive, microscopic visualisation of regeneration processes and occasionally be treated with existing and new drug therapies in the following 90days. During the procedure, fish will be regularly monitored.

What are the expected impacts and/or adverse effects for the animals during your project?

For the breeding and maintenance of zebrafish to generate embryo/larvae, we do not expect adverse effects for the adult fish. Fish will usually be kept in holding tanks. Occasionally, fish will be transferred into breeding tanks for egg deposition overnight. On the following day, fish will be transferred back to the holding tanks.

For regeneration experiments, we expect the tissue regeneration to resemble human wound healing. For example, on the fin, healing will likely include the formation of epithelial appendages at a wound edge, resulting in scarring of the epidermis. We will use optimised procedures including analgesia to minimise adverse effects and will monitor the behaviour of the fish daily. Fish are not expected to lose their balance in the water, ability to swim or perform other normal functions. They are expected to recover within 7 days and the regeneration process, e.g. for fin or heart, is expected to be completed within 60 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Zebrafish 80% mild
20% moderate

Most animals will be under breeding and maintenance protocols undergoing no procedures with no expected adverse effects. These animals will experience no more than mild severity (<10%), many of them are likely to experience sub-threshold severity (>90%).

15% of animals will have a GA in proteins affecting Wnt or Shh signalling, which may affect their ability to swim. This may cause moderate suffering in the affected animals.

5% of animals will be under experimental protocols where wounds will be made under anaesthesia, then the animals monitored for a number of days to assess regeneration of tissue. These animals will experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The majority of our experiments are actually conducted with cells in Petri dishes using cultured cell lines. This is where we generate preliminary data to escalate to animal work, should the data support this.

However, the embryo/larvae, the fin, the heart, and the brain are complex 3-dimensional structures containing many different tissues such as neuronal tissue, muscles, ligaments and bones, subject to frequent movement. None of the 2D models resembles all aspects of cell behaviour in these complex tissues. We, therefore, need animals to understand what happens to the different cell types as a model for common human disorders such as during organ formation, wound healing and regeneration. Therefore, we will seek, review and incorporate alternative assays to replace animal experiments throughout the project duration if appropriate.

Which non-animal alternatives did you consider for use in this project?

We have searched the Fund for the Replacement of Animals in Medical Experiments (FRAME) website for alternatives to the use of animals for these studies. Possible alternatives found are listed below:

Computer modelling

Cell lines

The use of early developmental stages of protected animals

Human tissue samples

Whenever possible, we try to use established cell lines, these can be either animal or human. Ideally, primary zebrafish cells would give us a great in vitro model but these are hard to come by and difficult to maintain. Similarly, the use of early developmental stages of protected animals can be a good alternative.

Why were they not suitable?

The embryo/larvae, the fin, the heart, and the brain are complicated tissues containing several different cell types subject to frequent movement. No computational or cell culture model exists, which recapitulates all aspects of the complex cell behaviour in these tissues.

However, with increasing knowledge through the project, there is the potential for the replacement of protected animals. Therefore, we develop appropriate fish and mammalian tissue culture systems in parallel to our zebrafish work. The proportion of work with tissue culture has increased over time, and about 50% of our experiments are carried out in vitro. We will expand our knowledge on the development of complex in vitro models as we have done in the course of the former project licence.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are based on the number of projects we are currently running and the future planned projects. These include existing and planned funding applications. The number is based on the number of animals typically used for pilot studies and the specific numbers used during an investigation. For example, for our work blocking the function of signalling genes (by using gene knockouts) in adult fish, which we have been doing for several years, we use 6 animals per time point in each experimental group.

A significant contributing factor to the total animal numbers is the number of animals used for breeding genetically modified animals. We have estimated this number based on our extensive prior experience with similar studies. In our work, we mainly focus on early development. This work is performed on young embryo/larvae pre-independent feeding (pre-ASPA), allowing us to reduce the number of animals used at later stages of development. Therefore, most adult animals (ca. 95%) will be kept in breeding colonies during the course of the project, and only a small number (5%) will be used for active animal experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The outcomes of the experiments in tissue culture and on embryo/larvae pre-independent feeding serve as the basis for refined wound healing experiments.

Before animal experiments start, we use the PREPARE guidelines & checklist and liaise with the animal facility to design the experimental strategy. We further use the NC3R's research design tool, which feeds into the ARRIVE guidelines. Finally, based on the NC3R's experimental design assistant (EDA), sample size calculation is performed to define the minimum numbers required to achieve defined levels of statistical significance. For example, power calculations include 90% power at 5% significance to show a 25% point difference in any parameter.

In addition, we will do pilot experiments and use appropriate endpoints to reduce the number of animals further.

In parallel, we use computational models for zebrafish early development, allowing us to computationally alter some aspects of migration. These in silico models allow us to make better predictions about downstream signalling pathways, variability and therefore the number of animals per experiment.

Alongside the animal work during these 5 years, we propose further refining mathematical models for the zebrafish organ formation; these models will allow us to run more predictive experiments reducing the number of animals used. We have collaborated with mathematicians to generated computational models that replicate the dynamic action of tissue migration in shaping organs during development. We will share biological data from our in vitro and in vivo experiments to allow these groups to refine their computational

models to test ‘real’ organ formation in the hope that in future, we will be able to run more of our experiments in silico rather than in vivo.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All studies are carefully designed to minimise animal usage. This includes carrying out preliminary studies, e.g. in cell culture & in embryo/larvae followed by pilot studies. The results are then used to calculate the minimum number of animals needed in the full study. Furthermore, we also will use tissues from one fish for multiple purposes/ experiments, e.g. control samples will be used for heart tissue/ fin tissue etc. to optimise the number of fish.

In parallel, we will collaborate with mathematicians and statisticians and with other leading fish signalling groups worldwide, who use similar numbers to our own.

Finally, efficient breeding practices will be incorporated to reduce animal numbers. Working closely with the experienced zebrafish husbandry team, we will ensure appropriate colony management and health monitoring of all of our zebrafish lines with the aim of maximising welfare resulting in higher productivity from fewer animals. Specifically, this will also include cryopreservation of GA colonies not in active use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use zebrafish at embryo/larvae and adult stages.

Zebrafish is a widely used research model for studying regeneration; therefore, a significant amount of research comes from studies in this model.

Zebrafish as model organisms has several advantages: They form the same major organs and tissues as humans. The zebrafish genome is fully sequenced to a very high quality and over 70% of human genes have a true counterpart (ortholog) in the zebrafish genome. Specifically, important for these studies, zebrafish are able to regenerate different organs, including all fins, the spinal cord, the retina, the heart, the telencephalon, and the kidney. A further advantage of zebrafish is their translucence which enables their forming tissue to be visualised using non-invasive microscopic imaging, additionally, this species is open to genetic manipulation and has the lowest neurophysiological sensitivity of the species suitable for these studies.

Specifically, we have chosen zebrafish as the most refined animal model available and complement our studies with complex tissue culture experiments, computational modelling and experiments at the embryo/larvae stage pre-independent feeding/pre-ASPA. By using the translucent zebrafish in which we express fluorescent proteins in cells of interest we

can non-invasively watch many cellular processes in the embryo/larvae and - based on these results - investigate these processes in the regenerating tissue, allowing us to collect dynamic data with minimal surgical intervention.

Why can't you use animals that are less sentient?

The majority of our work is performed either in vitro, or on zebrafish embryos/larvae prior to independent feeding. The embryo/larvae possess a number of features that make them particularly valuable for use in assays that address growth factor function in development. However, as the project is also studying the function of growth factors in tissue regeneration there is some work that currently cannot be performed without working on adults. Therefore, we have chosen zebrafish - a model which belongs to the less sentient animals within the group of vertebrates to study regeneration.

We will always endeavour to use the least invasive approach possible to answer our scientific questions. To further minimise suffering and discomfort, the adult fish will be monitored daily and when there is any concern advice will be sought from the named veterinary surgeon and/or the Named Animal Care Welfare Officer and appropriate action taken.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

At all stages of the project, we will conduct regular welfare assessments to evaluate the impact of procedures and regularly review our experimental processes with a view to minimising adverse effects without impacting scientific outcomes.

To refine the procedures in animals post-surgery, we will usually use an analgesic regimen to reduce the suffering of the animals during the wound healing process. In particular, we will give appropriate analgesia such as Lidocaine non-invasively by immersion for the heart regeneration experiments if no cross-reaction with, i.e. the drug treatment is expected.

By using non-invasive imaging of genetically modified zebrafish, i.e. fluorescent reporter fish lines, we can visualise the earliest events in signalling alterations, and organ pathogenesis before external symptoms such as behavioural changes are manifest. By doing so, we can reduce the suffering of the animals by setting our endpoints much earlier than is possible in rodents or other models.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We actively use the NC3Rs Experimental Design Assistant tool to plan our studies, which helps incorporates best practices for the 3Rs into our study design. (https://www.nc3rs.org.uk/experimental- design-assistant-eda)

We will also use the ARRIVE guidelines to inform both the study design and reporting of the result of our work for full transparency and to help others reproduce our findings. (https://arriveguidelines.org/)

Throughout the tenure of this licence, we will also keep us up to date through publications, conference attendance, collaboration and funding body interactions.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have signed up for the email newsletters from the National Centre for the Replacement, Reduction and Refinement of the use of animals in research (NC3Rs) and we will regularly consult their website and attend webinars to keep our knowledge in this area up to date.

We also actively use their Experimental Design Assistant tool (https://www.nc3rs.org.uk/experimental- design-assistant-eda) to plan our studies, which helps incorporate best practice for the 3Rs into our study design.

Finally, we will effectively implement advances in the 3R in our studies after consulting with the Named Veterinary Surgeons and Named Animal Care and Welfare Officer.

129. Brain mechanisms of listening and learning

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

auditory, hearing, brain, cortex, mice

Animal types	Life stages
Mice	adult, juvenile, neonate, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand what brain mechanisms underlie normal listening, and how those mechanisms go awry in brain disorders that affect listening ability.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many people have difficulty listening in noisy environments that cannot be explained by problems within the ear alone. For example, children with developmental disorders, elderly adults, and people with brain disorders such as schizophrenia may have normal hearing sensitivity on audiological tests but nevertheless report unusual difficulty with listening in noisy environments. This difficulty is thought to arise from problems with mechanisms of listening in the brain rather than the ear. However, brain mechanisms of listening are still

poorly understood. We seek to understand what auditory brain mechanisms underlie normal listening, and how these mechanisms go awry in brain disorders that affect listening ability.

What outputs do you think you will see at the end of this project?

This work is expected to provide new information about the biological mechanisms that enable effective listening in noisy environments. The primary expected benefit is the publication of new scientific knowledge about these biological mechanisms.

This work is also expected to provide new insight into how brain mechanisms of listening are disrupted in brain disorders such as schizophrenia, tinnitus and developmental language disorder. The primary expected benefit from this output is the publication of new scientific knowledge about disease-related disruptions of biological mechanisms.

Additional outputs and benefits are expected to include new algorithms that could be used in hearing aids or other sound-processing devices to facilitate perception of speech in noisy environments.

Who or what will benefit from these outputs, and how?

In the short term, outputs from this project will benefit other scientists seeking to understand how the auditory brain works. Additionally, the project will benefit students and trainee scientists, who will learn to conduct high-quality, clinically relevant scientific research through their involvement in the work.
Short-term outputs in the form of scientific knowledge will be published in academic journals, shared with academic colleagues through presentations at national and international conferences, and communicated to the wider society through public lectures and other public engagement events.

In the medium term, outputs from the project will contribute to development of novel tools for scientific research and new technologies for improving human hearing. For example, our recent research has generated new technologies for brain research and has suggested new algorithms for sound processing that accurately mimic aspects of auditory brain function.

Also in the medium term, the project will benefit the UK economy by helping to develop a skilled workforce for scientific research. Over the past 17 years, our laboratory has trained 6 postdoctoral fellows, 8 PhD students, and more than 20 BSc or MSc students. Many of these trainees have gone on to careers in science or technology.

Finally, in the longer term, outputs from this project will benefit people with hearing impairment or with brain disorders that affect ability to listen effectively. In previous projects, we have used mice to test new treatments for tinnitus, to identify novel auditory brain abnormalities in developmental disorders that also affect humans, and to determine the likely cause of hearing impairment in a human genetic disease associated with schizophrenia. In the future, we expect this work and current projects to help improve the design of hearing aids, cochlear implants and assisted-listening devices for people with hearing impairment or brain disorders affecting hearing ability.
How will you look to maximise the outputs of this work?

Outputs from the work will be disseminated primarily through open-access research publications. Novel research tools and software will be shared through open-access

repositories. We will also seek to maximise outputs through collaboration with clinicians and scientists worldwide, continuing and expanding our current collaborations with NHS clinicans and with scientists in the UK, USA, Germany and France.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice in our experiments because the auditory brain in mice is very similar in structure to the auditory brain in humans. Moreover, there are many excellent mouse models of human diseases available. We use both normal mice and mouse models of human brain disorders that cause listening difficulties in humans, including schizophrenia, tinnitus and developmental disorders.

Most of our experiments are performed on young adult mice, because we are trying to understand how the auditory brain works in adulthood. We occasionally perform procedures (such as induction of hearing loss) on neonatal or juvenile mice and then later study the same animals when they become adults, so we can investigate how the function of the adult auditory brain depends on hearing in childhood. We also compare auditory brain function between younger and older adult mice (always before the age at which mice develop chronic age-related health problems), to help us understand how auditory brain function changes across the lifespan.

Typically, what will be done to an animal used in your project?

The most invasive of our typical procedures is intracranial measurement of brain activity using an implant. Typically, adult mice undergo a 2-4hr surgery where we make very small holes in the skull to implant tiny screws in the skull and to insert very thin, hair-like electrode probes in the brain. We secure the implant to the skull with dental cement and close the wound. Mice with implants typically resume normal behaviour shortly after waking from anaesthesia. After a one-week recovery period following the implant surgery, we measure activity of auditory brain cells using the implant while the mice listen to sounds or perform sound-discrimination tasks. These measurement sessions typically last about 1-2 hours per day and continue for several weeks in the same animal.

In other typical experiments, we do less invasive procedures either in the weeks before the implant surgery, or instead of the implant surgery. For example, we may disrupt hearing in juvenile mice using earplugs or minor ear surgeries; we may measure overall auditory brain activity in anaesthetised mice using electrodes briefly inserted just under the skin; and we may train mice on behavioural tasks. Mice used for behavioural training may have their food intake restricted in their home cage, with additional food given as rewards during behavioural training.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice typically recover very quickly from the implant surgery, resuming normal behaviours (e.g., running on wheels) within a hour or two after waking from anaesthesia. We give painkillers and monitor post- operative recovery in the mice in the days following surgery, just as would be done for people in hospital. Mice with implants are weighed and checked daily to ensure that any signs of weight loss or malaise are quickly identified and treated. We also weigh daily any mice that are having their food intake restricted in their home cage, and we provide supplemental food in the home cage as well as food rewards during behavioural training to ensure that their weights remain within normal levels for an animal of similar age without food restriction.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall, for the entire project, severities are expected to be moderate for up to 40% of mice, and no more than mild or non-recovery for the remaining 60% of mice.

Most of our experiments are performed in young adult mice. Those undergoing moderate severity procedures typically experience implant surgery with recovery, behavioural training involving food restriction and food reward, or repeated minimally invasive procedures performed under anaesthesia with recovery. Those undergoing mild or non-recovery procedures typically experience behavioural training without food restriction, measurement of brain activity under terminal anaesthesia, terminal anaesthesia for histological procedures, or standard breeding procedures alone.

A small percentage of our experiments (<10%) involve juvenile mice. Typically, these juvenile mice undergo mild or moderate procedures for inducing hearing loss, such as insertion of earplugs or surgery on the middle ear. Once these animals grow to become young adults, they may experience the same procedures that other young adult mice do.

An even smaller percentage of experiments (<1%) involve comparisons between younger and older adult mice, to analyse normal age-related changes in auditory brain function. Our interest is in adult brain function across the healthy lifespan, so these experiments are always conducted before the age at which chronic age-related health problems would emerge in mice (i.e., before mice would be considered "aged").

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Brain mechanisms of listening are not yet understood well enough to allow these mechanisms to be studied in computer models alone. Moreover, simpler biological systems such as cell cultures cannot replicate the complexity of the auditory system, which

consists of multiple interconnected brain areas in addition to the ear. To understand how the ear and brain enable listening, we need to study live animals.

Which non-animal alternatives did you consider for use in this project?

We use computer models heavily in our research, to refine and reduce our use of animals. For example, we have used computer models to refine predictions about what aspects of listening behaviour will be affected by auditory brain abnormalities we discovered in a mouse model of developmental disorder. We have also used computational methods to develop technologies for measuring and analysing data from the brain more efficiently, allowing both refinement and reduction in the use of animals. We stay well informed about advances in computer modelling of auditory brain systems in the scientific literature, to be ready to use these models in place of live animals when possible. However, no computer models are yet adequate to enable us to achieve the objectives of this project without experiments in live animals.

Why were they not suitable?

Most computer models of the auditory brain are either abstract models designed to study one particular aspect of listening (e.g. sound localisation) or detailed models of one particular auditory brain area or cell type (e.g. superior paraolivary nucleus cells). There are a few ongoing efforts to develop system- wide models of sound processing within the ear and auditory brain areas, but these are still not fully validated for the earliest stages of auditory brain processing, and definitely not for the auditory thalamus and cortex. While we try to make use of such models to refine our experimental designs and reduce our use of animals, they are not suitable replacements for animal experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimates of animal numbers are based on our past records of animal use under our previous project licences for related experiments; predictions about how those numbers are likely to change over the next 5 years given advancements in experimental technologies; and experimental design considerations. For example, our animal number estimates for protocols involving intracranial measurement of brain activity have decreased relative to our previous project licences, because we are now able to obtain far more data from each animal than would have been possible 5 years ago.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We design our experiments to optimise the number of data points that can be obtained from each animal, for example by using high-density multi-electrode technology to increase the number of neurons that can be recorded from each animal during intracranial measurements of brain activity. In many of our experiments, experimental units are

neurons rather than animals, so this approach is a very effective means of reducing animal numbers. We also seek to use both male and female animals in our experiments whenever the phenotype of interest is exhibited by both sexes, so that breeding colonies can be maintained at minimal size. Finally, we reduce animal numbers by designing experiments with advice from statistician collaborators and using internal statistics expertise in the lab. The lab leader has considerable statistical training and expertise, and co-leads a major research methods and statistics module at the university.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We make heavy use of computer modelling to refine our experimental designs and to optimise the number of animals used in particular experiments. For example, we use computer models of auditory brain abnormalities we are studying to predict the likely effects of those abnormalities on animal behaviour or on measurements of brain activity. This modelling allows us to estimate likely effect sizes and therefore animal numbers required to test our hypotheses. We also routinely perform pilot studies where information about likely effect size is not readily available from our previous experimental work, our computer simulations, or the published scientific literature.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use mice, including both normal mice and mouse models of human brain disorders such as schizophrenia, tinnitus and developmental disorders. Mice undergo experimental procedures such as behavioural training and/or measurement; minimally invasive measurement of brain activity under anaesthesia, for example using electrodes placed just under the skin or sensors placed on the scalp; intracranial measurement of brain activity under terminal anaesthesia; or intracranial measurement of brain activity in awake animals using devices implanted in the brain under anaesthesia. Even the most invasive of these procedures (intracranial measurement of brain activity using an implant) do not cause lasting harm or pain to the animals. Mice with brain implants typically recover rapidly from the implant procedure and return to normal behaviour such as running on wheels soon after waking up from anaesthesia.

Some of our mouse models of human brain disorders may have health problems other than the auditory brain abnormalities that we are studying. For example, BXSB/MpJ mice are the only known animal model of a newly discovered auditory brain abnormality in developmental disorders, but male BXSB/MpJ mice are also susceptible to adult-onset autoimmune disease. Our experiments are designed to avoid causing any suffering from health problems other than auditory brain abnormalities (which do not cause suffering for mice). For example, we ensure that male BXSB/MpJ mice are used in experiments before

the age at which autoimmune disease symptoms typically appear, and that any of these animals developing symptoms earlier than expected are terminated promptly.

Why can’t you use animals that are less sentient?

Our aim is to understand mammalian brain mechanisms of listening to temporally varying and noisy sounds, and how those mechanisms go awry in human schizophrenia, tinnitus and developmental disorders. Mice are the least sentient mammalian species with an auditory brain similar in structure to that of humans. Techniques for genetic manipulation in mice are also much more advanced than in any other mammalian species. Genetically altered mice bred under this protocol will make it possible for us to examine the roles of specific cell types and neural circuits in the auditory brain during normal listening with a precision that could not easily be achieved in any other mammal. Furthermore, our genetically altered mouse models of human developmental disorders (BXSB/MpJ mice) and schizophrenia (*Df1*/+ mice) are among the most refined and powerful animal models of these conditions available.

Our protocols include experiments conducted under terminal anaesthesia, which we use whenever scientifically feasible. However, it is not possible to fully understand the relationship between listening behaviour and brain activity by studying brain activity only in anaesthetised animals. Measurements of brain activity in awake animals can be related to simultaneous measurements of listening behaviour in the same animals, allowing for a significant refinement of experimental design.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will seek to refine behavioural training paradigms to avoid any need for food restriction or mildly aversive stimuli.

We already use best-practice methods for monitoring, post-operative care and pain management. We will seek to improve these methods with any new refinements suggested by NC3R or the NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We rely on information from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (www.nc3rs.org.uk) and the Laboratory Animal Scientists' Association (www.lasa.co.uk) when designing experiments. We receive regular newsletters from the NC3Rs and review the published literature regularly to stay informed about developments in best practice for in vivo experiments in mice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We monitor the NC3Rs website and receive regular updates from NC3R regarding advances in the 3Rs.

We are always seeking to implement advances in the 3Rs in our experiments. For example, we have sought to develop a behavioural training paradigm using wheel-running as a reward rather than food restriction and food rewards. This strategy for behavioural training would essentially amount to a form of environmental enrichment for the animals.

130. Safety and Quality Control Testing of Human and Veterinary Medicines for Batch Release

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Abnormal, Toxicity, Safety, Quality, Control

Animal types	Life stages
Mice	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Drug Products for both human and veterinary use must be effective and safe. Their production is monitored carefully to make sure it complies with Good Manufacturing Practice (GMP). Quality control tests must be performed on samples from each new batch to comply with national and EU regulations.

Although some information on safety can be obtained without using animals, some tests must be carried out using animals to better understand how these medicines might affect the human body.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The test procedures detailed in this licence form an essential part of the data required to monitor the safe development, production, and release of medicinal products for use by consumers.

The ability to test these products ensures that they have been produced safely and to appropriate standards. These results provide satisfaction to the relevant Marketing Authorization that the tested products are safe to use by the end consumer. The prevention of the tests listed would result in the release of these products being delayed or denied. Depending on the exact nature of the medicinal product this could lead to serious health implications for the intended patients. As the nature of this work is quality control on each batch produced any prevention of testing would have an immediate impact.

What outputs do you think you will see at the end of this project?

The test procedures detailed in this licence form an essential part of the data required to monitor the safe development, production and release of medicinal products for use by consumers. The ability to test these products ensures that they have been produced safely and to the appropriate standards. The results provide satisfaction to the relevant Marketing Authorisation that the tested products are safe to use by the end consumer. The prevention of the tests listed would result in the release of these products being delayed or denied. Depending on the exact nature of the medical product, this could lead to serious health implications for the intended patients. As the nature of the work is quality control on each batch produced, any prevention of testing would have an immediate impact.

Who or what will benefit from these outputs, and how?

This work is being carried out as a service therefore the end user will benefit in that they will have access to health improving medicines.

How will you look to maximise the outputs of this work?

The work performed under this project licence is for clients with whom a Confidentiality agreement is in place. The tests are to ensure safety in batch release and the knowledge gained is not transferable to other products.

Species and numbers of animals expected to be used

- Mice: 125
- Guinea pigs: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult CD1 mice and Dunkin Hartley Guinea Pigs

Typically, what will be done to an animal used in your project?

Abnormal toxicity and absence of toxicity tests involve temporary restraint (e.g. scruffing), and the administration of a test substance via the intraperitoneal route. Typically, the tests have a duration of up to 7 days as advised in the Pharmacopoeia.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals may encounter weight loss or reduced weight gain. However, this is usually only minor.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice and Guinea pigs used in these studies are expected to undergo mild severity. Moderate severity may be observed in a failed result, however these tests are expected to pass.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The methods listed are specifically required by legislation and/or regulatory authorities to confirm safety of the product(s), leaving little opportunity for non-animal methods. It is not possible at present to reproduce in-vitro the complex composite whole-body response produced in vivo and the availability of validated alternatives for regulatory use is somewhat limited.

The Abnormal Toxicity Test has been removed from the European Pharmacopoeia. It is still in the United States and other reginal Pharmacopoeias. The use of ATT as a method to identify potentially harmful batches and contaminants has been questioned and modern pharmaceutical manufacturers have appropriate quality control in place preventing the risk of contamination. These improved quality control measures are seen to be suitable for ensuring product safety rather than testing.

In some ROW territories where the release of a pharmaceutical won't be accepted without an ATT or GST then a case may be made to perform the test in order to allow the end user access to essential medicine.

Which non-animal alternatives did you consider for use in this project?

There are currently no non-animal alternatives for an abnormal toxicity or absence of toxicity test.

Why were they not suitable?

There are currently no non-animal alternatives for an abnormal toxicity or absence of toxicity test.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Testing at a frequency of five assays per year using five mice and two guinea pigs each time (for duration of licence, five years).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design is defined in the Pharmacopoeia.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The tests procedures are closely defined and must be carried out to a strict protocol for compliance with the requirements of the various regulatory authorities and there is therefore little opportunity to reduce animal numbers used in any specific procedure.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal to be used in these studies have been established over many years and found to be appropriate to monitor the safety of the product for use by the consumer. Historically mice have been chosen as the lowest mammal in the hierarchical level of testing where whole body response must be monitored as in Abnormal Toxicity (Safety) tests and absence of toxicity tests of chemicals. Guinea pigs have been identified for some tests where biological materials are used as they produce a similar immune response (for example an anaphylactic response) to humans.

Why can’t you use animals that are less sentient?

The animal models required for these tests are described in the pharmacopoeia monographs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Dosing and observation of the animals will be performed by fully trained staff. The animals will be monitored on a daily basis once dosed and any adverse effects reported directly to the PPLh and NACWO.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The NC3R's are used to keep up to date with the latest science technology, new approaches, and the best experimental designs. The NC3R's also provide guidance on the latest knowledge to improve laboratory animal welfare.

Being a member of The Institute of Animal Technology (IAT) also advances knowledge and promotes excellence in the care and welfare of animals in science.

Harm-Benefit Analysis Process, Code of practice for the housing and care of animals bred, supplied or used for scientific purposes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The pharmacopeia updates are reviewed annually for any changes to specific monographs. Other changes are not always possible without changing the scope of the test and therefore it's acceptability to the receiving authority.

131. Pesticide metabolism and residues in livestock

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Pesticide, Residue, Feeding, Metabolism, MRL

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	adult
Cattle	adult, juvenile
Goats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To measure pesticide levels in animal tissues and other matrices (e.g. milk and eggs) after intake of pesticides and their metabolites.

To generate data to be used in assessing the dietary risk of pesticides to humans from consumption of meat, milk and eggs and to generate data to be included in dossiers submitted for registration of plant protection products.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Livestock residue and metabolism studies are required under various global directives including; EC Council Directive 91/414/EEC, US EPA (OPPTS 860.1480 Residue Chemistry Test Guidelines Meat/Milk/Poultry/Eggs) and Australia (APVMA Residue Guideline No. 1 – Animal Transfer Studies), when residues of a pesticide are expected to

be present in livestock feed and might cause detectable residues in livestock. The conduct of the studies, including minimum numbers of animals, dose levels and duration, is specified in guidance documents.
The use of live animals is needed in order to determine transfer of pesticide and/or their metabolites into meat, milk and eggs. Farm animals (cows, hens, etc) are required by the regulator as the objective is to measure potential dietary exposure to pesticides in their edible tissues. The minimum number of animals required is specified in the relevant guidelines and the minimum number will be used wherever possible. In some cases, the use of one particular type of animal removes the need to generate data for other animals. For example, in most cases the results of a cattle feeding study can be used to establish tolerances in goats, pigs, horses and sheep. Similarly, data on chickens is normally accepted in lieu of data on other livestock poultry, e.g. turkeys, geese and ducks. This licence allows the use of farm animal species (cattle, goats and poultry) to achieve the regulatory requirements.

All planned studies are assessed by an ethical review committee to determine if the study can proceed and all studies will be subject to ongoing review. Studies will be undertaken under commercial husbandry conditions and according to the relevant Defra Codes of Recommendation for the Welfare of Livestock.

What outputs do you think you will see at the end of this project?

Livestock metabolism studies fulfil several purposes:

Provide an estimate of total residues in the edible livestock commodities, as well as the excreta.

Identify the major components of the terminal residue in the edible tissues, thus indicating the components to analyzed in residue quantification studies (i.e., the residue definitions for both risk assessment and enforcement).

Elucidate a metabolic pathway for the pesticide in ruminants and poultry. − Provide evidence whether or not a residue should be classified as fat soluble.

The primary purposes of the Residues in Livestock study are to provide the basis for establishing maximum residue limits (MRLs) and for conducting dietary intake assessments for consumer safety.

Who or what will benefit from these outputs, and how?

Metabolism in Livestock studies are used to determine the qualitative and quantitative metabolism and/or degradation of the active ingredient resulting from pesticide use in feedstuffs, direct application to livestock, or premise treatment. Metabolism in Livestock studies are generally carried out on lactating ruminants and poultry.

Residues in Livestock studies are conducted in order to quantify levels of residues in meat, milk, eggs and edible meat by-products, such as fat, liver, kidney of ruminants, following the use of a pesticide product. The situations to which such studies apply include application of a pesticide to raw agricultural commodities (RACs), and the feeding or grazing of such commodities and their by-products by livestock; pesticides that may be directly applied to livestock; and pesticides that are used in livestock premises.

How will you look to maximise the outputs of this work?

As we are a Contract Research Organisation most studies provide accurate data which is acceptable to regulatory authorities. The data is likely to be included in dossiers submitted to the regulatory authorities when registering plant protection products. This data will enable accurate decision making with regard to labelling of the chemicals, for example.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 860
- Cattle: 300
- Goats: 40

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of live animals is needed in order to determine transfer of pesticide and/or their metabolites into meat, milk and eggs. Farm animals (cows, hens, etc) are required by the regulator as the objective is to measure potential dietary exposure to pesticides in their edible tissues. The minimum number of animals required is specified in the relevant guidelines and the minimum number will be used wherever possible. In some cases, the use of one particular type of animal removes the need to generate data for other animals. For example, in most cases the results of a cattle feeding study can be used to establish tolerances in goats, pigs, horses and sheep. Similarly, data on chickens is normally accepted in lieu of data on other livestock poultry, e.g. turkeys, geese and ducks. This licence allows the use of farm animal species (cattle, goats and poultry) to achieve the regulatory requirements.

Typically, what will be done to an animal used in your project?

Metabolism studies (OECD 503)

The guideline indicates that metabolism studies should be conducted using radiolabelled test compound.

The guideline recommends that the dose is administered orally via a dosing gun, capsule or gavage. Ruminants should be dosed daily for at least five days and poultry daily for at least seven days.
However, if a feeding study is not to be carried out, the dosing period may need to be extended so that a plateau of residue is reached.

A ruminant metabolism study can be carried out on one animal, whereas for poultry a minimum of 10 birds per dose level is recommended. For ruminant studies a companion animal will always be sourced.

Milk and eggs will be collected in the normal way. Animals will normally be penned individually in metabolism crates to enable the complete collection of excreta passively, and the separation of urine and faeces passively in the case of the goat. The desired goal is to characterise 90% of the total radioactive residue i.e. characterise the destination of

90% of the dosed material. Animals will remain within sight of others. Animals will usually be killed at the designated establishment by a Schedule 1 method. The time of killing needs to be justified to the regulator. For this reason, blood samples will usually need to be taken before and at various intervals immediately after the first dose. This is in order to calculate the time of maximum concentration in the blood. Animals should not normally be killed before this maximum concentration is reached. If frequent blood samples are required, particularly from birds, indwelling cannulae may be used, these will be inserted by non-surgical means. Tissue specimens (skin, fat, muscle, liver and kidney) will be collected post mortem.

Livestock residue studies (OECD 505)

Livestock residue studies will typically involve administration of pesticide to animals by addition to the feed or by dosing. Dosing of cows will usually be conducted by addition of the pesticide on top of their feed twice daily. However, where pesticide is unpalatable it will need to be administered via a dosing gun, capsule or by gavage. Dosing of hens will usually be once daily via an oral capsule. Animals will be dosed for a minimum of 28 days or until residues plateau in milk or eggs, if they have not done so after 28 days.

Milk and eggs will be collected in the normal way. Animals will normally be penned individually so that individual feed intakes can be measured, but they will remain within sight of others and will have nose- to-nose contact with animals of similar treatment group. Poultry will be kept on perforated / slatted / mesh floors to prevent recycling of the pesticide. Animals will usually be killed by a Schedule 1 method at the designated establishment. Tissue specimens will be collected post mortem, so no invasive sampling is required.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects are expected to be mild in nature and the incidence is expected to be low. Blood sampling of laying hens during metabolism studies will lead to haematoma in approximately 50% of cases. However, our experience is that these heal rapidly with no observable consequences to the birds. All other adverse effects are expected to be infrequent i.e. an incidence of less than 1%. All animals will be euthanased by a humane method at the end of each study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity of all procedures is expected to be mild (99% of animals are expected to fall into the mild category).

What will happen to animals at the end of this project?

- Killed
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Livestock residue and metabolism studies are not required for all crop protection chemicals and clients usually make strong representations to the regulator to avoid the need to conduct them. However, once the regulator decides that animal feeding or metabolism studies are necessary they usually specify that they need to be carried out to OECD Guidelines for the Testing of Chemicals, Test No. 505: Residues in Livestock or Test No. 503: Metabolism in Livestock respectively. The use of animals is specified in these guidelines. For each study conducted under this licence we will ensure that, as part of the Ethical Review Process, the client has made representations to the regulator questioning the need to conduct an animal feeding study.

Which non-animal alternatives did you consider for use in this project?

As these studies are for regulatory purposes once the regulator decides that animal feeding or metabolism studies are necessary they must be tested in the animals. There are no non-animal alternatives.

Why were they not suitable?

Studies must be carried out in the animal as required for regulatory purposes

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The minimum number of animals is specified in guidance documents and these numbers will be used unless there is a strong case to use more. If more than the minimum recommended number is requested, this will need to be justified by the sponsor and/or regulator and statistical advice will also be taken. In all cases, any increase over the minimum recommended numbers will need to be approved through the AWERB.
Over the five year life of the project approximately 50 studies are likely to be conducted, each providing information to allow different pesticides to be introduced onto the market in a manner which is safe to consumers, animals and the environment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals per study is rigidly laid out in the OECD guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of animals per study is rigidly laid out in the OECD guidelines. However the data collected will often be applied for other species. For example data on residues in milk from dairy cows will usually equally apply to dairy goats. In most cases the results of a cattle feeding study will be used to establish animal commodity maximum residue limits for goats, pigs, sheep and horses. Within the poultry group, data on chickens will usually be accepted in lieu of data on other livestock poultry e.g. turkeys, geese and ducks.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The choice of animal, model and method is rigidly laid out in the OECD guidelines, OECD 503 for metabolism studies and OECD 505 for feeding studies:

For metabolism studies, OECD 503 indicates that separate metabolism studies should be conducted in ruminants and poultry. The species of choice are lactating dairy goats and egg-laying hens.

For residue studies, OECD 505 indicates that separate feeding studies should be conducted for ruminants and poultry whenever residues are likely to occur in the feeds of these classes of livestock. The species of choice are lactating dairy cows and egg-laying hens. Data on residues in milk from dairy cows will usually equally apply to dairy goats. In most cases the results of a cattle feeding study will be used to establish animal commodity maximum residue limits for goats, pigs, sheep and horses. Within the poultry group, data on chickens will usually be accepted in lieu of data on other livestock poultry e.g. turkeys, geese and ducks.

It is unlikely that any toxicological effects will result from administration of pesticides at the levels to be used in such studies. In all studies conducted under the previous project licences no adverse effects from the pesticides were observed. It is likely that the sponsor will already have conducted some livestock studies, results from these will inform the AWERB on the likelihood of adverse effects being observed in the residue study. However, twice daily observations of the animals for adverse effects which may be associated with the pesticide will be conducted.

Why can’t you use animals that are less sentient?

The choice of animal, model and method is rigidly laid out in the OECD guidelines, OECD 503 for metabolism studies and OECD 505 for feeding studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Twice daily observations of the animals for adverse effects which may be associated with the pesticide will be conducted.

Animals will usually be acclimatised in their individual pens for a minimum of one week, usually two, before dosing / feeding of the pesticide commences. Individually penned animals will be located within sight of each other to minimise any distress caused by individual penning. For metabolism studies involving one goat, a companion animal will be located within sight of the study goat. Goats will be acclimatised to new diet in group pen before placing in metabolism pen to acclimatise to new pen.

For residue studies administration of the pesticide on top of the daily compound feed allowance for dairy cows has been successfully implemented on most occasions. This refinement means that cows do not have to be restrained for administration of a bolus twice a day for 28 days. However due to the composition and palatability of some products this is not always possible in cattle. When not possible staff will be fully trained in methods of restraint, the animals head will be held securely and lubricant such as liquid paraffin may be used on the dosing gun. This refinement was trialled for laying hens but failed due to palatability problems. This refinement is not possible for metabolism studies as the method of administration is prescribed in OECD 503.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

OECD guidelines, OECD 503: OECD Guidelines for the testing of chemicals, Metabolism in Livestock and OECD 505: OECD Guidelines for the testing of chemicals, Residues in Livestock (sometimes referred to as feeding studies or transfer studies)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attend HOLTIF meetings, be on email lists of ASRU, HOLTIF, NC3RS, Large Animal Research Network and IAT. Discuss 3Rs regularly in AWERB and with NVSs and NACWOS.

132. Endothelial function and vascular homeostasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Cardiovascular disease, Endothelial cells, Vascular Function, Signalling Pathways, Therapeutic Targets

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Endothelial cells form the inner layer lining every blood vessel in the body of vertebrates. The function of endothelial cells is essential to regulate cardiovascular function, including blood pressure, blood clotting and inflammation. Thus, investigating the mechanism regulating and maintaining endothelial function in the adult organism will shed light on the pathological mechanisms driving the onset and progression of cardiovascular diseases including hypertension and atherosclerosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Around 7.6 million people live with heart and circulatory diseases in the UK with 168,000 annual death from heart and circulatory disease (BHF Stats, https://www.bhf.org.uk/). Although lipid-lowering drugs such as statins have significantly reduced mortality from Cardiovascular Diseases (~25%), significant levels of mortality remain. The work described in this project licence will provide information and increase our knowledge on the mechanisms promoting endothelial and vascular function and shed light on the

pathogenic mechanisms and signalling pathways involved in the onset and progressions of cardiovascular diseases such as hypertension and atherosclerosis. This knowledge will contribute to identifying new therapeutic targets and to inform translational research that aims to improve the condition of patients affected by vascular diseases. The project will employ genetically-modified mice and pharmacological tools which will allow to modulate specific signalling pathways in endothelial cells and the vasculature and to investigate their role in endothelial and vascular homeostasis and cardiovascular diseases. While pharmacological tools such as inhibitors and activators could modulate specific signalling pathways in all tissues and organs, genetic modification permits selective tissue or cell-type targeting of specific pathways.

What outputs do you think you will see at the end of this project?

The project will identify new pathways and mechanisms involved in endothelial and vascular function. The data produced during this project will be included in publications in high-impact international scientific journals and shared with the scientific community at national and international scientific conferences. Also, the data generated will be included in expert peer-reviewed grant, seeking further funding to investigate how the molecular mechanisms and signalling pathways regulating endothelial function control the function of the cardiovascular system in physiological conditions and how their dysregulation promotes the onset and progression of cardiovascular diseases.

Who or what will benefit from these outputs, and how?

The knowledge produced during this project will contribute to advance the vascular research field by expanding our understanding of the signalling and molecular mechanisms involved in the pathophysiology of vascular homeostasis. Thus, the project will give insight into the pathogenic mechanisms associated with cardiovascular disease, with the ultimate goal of identifying novel therapeutics to treat this disorder. As the project has the potential to identify novel therapeutic targets and medicines or biomarkers for vascular diseases, data from this project will contribute to improve current treatments for cardiovascular diseases and will benefit patients suffering from these conditions in the long-term.

How will you look to maximise the outputs of this work?

Findings from this project will be included in publications in peer-reviewed high-impact international scientific journals and will be shared with the scientific community at international scientific meetings. We will take part in initiatives of public engagements through initiatives organised by the British Heart Foundation such as events organised in the BHF charity shops in which researchers in the vascular field explain to the general public the importance of cardiovascular research and how this contributes to saving lives.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To investigate the mechanisms and the signalling pathways regulating endothelial and vascular homeostasis and how their deregulation leads to cardiovascular diseases, we will use an array of in vitro techniques and cell culture. While these in vitro techniques will provide essential data to identify signalling pathways involved in endothelial and vascular homeostasis they lack the biological complexity of an organism and provide limited physiological and pathological insight. Thus, key findings obtained in vitro will be translated in vivo using mice, to reach meaningful results and corroborate our findings. We elected to use mice for our project because mice are the most extensively used animal model for cardiovascular research and genetically modified mouse models allow for rapid establishment of proof-of-principle, which can later be extended into larger animal models and, eventually, into humans.

Typically, what will be done to an animal used in your project?

To perform cardiovascular phenotype studies the animals will be treated with specific inhibitors/activators of pathways we suspect to be involved in the maintenance of normal physiology, or with drugs that activate/inactivate gene expression in genetically modified mice. Typically mice will be pre-treated with established or novel drugs or control substances/vehicles by one route such as oral (i.e. gavage or ingestion with food/water), injections (i.e. subcutaneous, intraperitoneal). In addition, some animals may be subjected to dietary intervention and will receive standard or modified, enriched or deficient diets (altered in fat and/or protein and/or carbohydrate and/or specific drug content) during a variable period. In some animals, we will monitor blood pressure using the non-invasive tail-cuff method. We will collect cells/tissue/organs from terminally anaesthetised animals. Typically animals will be injected at 4-6 weeks of age, and kept for further 20 weeks, depending on the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Treatment with drugs is not expected to cause adverse effects because doses will be selected which are believed to be safe. Animal subjected to treatments will be observed and monitored for any of the following signs: pain, laboured breathing, piloerection, orbital tightening, not eating/ drinking, or loss of body weight. No treatments in this license are anticipated to cause more than minor and transient discomfort. Any animal showing signs of suffering that are greater than minor and transient or in any way compromises normal behaviour will be immediately killed by an approved method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The overall severity for animals undergoing the above-mentioned procedure is moderate

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because of the dynamic interactions between different cell types forming the vasculature and the interaction between the endothelium and the immune system that typify the maintenance of cardiovascular function and pathological processes occurring in vascular disease, it is necessary to use animals and animal models of cardiovascular disease. Mice are phylogenetically related to humans, with the two species sharing virtually the same set of genes (99% of human genes have direct murine orthologs) and physiology. The cardiac developmental stages observed in mouse and human embryos are comparable, as well as the overall function and physiology of the cardiovascular system, although differences remain mainly due to the difference between the two species in the length of the gestation period, size and lifespan. Because of their genetic and physiological similarities, several mouse models of cardiovascular diseases such as atherosclerosis, hypertension, heart failure mimicking the related human conditions have been established and represent an invaluable tool to understand these diseases. Whilst there are few animal models that faithfully reproduce all the pathology of the analogous human cardiovascular condition, it is possible to produce certain fundamental processes in mice and in genetically modified mice that may either reveal new mechanisms or potential therapeutic targets. Thus, provided one is aware of the limitations of animal models, they play a valuable role in increasing our understanding of the pathophysiology of vascular disease.

Which non-animal alternatives did you consider for use in this project?

We will perform experiments using animals only after having performed and obtained meaningful data on the pathways and mechanisms involved in endothelial and vascular function using cell culture in vitro models. For these experiments, we will use commercially available human endothelial cells in which we will modulate specific signalling pathways using molecular (i.e. small interfering RNA) or pharmacological approaches (i.e small-molecule inhibitors, drugs). We will use these cells to perform traditional biochemical analysis, transcriptomic and proteomic analysis profiling assays. We will also use devices to mimic in vitro the physiological conditions of blood vessels in which endothelial cells are exposed to the forces applied by the flow of blood. In these experimental conditions, we will investigate how modulation of these pathways regulate the communication between different cell types (i.e. smooth muscle cells, immune cells, etc.) by performing co-culture in vitro experiments. We will also take advantage of clinical and genomic data from patients affected by cardiovascular diseases to investigate whether genetic variants associate with cardiovascular disease. Then will study the biological effect of these variants in vitro in using human cells. Together, these in vitro experiments will replace the use of animals in the initial phase of this project to identify signalling pathways and mechanisms regulating the biological processes addressed by this project. Data obtained with these in vitro approaches will then be used to guide a very targeted experimentation of these pathways and mechanisms in the in vivo setting (i.e. whole animal) or ex-vivo (i.e. organs and tissues).

Why were they not suitable?

The studies using animals described in this project form part of a larger initiative that involves the use of cell culture and other in vitro techniques. In vitro systems such as cell culture models are powerful tools to determine molecular mechanisms and investigate signalling pathways in specific cell types that could be relevant to regulate biological processes. However in vitro experiments lack the complexity of a whole organism and do not account for physiological interactions between organs and tissues, different types of cells and the effect of changes in vascular function on tissues and organs physiology and on an overall organism. The onset and progression of cardiovascular diseases such as atherosclerosis are multifactorial and characterised by local (i.e. formation of atherosclerotic plaques in specific area of the aorta and coronary arteries,) and systemic changes (i.e. lipid metabolism, inflammation, increased immune response) which are responsible for the initiation and maintenance of cardiovascular inflammation. Thus, while the in vitro approaches allow to identify potential molecular mechanisms and signalling pathways that regulate vascular function, the in vivo approaches allow us to study their relevance in physiological and pathological contests and to evaluate potential biomarkers and therapeutic targets to treat vascular disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The employment of commercially available human cells for the in vitro experiments together with the use of devices to mimic in vitro the physiological conditions of blood flow on endothelial cells, and the availability of clinical data from patients with cardiovascular diseases, will allow to reduce the number of animals and to design a very targeted animal modelling approach. In addition, our extensive experience in pre-clinical models entails we have a substantial bank of data upon which to draw to establish the minimum number of animals required to detect a statistically significant effect in the experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used statistical methods to determine the smallest number of animals to use in each set of experiments. We used NC3Rs' experimental design assistant which helps with the experimental design and statistical analysis plans by providing support for randomisation and blinding, sample size calculations and advices on the more appropriate statistical analysis methods for each set of experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Minimum numbers of breeding pairs will be mated to provide offspring to enable ex vivo and in vivo experimentation. Working on the basis that a breeding pair produces a litter once a month of approximately 8 animals we would need approximately 4-6 breeding pairs to provide a minimum of 1 animal per day for experimentation. Our breeding design will allow to produce perfectly stage- and strain-matched controls animals. Animal of both

sexes will be used in the experiments. The members of the group will share tissues harvested from these animals to analyse different aspects of the project, thus maximising the use of experimental animals and avoid waste.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All of the models described in this licence are mild to moderate; there are no models that fall into the severe category. Each is well-validated and widely used for investigation of the mechanisms underpinning cardiovascular diseases, and gleans robust & informative with minimal animal suffering.

Why can’t you use animals that are less sentient?

The work will be conducted exclusively in mice to enable the exploitation of transgenic technology that enables gene targeting (i.e. gene deletion or gene expression) in the whole animal or in a tissue- specific manner. Relevant to this project, the availability of mouse mutants in which gene deletion can be pharmacologically induced in the endothelium makes the use of these animals an asset to determine the role of specific genes in the function of the endothelium, the vascular system and cardiovascular diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All protocols described in this PPL involves minimally invasive techniques and no animals will undergo invasive procedures such as surgeries. For instance, we will use non-invasive ultrasound imaging systems and/or cuff systems to measure blood pressure. Analgesics and anaesthetics will be used whenever necessary, and close monitoring of all animals undergoing licensed procedures will be undertaken. Any animal deemed to be experiencing unnecessary suffering by the investigator or veterinarian will be culled immediately by an approved method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will monitor published scientific literature in which similar models described in this licence have been used, to ensure that we will conduct the experiments in the most refined way. We will check and follow the latest guidelines on animal welfare. All researchers involved in the current project will follow the guidelines. “The Responsibility in the use of animals in bioscience research” general guidance document will be used as a reference document, as it sets out the expectations of the funding bodies for the use of animals in research. The updated ARRIVE guidelines (2.0), designed for transparent reporting of

animal research methods and findings, will be consulted for the planning and design of new experiments, together with the “Guidelines for planning and conducting high-quality research and testing on animals” (ref. 1) and PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines (ref. 2). Finally, we will follow the guidelines of the UK Research Integrity Office (UKRIO) and will aim to register our study protocols in an international online register of protocols for preclinical animal studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

PIL holders working under this licence will regularly attend NC3R, BPS or similar meetings to keep abreast of new developments, and to maintain awareness of current best practices.

133. The Regulation of Energy Balance

Project duration

2 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Body composition, Calorie restriction, Energy Expenditure, Healthspan

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to investigate the complex mechanisms regulating body weight which ultimately affects health and lifespan.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With a better understanding of the mechanisms controlling body weight we can help tackle 2 key worldwide issues – obesity and an increasing ageing population.

What outputs do you think you will see at the end of this project?

Results will be disseminated by peer reviewed publications. Outputs will further our understanding of the regulation of body composition remodelling under negative (calorie

restriction) or positive (high fat diet) energy balance in males and females. The impact on reproductive investment under calorie restriction will be determined.

Who or what will benefit from these outputs, and how?

Outputs from the work of this licence are specifically related to understanding the fundamental biology of energy balance controlling our body weight. Our research outputs are clearly relevant to major public health issues such as obesity and ageing. Calorie restriction, ie. dieting is the primary General Practitioner and self-prescribed treatment against obesity. In many species calorie restriction improves health and extends lifespan with recent work finding similar benefits in humans. Establishing the mechanisms by which calorie restriction exerts its beneficial effects is a key priority for research because it may open the door to interventions that will allow us to capture the health benefits of eating less and ultimately retard the rate of ageing. Benefits will be realised by other scientists working in the field of ageing as well as healthcare, specifically the quality of life for the elderly and improvements in health of obese population.

How will you look to maximise the outputs of this work?

We are committed to open science and generated data will be deposited in our open access database. We have a strong history of promoting our work among the academic and lay communities ensuring the results are widely available. Our work will be published in high impact journals with summary forms available via social media, ResearchGate, academia.edu etc. We have a strong network of collaborators worldwide who have contributed in various ways to our research. Tissues are regularly shared with our collaborators generate maximum output from minimal numbers of animals.

Species and numbers of animals expected to be used

- Mice: 1150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our work will use mice, wild type and genetically altered (GA). The mouse is an ideal choice because they share a mammalian physiology and high genetic homology with humans. There are of course also differences between mice and humans that we should not ignore, but as a first step, studies of mice allow us to carry out calorie restriction studies and explore ideas about ageing that can then be expanded in other models and humans themselves.

The majority of work on this licence will use the C57BL/6 mouse which is a well-established model for the study of energy balance. The genome of the C57BL/6 mouse has been fully sequenced and therefore this model is indispensable for our studies.

The use of GA mouse models will allow us to validate the function of any gene of interest we identify as playing a key role in energy balance.

Generally, our calorie restriction protocol is introduced at 20 weeks of age, approximately equivalent to early human adulthood, and close to the time when mice reach skeletal maturity. Allowing mice to mature avoids impacts of calorie restriction on developmental processes. In the case of GA animals which may become obese rapidly an earlier start age may be necessary for start of protocol. The duration of our studies is generally 3 months but be shorter or longer.

Typically, what will be done to an animal used in your project?

A typical calorie restriction study would involve 6 procedures generally performed pre- and post- dietary regime (ie. 12 weeks apart) or following the administration of substances:

Single housing,

Intraperitoneal transmitter implantation for logging body temperature and activity continuously throughout the study.

Dual x-ray absorptiometry (DXA) or Echo MRI. Scanning may be carried out at any stage and on multiple occasions throughout the protocol. For DXA, scans are generally every 4 weeks but no more than 10 times over a 3-month period. Echo MRI may be weekly.

Glucose tolerance tests (GTT) Mice are fasted, injected with glucose and blood withdrawn by tail prick. Tests take 2 hours from injection.

Resting metabolic rate (RMR) is a non-regulated procedure.

Calorie restriction by reducing energy provided to mice by a % of their individual ad libitum intake Where appropriate alternative Energy Expenditure methods may be used:

Doubly labelled water technique requires intraperitoneal injection followed by 2 tail blood samples taken between 1 and 48hrs post-injection.

TSE Phenomaster

Daily energy expenditure may be measured using home cage analysis systems. Measurements are made over a 72-hr period (includes a 24-hr acclimatisation) at the end of the study.

Animals may also be Pair-fed or have their dietary content (protein, fat, carbohydrates) manipulated

Withdrawal of blood Repeated blood samples may be taken through the course of the study. Volumes and frequencies will comply with the local LASA guidelines unless otherwise stated.

Non-central administration of substances and relevant control. Several routes (topical application, injection via the subcutaneous, intraperitoneal, and oral routes, such as gavage) may be used over varying durations.

What are the expected impacts and/or adverse effects for the animals during your project?

Anticipated adverse effects are reported below.

Stress Single housing may cause stress. When transmitters are used, they will be single housed from time of surgery ~12wk for 20 weeks

Weight loss is expected to occur in calorie/ dietary restriction and pair feeding studies. Calorie restriction is known to improve health & lifespan and weight loss is not detrimental unless excessive. Animals used in dietary manipulation studies may also lose weight. Following DXA which uses gas anaesthesia, in a few cases, a small drop in body weight (and food intake) may occur (generally no more than 1g of either) may occur. This is generally overnight, and mice recover within 24 hours.

Torpor is defined as a body temperature <31°C. This is a natural energy saving mechanism and not detrimental. Calorie restricted or pair-fed mice are expected to experience torpor. Some GA models, e.g. ob/ob and db/db also experience spontaneous torpor due to the lack of functioning leptin system.

Hypothermia is a drop in body temperature which some GA models, e.g. ob/ob and db/db spontaneously experience. The duration should not be greater than 8 hours.

Food Anticipatory Activity known as FAA is a marked increase in activity in the 2-3 hours prior to food provision. FAA is thought to be normal food seeking behaviour.

Risk of infection or changes in behaviour following surgery. There is also a slight risk of wound re- opening.

Hypo/ hyperglycemia may occur in rare instances immediately post injection of glucose for GTT.

Excessive urination in ob/ob and db/db mice which become diabetic. These may lead to further prepuce disorders.

Skin conditions Some mice may develop dry patches of skin which may become irritated, inflamed (red). We have found this in the ob/ob and db/db mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

75% of mice are expected to suffer moderate adverse effects due to the effects of transmitter implantation surgery. The rest of the mice should suffer no more than mild adverse effects.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work requires a whole animal system. There are no feasible alternatives which allow us to meet our objective. With close genetic and physiological similarities to humans, the mouse is the premier mammalian model system for genetic research. Using mice, we can probe the complex physiological systems that humans and mammals share, ie. immune, hormonal, nervous, cardiovascular, skeletal etc. With the key objective of this license to investigate energy balance, the mouse is ideal, specifically the C57BL/6 mouse which is a well-established model for such studies and is known to respond positively to calorie restriction. We have an extensive data set from the C57BL/6 which we have used for the past 12 years to characterise the response to calorie restriction. Measures range from physiology to genes, hormones to behaviour, body temperature to metabolomics etc. Using mouse models we can manipulate intricate interactions of biology, behaviour and environment which would be impossible using in vitro modelling techniques which lack the whole body integrated responses of different cell types, hormones etc. From our post-mortem we collect 22 tissues. From the dissection weights, tissue remodelling following the dietary interventions can be determined. All tissues are stored appropriately at -80°C for further analysis eg. transcriptomics allowing us to pin-point tissue and gene specific responses. Most importantly we have access to the hypothalamic region of the brain which controls energy balance regulation. GA mouse models are also invaluable to our research determining the function of genes involved in energy balance.

Which non-animal alternatives did you consider for use in this project?

There is no feasible alternative to investigation of the whole body regulation of energy balance. Calorie restriction for instance elicits varying response in numerous tissues, some losing and some gaining mass at different timepoints and levels.

If appropriate we will use tissues available from specific data banks such as the NIA https://www.nia.nih.gov/research/dab/aged-rodent-tissue-bank-handbook/available-tissues

Why were they not suitable?

Energy balance is a complex interaction of many factors. While cell culture work may test responses to compounds how this response is integrated in a whole body system cannot be measured.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All experiments performed will be based on the principle of using the least number of animals compatible with having sufficient statistical power to achieve statistical significance using appropriate statistical tests.

Our calorie restriction protocol using a graded approach at 4 levels from 10 to 40% less food, plus control group, with an n of 8-10 per group for a short-term study this totals 50 mice. We will use both sexes and several GA mice. (250)

Leptin replacement study = 50
Breeding may be required for some GA models (allow for 250) BBSRC Grant submission 2022 = 500
Possible pilot studies = 100

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Study plans are rigorously designed to obtain the maximum information from the minimum number of animals. As part of the design, we seek statistical advice to ensure animal numbers are adequate to meet statistical significance.

We have used the graded calorie restriction protocol for 12 years. Our protocol is robust and generates reproducible data. Recent experience with GA animals indicated starting with higher numbers to address unanticipated responses to surgery.

We have a very stringent dissection procedure taking 22 organs for further analysis. This ensures the data from every animal is utilised to its full potential and avoids repetition of studies. We have a large collaboration network and have provided several tissues to other research groups with an expertise in specific fields.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where available GA animals will be bought in from external suppliers. Where appropriate breeding of GA models will be carried out in-house under the guidance of staff to achieve the most efficient breeding protocol.

As stated above we collect 22 different tissues for further analysis. Tissues are stored at -80°C for future analysis. We regularly share tissues, reducing repetition of studies and unnecessary use of animals.

Where appropriate pilot studies will be used to determine efficacy of administered substances or use of GA mice. A successful pilot study will also help to guide refinements and humane endpoints.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

C57BL/6 mice are the most refined model for use in calorie restriction. Where appropriate other models may be used.

Calorie restriction will be used on models with ‘normal’ food intake. Pair-feeding is used when we know animals are hyperphagic, ie eating excessive amounts. Pair-feeding will reduce their food intake to that of appropriate controls.

Where GA animals are used relevant approval will be requested and adverse effects assessed.

While implanted transmitters to measure physical activity and body temperature involve an initial surgery they provide non-invasive continuous assessment of the parameters. In addition, the transmitters are beneficial post-surgery allowing us to monitor recovery of the mice via their body temperature.

Why can’t you use animals that are less sentient?

Our calorie restriction protocol is initiated at 20 weeks, equivalent to early adulthood in humans. Beginning earlier has been shown to have detrimental effects on development.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All appropriate refinement measures will be applied to eliminate or minimise welfare costs ie pain, suffering, distress or lasting harm experienced by animals during a study.

Advances in 3Rs are received via the NC3Rs newsletter. The most refined methods are currently used and updated where appropriate following discussion with the NACWOs/ NVS, eg cupping/ tube handling has recently been introduced for all animal handling to reduce stress.

Refinements arising during a study will be applied to future experiments.

Monitoring methods were refined to use body condition score as opposed to body weight loss.

Equipment and methods will be continuously reviewed and updated should they more refined alternatives become available in the future.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I subscribe to NC3R and receive regular emails, from NC3R News which provides updated information.

134. Teleost models of haematopoietic diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Bone Marrow Failure, Leukaemia, zebrafish, haematopoiesis, therapy

Animal types	Life stages
Zebra fish (Danio rerio)	adult, juvenile, embryo, neonate
Killifish	juvenile, adult, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of our project is to better understand the development of blood cancers and other related blood conditions. Our studies address the genetic basis of these diseases and how they evolve. We will also use models of these diseases to define new treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have a large amount of knowledge about errors (known as mutations) in genes that lead to the development of blood diseases (bone marrow failure syndromes such as Diamond-Blackfan Anaemia) and blood cancer (leukaemias). Much less is known about the consequences of these mutations, how they result in disease, and what modifies how severe the disease is.
Some blood cancer causing mutations can also be found in people without clear evidence of disease. These individuals have an increased risk of blood cancers. This risk increases

as we get older. What is lacking is a better understanding of what converts mutations in one gene into a cancer. This can be because other mutations have been acquired as part of the aging process. Alternatively it can be because the environment in which the cells with the mutation sit is abnormal. There may be other additional factors contributing to this process, such as how the cell gets its energy (metabolism) or how much of a gene is present or other ways that we don't know yet. These non-genetic ways such as these that occur due old age are called epigenetic effects.

Our project aims to understand the process of the development of blood cancers and related blood diseases. In particular we are looking to find out how age contributes to the development of blood cancers using a type of fish that ages very rapidly. We are also looking to find new treatments for these diseases. This includes identifying therapies that might potentially prevent the onset of cancer. The ultimate goal is to provide a detailed understanding of how blood diseases evolve to facilitate new treatments that improve human health.

What outputs do you think you will see at the end of this project?

This project will generate new information about what causes the development of blood cancers and related diseases. Our project also aims to define new treatments for blood cancers. The outputs will include datasets (genetic sequencing data) that will be made publicly available and scientific publications presented at scientific meetings and published in high impact journals and potentially new drugs that can be moved to the next steps of testing in human samples and eventually patients.

Who or what will benefit from these outputs, and how?

By the end of the project we aim to have detailed information on

How leukaemia evolves from the combination of two or more genetic mutations in combination

Why people with inherited predisposition to leukaemia go on to get leukaemia later in life

Potential new drug treatments that can target leukaemia cells which carry specific genetic mutations.

How different energy sources are used in models of Diamond-Blackfan Anaemia and how we may utilise this knowledge to create novel treatments

These benefits will be across the scientific community and clinical researchers in the leukaemia, anaemia and bone marrow failure field.

How will you look to maximise the outputs of this work?

I will publish the results arising from the studies in this licence in the scientific literature. This will be maximised by presenting the work at national and international conferences, sharing data, publishing on pre-print servers (e.g BioRixv - this means work can be published prior to peer review in a timely manner) . I also have strong links with patient support groups (MDS UK, DBA UK and Children with Cancer) as well as Cancer Research UK, with whom I regularly engage with to disseminate the results of my research across patient groups and their families.

Species and numbers of animals expected to be used

- Zebra fish (Danio rerio): 13700
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish are the least sentient animal that develops blood akin to that seen in humans. The programming of blood cell development occurs in a similar manner to that seen in humans. In addition, using fluorescently labelled blood cells, we can observe the development of blood cells and we can see the development of blood and blood cancers in real time using a microscope, especially during the early stages of development (first 5 days) when the embryos are transparent. We think that for conditions where there is an inherited predisposition to blood cancers, how blood is made during development contributes to the development of leukaemia or bone marrow failure later in life.

Therefore zebrafish are the best model to use to study this process as it can be studied in the embryos which are transparent and develop outside the mother.For our studies of blood cancers that are acquired in older adults, we know there is an increase in the incidence of these cancers as we age. We use killifish to model these cancers rather than zebrafish because they naturally age very quickly over only a few months compared to 2-3 years with zebrafish, and show the signs of aging we observe in humans. Using killifish allows us to determine the effects of aging in combination with genetic errors over time without having to wait many years to obtain results.

The use of both of these types of fish is complementary in our approaches to minimise harm (using zebrafish for mainly developmental studies before 5 days of life where possible and killifish where we would like to assess specific effects of aging).

Typically, what will be done to an animal used in your project?

Adult zebrafish and killifish will be bred to maintain stocks required and to generate embryos/larvae for experiments where necessary. These fish will live a normal, healthy life as any aquarium fish. A small biopsy of the tail fin will be taken from some fish in order to determine certain genetic characteristics, typically only once in an animal's lifetime.

We will use fish with fluorescently labelled blood cells to aid our assessment of blood development. This will allow us to visualise blood cancer development while the fish is alive by using a microscope. Fish will be anaesthetised to allow this assessment which may be done several times (up to 8, however usually once or twice) to observe the effects over time. We may also take a small sample of blood from the fish to look at it in more detail.

We also aim to look for possible new treatments. This means that some fish will be treated with compounds aimed to prevent or treat the blood diseases we are studying. The majority of this work will be undertaken prior to the onset of independent feeding. An adult fish receiving a treatment would only receive one treatment over its lifespan. The

treatments are usually administered in the fishes water, although sometimes we may need to administer the treatments directly into the fishes digestive system, which is done when they are asleep using a small tube.

The forms of leukaemia we see as a result of older age are thought to be partly caused by the environment in which the leukaemia cells grow. For a small subset of animals (around 1%) we will take blood stem cells from one animal after euthanasia, and transplant them into another, using a small injection into the belly of the fish. This will help us understand whether if we change the "aging" environment we can prevent leukaemia. This will only be undertaken once in a fishes lifetime.

Most blood diseases occur because of the presence of genetic abnormalities. In humans some of these genetic abnormalities are inherited. In order to study these diseases accurately we will introduce these same genetic abnormalities into the fish. This is typically done when the fish are at the egg stage so that all the cells of the fish carry the genetic defect. This is done using microinjection of gene editing RNA (CRISPRs) at the one-cell stage. However, in some instances (around 5%) we will induce these changes in adults and in only some of the tissues in the fish (usually blood for our studies). This is done using drugs such as tamoxifen or heat to activate the genetic changes. This is important most human cancers evolve due to several genetic changes that occur only within the tissue of that cancer as we age.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of fish, adverse effects are not expected. We know this because we have experience with many of these models already from our prior work. For protocols where there are treatments to the fish, or where the fish develop the diseases we are studying (anaemia or leukaemia) there may be adverse effects in some animals. The expected adverse effects may include reduced food intake, reduced or abnormal swimming, infection and some developmental abnormalities such as small size or heart problems. This will affect a very small number of animals for a maximum of a few days where the animals are undergoing experimental purposes within the limits of the designated protocols.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity limit for the majority of experiments is mild. Some of our animals may develop features of the diseases we are studying such as leukaemia. We will only permit this to happen if it is essential for our protocol, for example testing the effects of a new drug to treat leukaemia. In such cases we don't know what the effects of the drug on the fish in this setting might be, so a small number of animals may endure moderate severity limit in these experiments. Procedures are in place to closely monitor these effects during these protocols. These include assessing animals changes in swimming behaviour, pallor, or reduced growth.

We know that our zebrafish model of Diamond-Blackfan anaemia has some features of this condition. Most of these are obvious during very early development prior to the onset of independent feeding. We only raise animals that are healthy prior to the onset of

independent feeding. These animals show signs of being small but otherwise appear indistinguishable from their siblings during normal aquarium lifespan. Although we do not observe any clear signs of harm to the vast majority of these animals we attribe a mild phenotype to these animals since we may not be able to detect this. The proportion of animals in a moderate severity category we expect to be less than 1% based on our prior experience.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Blood cancers develop as a result of genetic defects. While these can be and are studied using cells in a dish or cells directly from patients there are 2 main confounding factors that mean animals are needed for our studies:

We are interested in how blood cancers develop over time. It is not feasible to follow humans over many decades and examine their blood system in depth regularly to assess the effects of different genetic errors in their blood. The fish species used in this project (particularly killifish) age very rapidly with features of aging that we see in humans. This allows us to see the effects of a genetic error over a lifespan.

The effects of genetic errors cannot be assessed in isolation outside their natural environment. We are particularly interested in myelodysplastic syndrome (MDS) which is a kind of pre-leukaemia. There is good evidence that chronic inflammation, which comes from cells that are in the vicinity of blood, but not the actual blood cells themselves contribute to the development of this disease. Therefore looking at cells in a dish or even from a patient outside the body does not give us the necessary understanding about what happens to the cells in their natural environment and how this contributes to leukaemia.

Which non-animal alternatives did you consider for use in this project?

We have other projects in our lab that are being conducted in parallel using human tissue from MDS patients and normal humans. Our studies using fish are designed to answer the questions it is not possible to address using human samples. Importantly, we will use human tissue to validate our findings from fish work. These combined studies will help us in addressing the important next questions so we only use animals when they are absolutely needed.

We also considered using 3D bone marrow scaffolds to grow human stem cells. However, disease cells do not grow well in these and we cannot readily test the environment in which the cells grow using this technique because disease cells do not exist in isolation but are supported by lots of other types of cells such as bone cells and blood vessel lining cells.

Why were they not suitable?

Bone marrow samples from patients and normal individuals provide critical information about the biology of blood development and disease. However these only give a snapshot of information at the point in time when the samples are taken. As these are invasive tests for patients it is not ethical to do sequential tests, rather we use surplus tissue following diagnostic testing for our analysis. Our studies in fish permit us to assess what happens to blood over time due to certain genetic abnormalities and how this leads to leukaemia.

Bone marrow scaffolds allow short term culture of human blood stem cells. To date however these scaffolds still rely on animal material (bovine bones) or do not provide extended longer term support for cell growth and so again do not allow us to assess over time. Furthermore, these changes occur over years to decades in humans, and so to study effects over a lifespan with natural aging there is no viable alternative than using a rapidly aging organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we will use is based on our usage of animals in prior project licences and the proposed experiments we will undertake in this new licence. Our approach of using as many animals under the age 5dpf for the majority of experiments means that we are able to use relatively few juvenile/adult animals for our project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs experimental design assistance to allow us to calculate the minimum number of animals needed for our studies. We have also gained considerable experience from our prior studies. These allow us to more accurately assess the range of what is normal and the kind of measurable changes we expect and to allow us to predict with more certainty the actual number of animals we will require to assess our endpoints. Where possible relevant experiments will be conducted prior to the onset of independent feeding to reduce the use of older fry and adults.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Some of our studies use methods to knock out genes of interest that we think play a role in cancer or might protect from cancer or blood disorders. We have adopted methods that allow us to do this only in embryos before 5 days which in the past would have required developing and breeding a knockout animal for 2-3 generations to obtain the same information. These methods dramatically reduce the need to keep as many fish and allow us to prioritise the genes of interest to undertake the most important and relevant experiments only.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using zebrafish and Killifish in our experiments. We have structured our experimental approach to use animals before the onset of independent feeding where possible. Killifish are used instead of zebrafish for experiments in which we want to assess the effects of aging of cells (pre-leukaemia cells, or the cells of the environment) because killifish age very rapidly and allows us to conduct our experiments in a more timely manner. By contrast zebrafish produce more embryos and have a wider spectrum of existing tools and methods for use in experiments where we are able to use direct imaging and animals before the onset of independent feeding.

Why can’t you use animals that are less sentient?

We are making every effort to balance harm/benefit and to refine our methods and to use fewer animals in accordance with the 3Rs. In particular the majority of our studies will be undertaken in immature forms or terminally anaesthetised animals. These experiments will help guide the experiments we need to undertake in larval and adult forms. For example we will define the most important genetic defects that may protect from cancer in early embryos using a surrogate output, such as the number of blood stem cells present, before assessing if this is the case in adults.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I have developed structured standard operating procedures to follow for experiments that involve larvae and adults. These stepwise protocols are laminated so they can be utilised in the fish facility in real time for the relevant experiments and provide clear instructions on timings and monitoring of each component of the protocol.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the PREPARE guidelines (Planning research and experimental procedures on Animals) to ensure experiments adhere to the standards for animal research. I will utilise the ARRIVE (Animal research: Reporting of In Vivo Experiments) guidelines for reporting. Animal lines that are not in current use will be sperm frozen in order to minimise live animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will remain updated using local and national channels that inform me about 3Rs updates. First our local biological services unit provide regular 3Rs updates. Second, our fish facility provide regular advise and updates on 3Rs specific to fish studies. And finally, I subscribe to the monthly updates from the NC3Rs website and their twitter channel. I will use this information to incorporate relevant advances into my work in a timely manner.

135. Understanding the mechanisms mediating local and whole-body functions of the intestine in health and disease.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

stem cells, regeneration, cancer, enteroendocrine system, whole-body health

Animal types	Life stages
Mice	embryo, juvenile, adult, pregnant, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to answer three fundamental questions about gut health and disease: a) How does the gut repair following damage or infection? b) How do intestinal diseases, such as cancer or inflammation arise? c) How does gut illness impact whole-body health?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The gut performs vital functions, including the absorption and digestion of nutrients and is the body’s defence against ingested harmful substances and infections. Maintaining the capacity to repair itself following injury—a process known as regeneration— is key to

preserving gut integrity and the fitness of the entire body. However, because of its regenerative power, the gut is highly susceptible to cancer and other diseases. Therefore, understanding these fundamental processes is important to develop treatments to aid gut repair and prevent gut disease and its impact to whole-body wellbeing.

What outputs do you think you will see at the end of this project?

Towards the end of this project, we will have a more in depth understanding of the processes that promote repair of the intestine and those that may cause intestinal disease, such as cancer. We will also obtain a more detailed understanding of how and why break down of intestinal function affects the health of multiple organs within the body.

This knowledge will lead to new publications in this field of research and contribute knowledge useful towards the design of treatments for intestinal disease.

Who or what will benefit from these outputs, and how?

The most immediate beneficiaries of this work will be the academic and scientific community interested in the study of stem cells and intestinal biology.

Colorectal cancer (CRC) is the third most deadly type of cancer worldwide. Over 40,000 people per year have been diagnosed with CRC in the UK between 2016 and 2018. During this period, CRC accounted for 11% of all cancer deaths in the UK. An estimated 230,000 people diagnosed with CRC between 1991 and 2010 were alive at the end of 2010.

Inflammatory bowel disease (IBD), causing prolonged inflammation of the digestive tract, affects at least 1 in 250 people in the UK. Patients with IBD are at higher risk of developing CRC. UK prevalence estimates for IBD range from 328 cases per 100,000 people in the 1990s to 970 cases per 100,000 people in 2017.

In the longer term, our work may be of impact to healthcare professionals and pharmaceutical companies interested in the development and application of therapeutic approaches aimed to improve intestinal function and prevent or revert intestinal malignancies, including CRC and IBD.

How will you look to maximise the outputs of this work?

We will maximise the output and impact of our research through several means: 1- Collaboration with basic and clinician scientists.
Communication of research results in scientific meetings/seminars.

Dissemination of our work and its impact to society to the general public through public engagement events.

Publication of results through Fully Open access platforms/journals.

Species and numbers of animals expected to be used

- Mice: 5,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will firstly and primarily use the adult fruit fly, also known as *Drosophila melanogaster*, as a model system to perform large scale/unbiased experiments in live animals to assess how intestinal homeostasis, repair and cancer are regulated. However, translation of our work into live mammals will provide greater clinical relevance to our fruit fly data. Mice (*Mus musculus*) are the gold-standard laboratory animal for research on intestinal health and disease. Due to their close physiology and genetic conservation with humans, work in live mouse models has been instrumental for the discovery of processes regulating intestinal health and disease in humans. Therefore, mice represent the most appropriate live mammalian model of research for the translation of our fly work. Because our work is based on the study of the adult intestine and its interaction with surrounding tissues and organs, adult is the life stage we need to in our mouse research and using live animals rather than cultured cells is essential, as available cell culture systems fail to recapitulate the tissues and organs that surround the intestine in real life.

Typically, what will be done to an animal used in your project?

Animal breeding and maintenance.

Whole body irradiation to induce intestinal damage. Single procedure. Total duration of the experiment: 3 days. Or;

c-Feeding of drugs or chemicals to induce intestinal damage, inflammation or cancer initiation, the latter known as tumourigenesis. Intestinal damage: single procedure; Total duration of the experiment: 5-7 days. Inflammation or cancer initiation: at least 3-day procedure. Experiments last between 4 and 180 days.

Injection or feeding of drugs. Single or multiple occasions depending on the process and agent. Total duration of the experiment: 5-7 days to assess the effect on intestinal repair; between 4 and 180 days to assess the effect on cancer initiation.

Injections to: a) induce gene expression (1 to 3 times per experiment); b) incorporate a cell labelling agent (single procedure)

Injections or surgery for introduction of cancer cells. Done as a single procedure. Total duration of the experiment is 180 days.

What are the expected impacts and/or adverse effects for the animals during your project?

Injections might cause mild discomfort/pain. This only lasts for a few minutes, while the procedure is carried out. Pain relief is used where appropriate.
Our intestinal regeneration experiments lead to no visible signs of pain or physical deterioration.

Experiments leading to the generation of cancer can last a maximum of 180 days. Induction of intestinal inflammation and cancer initiation lead to weight loss, possible whole-body discomfort and lethargy.

These are physical signs we closely monitor for, are manifested towards the last few days of the experiment until the animals reach what is considered end point, as per the established project licence guidelines.

Surgery is performed under anaesthesia and appropriate analgesia to avoid pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All our experiments are of mild to moderate severity.

Intestinal regeneration experiments are of mild severity (80-100% of the animals), moderate severity (0- 20% of the animals).

Induction of chronic intestinal inflammation and tumourigenesis are of moderate severity (80-100% of the animals), mild severity (0-20% of the animals).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We firstly and primarily use the adult fruit fly (*Drosophila melanogaster*) in our research, to perform large scale/unbiased experiments in live animals to assess how intestinal equilibrium, repair and cancer are regulated. However, translation of our work into live mammals will provide greater clinical relevance to our fruit fly data. Mice (*Mus musculus*) are the gold-standard laboratory animal for research on intestinal health and disease. Due to their close physiology and genetic conservation with humans, work in live mouse models has been instrumental for the discovery of processes regulating intestinal health and disease. Therefore, mice represent the most appropriate live mammalian model of research for the translation of our fruit fly work.

Which non-animal alternatives did you consider for use in this project?

We firstly and primarily use the adult fruit fly (*Drosophila melanogaster*), a model system whose use does not require regulation by the Home Office and, therefore is not part of this application.

Intestinal tissue grown in the laboratory, commonly known as organoids, is often a good substitute to the use of live animals, which we will considered using to complement some of our fruit fly studies on the intestine. However, organoids are not suitable to study the interaction between the intestine and associated tissues or distant organs.

Why were they not suitable?

While laboratory-grown intestinal tissues are useful to assess processes restricted to intestinal cells themselves, they are less suitable to study how the intestine interacts with its surrounding environment. These types of studies are only possible when the whole organism is considered. Importantly, since the large majority of our work is based on the study of the adult intestine and its interaction with other tissues and organs, the use of live mice rather than laboratory-grown intestinal tissue is essential for the translation of our fly work into mammalian model systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The techniques we plan to perform using live mouse models are well established and have been previously done by us or collaborators with the highest expertise in mouse models of intestinal regeneration and cancer. Most of our experiments will involve single or double gene combination and, in general, 1 in 2 to 1 in 16 of the mice generated will be used in experiments. Tumourigenesis experiments require a minimum of 10-15 animals and regeneration experiments require a minimum of 6 animals per genotype/condition, to obtain statistical power.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We firstly and primarily use fruit flies— the core research model organism in our laboratory—to identify genes regulating intestinal homeostasis, regeneration and tumourigenesis. We then translate key findings from our fly work into mice. This greatly reduce the number of animals used. As part of our tumourigenesis studies we propose to do transplantations of intestinal cell lines and tissue into recipient mice. This approach will be useful to address interactions between intestinal tumours and surrounding tissues without the need to generate complex genetically modified mice, hence also reducing the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever possible, littermates will be used as controls for experiments or to set up new breedings that will provide a higher rate of desired animals. For example, in cases where we want to analyse the effect of gene ‘x’ on the intestine, animals with only one abnormal copy of gene ‘x’ will be used as controls and compared to those animals where the two copies of gene ‘x’ are abnormal. We will try to minimise excess mice by maintaining stock animals carrying as many multiple genetic alterations as possible.

Surplus material generated through ear identification markings will be used for genotyping

purposes. For any genotype and/or treatment where tissue samples already exist, we will use that to test our hypothesis (e.g., assessing gene/protein levels in the context of mouse intestinal regeneration or tumourigenesis) rather than generating new mice. In order to maximise the data obtained per animal, whenever possible, we will use longitudinal studies to assess phenotypes and, when culling an experimental animal, we will collect samples from as many tissues of potential interest as possible and process samples in multiple ways to account for different future experimental needs. For example, we will collect samples of the intestine as frozen tissue, fixed tissue and on RNA preserving solution for future experiments requiring protein extraction, tissue staining or gene expression assessment, respectively.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use adult mice to complement our research on the adult fruit fly *Drosophila melanogaster* intestine. The use of this animal model and age are important to assess the clinical/translational relevance of intestinal regeneration and cancer discoveries made in flies.

Genetic modifications in mice are done in a temporal and tissue specific fashion to avoid any unnecessary impact to organ function and associated health decline caused by broad/non-specific effects of genetic manipulations. In all cases, signs are monitored very carefully by highly expert staff familiar with every model used so suffering can be kept within or below moderate limits or animals are killed.
Why can’t you use animals that are less sentient?

Our research is focused on studying how the adult intestine interacts with its microenvironment and other organs in the body during the process of intestinal regeneration and also in malignant conditions, such as during tumourigenesis and intestinal inflammation. Therefore, we must do our research on live, adult mice, whose body functions similarly to that of humans and can therefore best recapitulate human intestinal health and disease. Having said that, we do most of our research in the less sentient model system, such as the fruit fly. Therefore, we use mice as a complement to our fly work rather than as the main model system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Examples of refinement measures include:

Study animals are weighed, and tumours measured at regular intervals to detect early clinical signs.

Mice will be inspected at least twice daily for the first 2 days following surgery. Wounds will be monitored closely for signs of local infection and mice will be monitored for signs of pain/discomfort. Aseptic techniques will be used during surgery and analgesia is given pre- and post- surgery as advised by the NVS.

We always refer to previous studies for adverse effects of therapeutic agents used. When a group is given a treatment for the first time, we initiate the study with a small number of animals (n=2-4) which is closely monitored before extending to a larger number. Where possible we use the least invasive method of drug administration.

We will receive training from experts within our institution to apply endoscope guided methods for the injection of cancer cells. This represents a new technique with reduced adverse effects when compared to laparoscopic approaches.

Welfare handling methods will be applied throughout the project. Researchers are trained for the handling of each animal model and signed off only when proficient in the clinical signs of the models.

Animals are housed in a dedicated facility proactive with environmental enrichment and receive anaesthesia and analgesia as appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

AWERBs and NC3Rs

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date with Home Office and NC3R guidance through the information published within their website but also by attending meetings and staff forums. We continually review our processes and take advice from the Named Veterinary Surgeons, Named Training and Competency Officer and Home Office Inspectors.

136. Studying cognitive function in animal models of brain disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Memory, Animal behaviour, Brain disorders, Schizophrenia, Negative symptoms

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify and assess the effects of drugs and other treatment interventions (e.g. exercise and environmental enrichment) in preventing or rescuing memory and other behavioural deficits in validated rat models for symptoms of brain disorders.

To determine how pharmacological agents and non-pharmacological treatments work. To develop new tests and new models for mimicking the symptoms of brain disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work to address the unmet clinical need of memory and behavioural dysfunction in a number of brain disorders. Currently there is no licensed medication for the treatment of memory problems and negative symptoms in schizophrenia. Also the medication available to treat the symptoms in other brain disorders do not work very well.

What outputs do you think you will see at the end of this project?

Scientific publications - developing new information around the causes of memory impairment and new targets for people working to develop better tests and treatments.

Testing new treatment plans in this project could lead to new medicines for clinical trials in people with brain disorders.

New tests and models for mimicking the symptoms of brain disorders.

Who or what will benefit from these outputs, and how?

The scientific community and general public, through furthering knowledge, and improving understanding. The pharmaceutical industry, and drug discovery groups, as we will assist in providing new knowledge around new treatment targets. We have close links with the pharmaceutical industry and will inform their drug discovery plans through these links and via publication of our findings.
Patients, carers and the NHS as ultimately this work will lead to new improved medicines for patients.

How will you look to maximise the outputs of this work?

We are committed to the publication of negative and positive results. We regularly present our findings at national and international conferences and publish in high ranking scientific journals. Further to this we have a strong background in public engagement, regularly presenting at SciBar events and taking part in events for the public. Some of the work carried out is in collaboration with the pharmaceutical industry and experts from academia. We routinely use tissue for other complementary studies (e.g. electrophysiological studies that utilise techniques to look at how brain regions talk to each other) and post-mortem analysis (looking at relevant brain markers) ensuring we are always developing our knowledge of the model and its relationship with human findings.

Species and numbers of animals expected to be used

- Rats: A maximum total of 9500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.
Much is already known about brain anatomy and chemistry, memory and how the brain works to control complex behaviours in adult rats. We have many years of experience in studying complex behaviour in rats, all our current tests are validated for rats and our

tissue analysis techniques and methods are validated using rats. Many of our tests e.g. for complex memory and mood are fully validated for adult rats and not for other rodents.

Typically, what will be done to an animal used in your project?

Rats may be given a drug treatment by injection, or an environmental treatment such as voluntary exercise in running wheels. This may be carried out before or after the administration of compounds that induce memory changes and changes to brain circuits, e.g., phencyclidine (PCP), a psychotomimetic drug that mimics some of the symptoms of schizophrenia in both rats and man, such as hyperactivity, issues with memory, decreased motivation and also not wanting to interact with others.

A small blood sample may be taken from the tail vein at specified times to measure drug levels and/or biomarkers.

Some rats may be mildly food deprived and trained in food motivated tasks, the effect of treatments as described above will be measured to determine their effects on cognition and other behaviours such as activity.

Alternatively, some groups of untreated rats will be assessed in tests of memory and behaviour using long delays between trials to measure forgetting, or task manipulation to make the task more difficult, resulting in an increased demand on the brain systems.

What are the expected impacts and/or adverse effects for the animals during your project?

The administration of phencyclidine (PCP) and other drugs may produce mild short-term pain from the injection site and also cause mild short-lived changes in behaviour such as an increase/decrease in activity.

Behavioural techniques are generally not stressful and can, in certain cases, be considered as enrichment.

Some animals will be placed on mild food restriction during testing and lose up to 10% of their free feeding bodyweight.

Some rats will have blood samples taken which may cause mild short-term stress from restraint and pain from the needle insertion.

At the end of the study, or as part of the experimental procedure rats will be killed humanely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected maximum severity for the three protocols in this license is moderate. Approximately 80% of the rats used will reach moderate severity and 20% will reach mild severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to measure the control of the brain on behaviour in cell systems. Much is already known about memory and how the brain controls complex behaviours in rats, so studies using live animals are essential to obtain a greater understanding of normal and abnormal states and to test the effectiveness of new treatments. Currently, this work must involve the use of whole animals as studying the effects on behaviour is a central feature of the project and as to date, there is no suitable alternative to using rodents for these types of studies.

Which non-animal alternatives did you consider for use in this project?

Where possible we perform studies using in-vitro cell models to aid our understanding or how cells in the brain work.

We also undertake a number of studies using human post-mortem brain tissue to help work out similarities and differences with our animal studies.

However, studying behaviour and how memory, mood and social impairment is related to brain disorders is extremely complex and cannot be fully studied using in-vitro preparations or computational approaches.

This work therefore must require the use of animals as behaviour and testing new treatments is the most important part of the project.

We only test new compounds that have been carefully selected using in-vitro screens to ensure only the most promising drugs go into our animals.

Furthermore, we first conduct pilot studies with each new compound, starting at the lowest dose to check for any potential side effects prior to larger studies.

Why were they not suitable?

Currently there is no suitable alternative to the use of animals for behavioural research.

It is necessary to use animals to model the complex memory and social deficits seen in brain disorders such as schizophrenia.

In-vitro preparations or computational tests cannot be used as they lack the required complexity due to insufficient biological data.

We will carry out in-depth analysis on tissue samples from animals as we are searching for biological and behavioural changes induced by our model and treatments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have 20 years' experience in developing and refining this model and behavioural tests so that the fewest numbers of animals are used. Estimations are based on the numbers of rats used in studies in previous years. In 2020 we increase the estimated number of rats used as study numbers had risen due to demand from pharmaceutical company clients.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken advice from an external, approved statistical expert, who has assessed our power analysis calculations to ensure that we have minimum number of animals for the maximum statistical power.

We have lots of experience of analysis of these datasets from our previous work and in consultation with other external statistical experts and colleagues within the Pharmaceutical Industry and at this University. We have a member of the team who works with the NC3Rs Experimental Design Assistant to help us to design robust animal experiments.

Where appropriate we minimise the overall numbers of animals used by re-using the same animal in different behavioural tests, and where appropriate, testing more than one drug in the same animal.
Numbers will be further reduced by using repeated measures designs where possible. Re-using the same animals is only carried out following veterinary examinations "fit to remain" immediately following a treatment/procedure and a second veterinary examination prior to re-use "fit to be re-used".

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use the literature and pilot studies in small numbers of animals to guide us when setting up new behavioural tests, ensure animal stress is kept to a minimum, ensure animals are used to the testing arenas before studies begin and we also provide our researchers with excellent training.

We will monitor the reliability of our studies closely and upon generation of new data we can alter group sizes as appropriate and in consultation with statistical experts.

We are working closely with colleagues to develop behavioural tests that improve data yield to reduce animal numbers further by minimising the potential negative effect of animal handling in our studies.

We have a number of behavioural tests that require minimum training so where appropriate we minimise the overall numbers of animals used by re-using the same animal in different behavioural tests, and where appropriate testing more than one drug in the same animals.

We routinely collect blood and brain post-mortem tissue and share tissue from our animals with other research groups, which optimises the numbers of animals used and will maximise data output from every experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal Models.

We use rats as we have detailed knowledge of their behaviour and brain organisation, which shows remarkable similarity to humans. Our rat models of human diseases show symptoms such as memory loss and subtle brain changes that are very similar to human patients. All our current tests are fully validated in rats and our tissue analysis systems are validated using rat brain.

We will use a sub-chronic (7 day) dosing schedule of psychotomimetics (e.g. phencyclidine) to produce long-lasting behavioural deficits in rats, which can only be seen when their memory and social behaviour is challenged, the effects are very specific to memory deficits with low impact to the welfare of the animals. We also use longer time-delays between experimental trials in some of our tests which allows the animals to naturally forget what they had previously learnt.

Methods and monitoring.

Welfare is very important for successful experiments and we continually aim to refine our techniques and practices. Our behavioural tests, which we often use to longitudinally assess our rats in a number of behavioural tasks, are not stressful to the animals, and could be considered as enrichment. We aim where possible to refine animal welfare for our laboratory rats.

In our recent experiments we started to investigate the use of playpens for cages of animals as a method of improving welfare in animals used in long term behavioural studies. These studies are ongoing and in collaboration with colleagues in academia. Making sure the playpen system works effectively could lead to a method that can be incorporated in to other animal facilities housing rodents and provide additional environmental and social enrichment.

We use a validated monitoring system to assess animals for adverse effects for any new treatment, which greatly reduces the number of animals that could experience a potential adverse effect. For animals that do receive a new treatment in this way, careful continual monitoring ensures termination is rapid if an endpoint is reached. This procedure ensures rapid decision making and actions that minimise any potential suffering to that animal. Before we test a new drug for a pharmaceutical company in one of our behavioural tasks, information is shared to prove that the compound has previously been checked for safety and the dose ranges we aim to use do not produce adverse side effects, thus ensuring that adverse effects in our studies are further minimised.

None of the models that we will use are expected to experience severe side effects; however, if seen in any animal it will be humanely killed.

Why can't you use animals that are less sentient?

An adult rat is superior for our studies compared to a less sentient species or a more immature life stage because the physiological systems involved in learning and memory have been so extensively studied and widely published in this adult animal.

We are unable to measure complex behaviour patterns in immature life stages, less sentient species or in a terminally anaesthetised animal. We have selected adult rats as their social structure enables detailed analysis of social behaviour. Furthermore, this work must entail the use of the whole animal as behaviour is a central feature of the project. If any relevant, non-animal alternatives become available during the course of this project, we will aim to implement them in our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have started to study the effects of time spent in playpens on rat behaviour with the aim of possibly introducing this to our experimental animals and highlighting the effects of this enrichment to other researchers and colleagues. We have also conducted a pilot study to assess the effects of playful handling of rats, which shares some similarities to the rat tickling technique, on behavioural outputs.
Our ongoing studies are comparing the positive effects of exercise on memory in the form of voluntary wheel running in rats.

Refinements include habituating rats to new behavioural test arenas in home cage groups to reduce any potential stress when habituated singly.

Animals undergoing dosing procedures are removed from the main holding room into a separate room to prevent the induction of stress to stock animals and other experimental animals due to vocalisations.

In our longer-term studies such as reversal learning, rats are placed onto soft paper bedding instead of standard wood-based bedding to prevent the risk of developing hock sores.

Further refinements include reducing the maximum total number of injections of pharmacological compounds from 28 to 21 days and also reduced the frequency of injections over the 21 day period to once per day instead of twice per day (after day 7). Recently we employed an expert in rodent handling and procedures to provide a training/refresher course in animal restraint and oral gavage dosing for our research

technicians. This expert training ensures improved handling, reduced restraint and improved dosing techniques resulting in reduced stress to the animals and improved animal welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We consult with other leaders in the field of behavioural research to implement any improvements in animal welfare and care. We have access to the extensive library of NC3Rs resources which includes guidelines, practical information, links to themed hubs and publications, other online resources, and video training materials. We routinely attend appropriate events organised by the NC3Rs and our local animal facility. We follow the PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) and the ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments) for guidance on how to plan and report animal experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We attend, and encourage other members of the team to register for the regular 3Rs symposiums and webinars organised by the NC3Rs. We have taken advice from our local NC3Rs manager, on implementing environmental enrichment using play pens and we are currently collaborating with researchers at others Universities, with the aim to apply for an NC3Rs project grant to study the effects of play pen enrichment on rat welfare and behaviour.

137. The physiological roles of phosphatidylinositol 3-kinases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cell Signalling Pathways, Genetically Engineered Mice, Translational, Disease, Therapeutics

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to investigate the roles of phosphoinositide 3-kinases (PI3Ks), a family of intracellular signalling molecules that transmit information from the outside of the cell to within the cell. This work has led to approved drugs and continues to inform ongoing drug development.

Our research focuses on diseases such as cancer and immune and metabolic dysregulation (where PI3Ks are not functioning normally) with the aim to develop therapeutics to correct them. We are also using approaches to activate PI3K for therapeutic benefit, such as in cardioprotection or wound healing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The experiments performed under this licence will not only contribute to the understanding of how signalling pathways operate in cells, and when disrupted, cause disease, but also allows us to develop therapeutics to alleviate these diseases. So far, we have found that disrupting the pathways controlled by the PI3K gene family (which act by transmitting signals from the outside to the inside of the cell) may result in, or protect against, diseases of metabolism, immunology and cancer. By carefully studying these disorders we can develop or fine-tune the design of therapeutics to mimic the genetic inactivation or genetic activation, whichever is best, to correct these disorders.

As a result of our work and those of collaborators, drugs have been developed that have now been approved or in clinical trials and are helping to treat people with cancer and immune dysfunction. We hope to develop more therapeutics through continuation of this work under this licence.

Other than treating cancer when it has developed, it would also be desirable to prevent cancer from arising in the first place. Given that medicines that block PI3K have now become available, we are now also using these drugs to test if they could be used to prevent cancer from developing. We hereby use a mouse model that faithfully mimics a human cancer predisposition syndrome driven by a PI3K- activating mutation in their genes. We postulate that the PI3K inhibitors will counterbalance the PI3K- activating mutation, and thereby prevent cancer from developing.

What outputs do you think you will see at the end of this project?

We aim to produce the following outputs whilst working under this project: -

Increased understanding of PI3K pathways in disease, including disorders of cancer, immunology, metabolism and development.

Translate this understanding into novel therapeutics to treat or prevent these diseases.

Publish our findings in peer reviewed journals and contribute to the body of scientific insight into the basic science of PI3K and its translational potential.

Use the knowledge gained to train a new generation of scientists.

Who or what will benefit from these outputs, and how?

The impact of the outputs in the short term will be the increased understanding of the role of PI3K molecules in cellular signalling pathways, in disease, and its translation into novel therapeutics to treat these disorders. This will be disseminated to the scientific community through collaborations, peer- reviewed publications and talks at conferences. The long-term benefit would be clinical trials of the novel therapeutics in humans and ultimately alleviation of the disorders mentioned.

How will you look to maximise the outputs of this work?
The studies undertaken under this project licence are often collaborations with other research groups, across the UK, and Worldwide. We have constructed over a dozen novel genetically engineered mice over the last 20 years that have been shipped to many Worldwide Academic and Pharmaceutical Institutions and have now all been deposited in

publicly accessible repositories. The project licence holder and his fellows continue strong ties with many of these collaborators, some of which were previous postdocs in the licence-holder's laboratory, continuing the work that they started during their training as independent scientists and passing on the new knowledge gained to a new generation of scientists. As the field of collaborations is large, approaches to the work can be quickly and easily refined, negating previous unsuccessful approaches, so that work can be channelled down more fruitful paths.

Once we are sure that the work has scientific validity, the data will be peer-reviewed by established scientists in the field, then disseminated through publication in scientific journals, talks at conferences, through general communication with collaborators and ultimately through the press to the public at large. In the case of important findings, we effectively engage with relevant Press Offices who provide effective communication of our findings to the wider world in print and on-line.

Species and numbers of animals expected to be used

- Mice: 24,000
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used in this study because they resemble humans in many ways, anatomically, physiologically and genetically. Unlike lower genetic model organisms such as flies and worms, mice share all eight PI3K genes with humans which when mutated can cause or protect against disorders such as cancer or inflammation. The administration of therapeutics to mice can be done in nearly identical ways that would be done in humans, therefore providing good insight and the groundwork for clinical trials. We are increasingly resorting to administration of drugs in the food, effectively mimicking the administration of an oral pill, with drug exposure over at least 12hrs (given that the mice do not eat when the lights are on).

Except for the creation and breeding of genetically altered mice, adult mice will be used for the majority of protocols where ageing, metabolism, cancer and the immune system are being investigated. This follows from the fact that these diseases usually present themselves in humans in adulthood. The exceptions being (1) overgrowth syndrome, where clinical signs are present from conception and therefore all life stages will be investigated; (2) mice in which genetic alteration leads to embryonic lethality. Investigating the biology of these embryos has been very powerful to uncover new biological functions of PI3Ks.

Typically, what will be done to an animal used in your project?

Within this project licence, the following procedures will be used in order to achieve our aims: -

In the case of the creation, breeding and maintenance of genetically altered mice, mice will either be sought from commercial suppliers or created ourselves using standard well-established procedures. Female mice will be superovulated by intraperitoneal injection of hormones such that they generate many hundreds of embryos that can be removed from the uterus by a Schedule 1 cull. These embryos will then be manipulated in vitro and genetically altered. A recipient female mouse, in parallel will be made pseudo-pregnant by mating with a sterile male mouse that has been made infertile by surgical means. The altered embryos can then be engrafted surgically into this female, where the embryos can develop to full-term, be born, weaned and maintained for further breeding or used for experiments described below. These embryos can also be archived by cryopreservation such that, if a time comes when the strain is not required, live mice will no longer be needed for breeding and maintenance.

Mice that have inducible genes that can be switched on or off, will be given inducers such as tamoxifen, either by intraperitoneal injection, or administration by gavage that enables gene expression control. Typically, this will be done once, up to several times, over consecutive days, before mice are engaged in the relevant experiment.

Novel genetically altered mice will be subjected to broad phenotypic characterisation by a dedicated mouse pathologist in the fields of immunology, cancer, ageing, metabolism and development to determine whether gene inactivation of the PI3K pathway can cause or alleviate disease and if therapeutics, based on genetic alteration, can correct any problems.

Therapeutic substances will typically be administered in the food or water for the entire life of the mice but may also be administered daily for shorter periods, for up to a few months, through routes such as oral gavage (forced feeding by a tube inserted into the stomach, or injection).

During ageing studies, mice, including those that develop cancer, will be kept for their entire lifespan; that is, up until the humane endpoint - for example, maximum tumour size or the limit of acceptable deterioration of health through observable body scoring. Therapeutics may be given, mixed in with their usual daily food and at specific time points mice will be culled by schedule 1 or non- recovery anaesthesia so that blood and tissue samples can be collected for examination. These can then be processed and analysed to determine whether genetic alteration or administered therapeutics have had any effect on the progression of the disease. Blood samples may also be taken periodically from the tail vein of these mice for pharmacokinetic studies, and also following insulin or glucose intraperitoneal injections to evaluate if these strains develop any metabolic defects. Measurements of blood parameters may be done up to 4 times during the lifespan of a mouse.

One novel therapeutic strategy that we are developing is obtaining bone marrow cells from normal mice and injecting them into irradiated mice that are genetically predisposed to develop cancer to see if this helps adjust the immune system to fight cancer progression. After engraftment of normal bone marrow cells, mice will be kept for their entire lifespan and investigated as above in ageing studies.

Cancer predisposition: we are using a mouse model that is predisposed to cancer, as the result of partial inactivation of a gene that downregulates PI3K activity. This mouse model faithfully mimics a human cancer predisposition syndrome called PHTS (PTEN Hamartoma Tumour Syndrome). Given that PI3K inhibitors have now become available, we are using these drugs to explore if they can prevent cancer in this mouse model.

Immune-deficient mice may also be injected with cancer cells, on one or two occasions, for example subcutaneously (under the skin), or by intraperitoneal injection (into the abdominal cavity) and again treated with therapeutics, usually in the food. These studies generally last 2 to 3 months and allow us to study the treatment and progression of human cancers and the role of the immune system in cancer. There now exists a fair number of immune-deficient mice where various compartments of the immune system have been removed. By comparing the growth of tumours in these different mice and the added effect of therapeutics in the food we can evaluate the effect of each immune compartment in isolation and the effect of therapeutics on these immune cells. That is, can we manipulate and enhance certain aspects of the immune system to better control or prevent tumour growth.

Experiments with subcutaneous tumours may also consist of dual therapeutic regimes, such as the use of radiation and therapeutic substances administered through the food or by daily gavage for several weeks. Such therapeutic regimes may not only be additive but may have a synergistic and therefore beneficial effect on tumour progression.

Cell signalling pathways are known to be involved in the way cells migrate and divide, a hallmark that is abnormal in cancer cells that may help them metastasise (migrate) to other organs of the body. It is known that some cancer cells may operate in a similar fashion to cells involved in wound healing, helping them not only to propagate through the primary tissue sites, but to move in and out of blood vessels such that they can spread to other organs. One method that we can use to investigate this is to cause up to two small skin wounds in a mouse and see how the gene inactivation or therapeutics alters the progression of the healing process over several days to a few weeks. Another method that can be utilised is ischemia reperfusion (tissue damage caused when blood supply returns to tissue after a period of absence or lack of oxygen), where the femoral artery, the main blood vessel in the leg is ligated, causing injury to the surrounding tissue by lack of nutrient and oxygen delivery. Again, mice will be observed for several days to a few weeks to assess how the injury resolves back to normal tissue.

This method also allows an insight into the roles of oxygen deprivation and blood vessels in the progression of wound healing and cancer metastasis. In the case of metastatic mouse cancer models, such as those of the breast, subcutaneous tumours may be surgically removed and mice kept for several months to assess the effects of gene inactivation or therapeutics on the degree of metastasis. This allows us to develop therapeutics for relapses in breast cancer, where even though primary breast tumours may have been successfully treated or removed, the patient later goes on to develop lung metastasis several months later.

As we know that genetic or therapeutic alteration of the PI3K pathway can enhance the immune system to treat the progression of cancer, we are interested in exploring if this immune manipulation could also be beneficial in treating infections or allergies where the immune response is required or behaving abnormally. During these studies, for example, mice will be injected with live or attenuated pathogens and their immune response measured by taking blood samples and tissues at specific time points. Therapeutics may also be administered typically in food or water, but may also be administered by gavage, or intraperitoneal injection. Such experiments would not usually last more than a week or two.

Colitis, a disease of the intestines, caused by abnormal immune function leading to chronic inflammation of the colon can in some instances lead to colon cancer. However, in

some strains of PI3K mutant mice where colitis is observed, progression to cancer has not been observed. It would be interesting to investigate why this is so by 'pushing the system' such that colon cancer does occur. To do this, mice will be administered with a carcinogen by intraperitoneal injection and colitis induced with a substance in the drinking water. Mice will be kept for several weeks, and blood and tissues analysed after culling by non-recovery anaesthesia or a Schedule 1 method.

PI3K mice do not develop diabetes, even though abnormal PI3K signalling alters the way glucose is metabolised. In order to investigate this further we will use a model of diabetes that is induced using a chemical called streptozotocin that is added to the drinking water, food, or administered by intraperitoneal injection. Mice will be kept for several weeks to further assess if the PI3K pathway resists the progression to diabetes.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts and/or adverse effects of these studies on animals would include: -

Weight loss - gradual over several weeks or more quickly over a few days. Not more than 15% deviation from the start of experiment.

Deterioration in general health caused by progression of disease such as inflammation or cancer as assessed by body scoring. For example, staring coat, laboured breathing and hunching that would last for no longer than 24hrs.

Tumours, inflammation or immunological agents may cause long lasting mild pain over several days, or moderate pain up to 24hrs.

Mice may be predisposed to, or subjected to developmental, metabolic, immunological and disorders that lead to cancer. These would develop over the course of the lifetime of the animals, most remaining subclinical such that the animal experiences no pain. However, some genetic models may develop mild distress slowly over a few weeks and others moderate distress up to 24hrs.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The creation, breeding, and maintenance of genetically engineered PI3K mice, should generally cause no more than sub-threshold severity in the case of mice that produce phenotypes (the observable physical properties of an organism) that have no clinical manifestation. In the case where phenotypes show clinical signs, they are generally mild and in the case of harmful mutants where tumours arise, mice will be culled before the onset of clinical signs such that breeding mice will not experience severity greater than mild or in a rare case, moderate.

In the cases where surgery is required in the creation of genetically engineered strains, or more the implantation or removal of tumours, mice will experience moderate signs of distress.

In the case where mice are injected with inflammatory substances, injected with cancer cells or develop spontaneous phenotypes with clinical manifestation, then mice will suffer no more than mild signs of distress if the scientific endpoint is reached before the humane endpoint. We should be able to generate and collect must of our data under a mild severity. However, if further data is required, then mice will be allowed to reach a humane endpoint where they will experience moderate signs of distress for no more than a day or two. This will also be the case for metabolic and developmental studies.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The reasons why we require live animals for our studies are discussed below.

Mammals such as mice and humans have 8 distinct PI3K genes, which determine the functioning of the PI3K signalling molecules, belonging to 3 separate families. Other widely used model organisms such as Drosophila and C.elegans only have a small subset of these genes (for example flies have 3 PI3K genes) and are therefore not suitable as model systems to study human biology. The complex disease processes that we investigate also cannot be modelled appropriately in these lower organisms.

Genes that regulate cancer, the immune system and metabolism are generally pleiotropic (have more than one function), often interact with many other genes and therefore may be relevant for many organs and biological functions. Therefore, in order to study a disease caused by a genetic alteration, the whole complexity of an organism is required. In addition, the systems that we would like to study such as immunology and development require thousands of genes.

In order to study tumour formation and especially metastasis, the whole animal is required. Specific cancers affect specific organs and often metastasize to other organs in unpredictable ways. Therefore, animals are required in order to dissect the roles of PI3K isoforms in specific cancers.

Therapy using inhibitors often give promising results in cell-based assays, only to fail in vivo. This is because the pharmacokinetics (the time course of drug absorption, distribution, metabolism, and excretion that determines its potency) is often dependent on route of administration, metabolism and many other factors that do not exist in cell culture. Therefore, live animals are required to make an accurate assessment of pharmacokinetics of the combined inhibitors, effect on tumours, or their immunosuppressive effects.

During the growth of tumours, a process called angiogenesis allows the formation of blood vessels from pre-existing vessels. This, for example can occur during tumour formation or during development. Both systems require the whole animal.

Rescuing mutant phenotypes and whole animal gene expression, such that the animal reverts back to its normal state, also requires the whole animal; there are no in vitro substitutes available.

When it comes to the study of metabolic regulation, many organs, such as fat, muscle, brain, pancreas often act together in relation to environmental factors. These factors also affect lifespan. Therefore, live animals are required in order to study metabolism and lifespan.

Which non-animal alternatives did you consider for use in this project?

In vitro studies using cell-based assays will be used initially to determine whether PI3K signalling pathways are operating in the organs or cells under study and whether therapeutics or modulators affect these pathways. If we have reasonable evidence to suggest this is the case, then in vivo models will then be carried out.

We are in the process of developing organoids, a mass of tissues and cells that resemble an organ - a miniature organ that you can propagate in vitro. These may negate some of the arguments that a whole mouse is required for some studies. For example, we are developing a system to evaluate cell signalling in small and large intestinal organoids, which will also involve inducing inflammation and testing of inhibitors.

Why were they not suitable?

Cell-based assays often give a good indication of how a specific cell responds to a specific inhibitor. However, inhibitors often perturb other systems or organs other than its target, and in order to evaluate these effects the whole animal is required. Also, the whole animal is required to assess how inhibitors affect for example cancer metastasis. Immunology, cancer, metabolism and related diseases are difficult to replicate in laboratory-based models such as tissue culture and organoids. This is because these diseases are the result of complex interactions between different tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice we would like to use for the experiments would primarily have been based on previous experiments or those performed in the literature or by collaborators. Numbers for experiments have been advised by a statistician who we communicate with regarding experimental design of these studies. In this way we are confident to produce meaningful scientific data with the least number of mice possible.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A specific mutant mouse will only be created if no other such mouse line exists. This will prevent unnecessary duplication of work and mice.

Mice will be bred on a need-for-experiments only. In other cases, the minimum number of mice will be kept in order to maintain the colony. In some cases, where a particular strain of mouse is not needed for long periods of time, mouse embryos will be kept as frozen stocks thus keeping mouse numbers to a minimum. These frozen stocks are also used for shipments to collaborators.

To prevent variation in data, technicians skilled in the techniques required will be used, along with high quality reagents and cells. For experiments, age and sex-matched animals will be used to discount bias from aging and gender. Inbred strains will also be used to discount the effect of genetic variation as would be the case in outbred strains. To further reduce variability and unwanted bias occurring in the data obtained from the experiment, mice from each cage will be randomised such that they have an equal chance of receiving a given treatment; each treatment being administered blindly. Data will be collected from all mice in an identical way.

Expression of all genes and therapeutics will first be tested in vitro to assess their suitability for in vivo work.

The NC3R's ARRIVE guidelines and EDA (Experimental Design Assistant) will be consulted before any experiment is designed or carried out.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
We have extensive databases of our mouse lines and record every breeder set up, and all pups born. We also have a good idea of the average number of pups born per strain and genotype ratios. This prevents overbreeding when maintaining lines and helps us to breed the correct number of mice for experiments from parents with the correct genotypes.

After the creation of a new mutant strain of mouse, mice are analysed by histology of most tissues by an expert mouse histopathologist, blood analysis and biochemical parameters, as a way to find phenotypes in mutant mice. It allows us to gauge the degree of disease in a particular mutant mouse and allows us to plan what experimental protocols, if any, are required to evaluate the mechanism of disease. It gives us an idea what group sizes are required for live experiments; for example, if the type of disease is highly variable or not fully penetrant in all mutants, then large group sizes will be required and vice versa.

One example of an experimental approach would be to observe tumour growth in mutant PI3K mice and their wild-type littermate controls. We can then determine, by comparing to wild-type controls whether PI3K isoforms ameliorate or exacerbate tumour formation or metastasis. Initially, pilot studies containing small numbers of mice, (not more than 5 per group) will be carried out to assess the aggressiveness of each tumour type with each isoform and the time taken to reach the humane endpoint of the study and whether sufficient scientific data has been collected within this time frame. This will be done in accordance with previous work and data that is accessible in the scientific literature or from collaborators. From the data produced in the pilot studies we can then design larger scale experiments if necessary and estimate group sizes based on statistical tests. If any PI3K isoform ameliorates tumour formation or prevents metastasis then we can then precede to therapeutic studies. When it comes to dosing animals with therapeutic compounds, we often use factorial designs; that is, often, more than one drug is tested, using one control group for all therapies, and often one therapeutic being a positive control.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be performing experiments that model animal diseases such as cancer, those that affect metabolism, or the immune system. These diseases are often interlinked and may also affect how development may occur.

The models we chose will use only minor technique's that will cause brief transient distress such as injections or oral gavaging. In the case of administering therapeutic agents such as PI3K inhibitors or activators, the drug will generally be given as part of their diet, thus avoiding the need for injections or gavaging.

Tumour models will generally be restricted to non-metastatic models where the tumour remains localised in one place, is unlikely to invade and harm another organ and will not be allowed to grow beyond 1.4cm^2 in diameter and therefore unlikely to affect the animal's ability to eat or drink. Spontaneous models will often be used, so avoiding techniques such as injecting cells to induce tumours.

For metabolic and ageing studies, mice will be restricted to the number of procedures that any mouse can receive in a lifetime such that a moderate degree of severity is not breached.

We will be performing experiments that model animal diseases such as cancer, those that affect metabolism, or the immune system. These organ systems are interlinked and together affect the development of disease or therapy response.

The models we chose will use only minor techniques that will cause brief transient distress such as injections or oral gavaging. In the case of administering therapeutic agents such as PI3K inhibitors or activators, the drug will generally be given as part of their diet, thus avoiding the need for injections or gavaging.

For immunological studies that require the administration of pathogenic agents, this will generally be restricted to using only attenuated forms of pathogenic agents or their analogs such that much milder infections are induced that are unlikely to be severe or fatal. In addition, these studies will generally be completed within several days.

Why can’t you use animals that are less sentient?

Mammals such as mice and humans have 8 distinct PI3K genes, belonging to 3 separate families. Other widely used model organisms such as Drosophila and C.elegans only have a small subset of these genes (for example flies have 3 PI3K genes) and are therefore not

suitable to use as model systems to study human biology. The complex disease processes that we investigate can also not be modelled appropriately in these lower organisms.

In order to study cancer, metabolism and immunology we require to model diseases in an organism that is very similar to man such as mice which also have the lowest neurophysiological sensitivity of vertebrates.

The mouse allows processes such as metastasis, the connection between the immune system, metabolism and cancer to be studied more accurately which wouldn't be achievable in less sentient organisms. Adult mice will generally be required due to the timescale of progression of diseases such as cancer and the maturation of the immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements that are included for the protocols in this project licence are described in the following paragraphs.

Novel mouse strains will be observed daily to monitor the onset of any phenotype; weight, piloerection, abnormal breathing rate, skin turgor, behaviour, eye discharge and mobility will be checked as indicators of suffering. Any deviations from the norm, including the timing of the onset of suffering, will be monitored and used to predict future occurrences. If sufficient scientific data is obtained before the humane end point of the experiment is reached, mice will be culled to prevent further suffering.

In addition, blood and tissue will be collected from culled mice and analysed to determine phenotypes. Additional monitoring can then be implemented as better understanding of the phenotype and the timing of the humane endpoint is reached. Mice will be observed, and a body score taken in accordance with Appendix 5 or 6, at least twice weekly, at around 3 days apart, or with greater frequency as the humane endpoints approach. This will enable the experimenter to assess the level of pain and distress that the animal is experiencing in addition to other welfare indicators specific to each protocol and to refine these if necessary.

During cancer studies, animals will be observed for signs of tumour growth for their entire lifespan by blood sampling and calliper measurements of external tumours. For animals with internal tumours, pilot experiments will be carried out with routine necropsies taken to determine the growth rate of the tumours and its effect on the welfare of the animals. This will enable the timing of scientific and humane endpoints to be determined.

“Guidelines for the Welfare and Use of Animals in Cancer Research,” by Professor Paul Workman et al, under the auspices of the UK's National Cancer Research Institute (NCRI) will be followed.

Therapeutics will usually be given to mice in food or water thus negating the need for handling, repeated injections or gavaging and undue stress to the animals resulting from these invasive procedures.

When mice are given therapeutic substances, such as PI3K inhibitors, that have been added to food or water, food or water intake will be monitored, and mouse weights recorded daily to ensure that mice are drinking and eating normally. If mice lose up to 15% bodyweight or show signs of dehydration as described above mice will be culled.

Compounds given to drinking water may be sweetened with 1% sucrose to improve palatability.

Initially, any topical therapeutic compound will be scrutinised for its suitability to be skin permeable or dissolved in an ointment that would facilitate its absorption into the skin. To minimise this risk, the dose of therapeutics used will be based on what has been effective by other routes of administration, from our own data or those of collaborators without causing complications. The ointment used containing the therapeutic will be based on those known not to cause any adverse effects in humans and animals. If any soreness is noted, for example flaky skin or redness, or if there are any other adverse effects, the application will be discontinued and advice from the NVS sought.

Suitable administered volumes and doses of therapeutics, immunogenic substances or cells will be determined by referring to our own, collaborators and published data. If suitable doses and volumes are not known, then pilot studies will be initially carried out. Pilot studies will consist of injecting one animal with a low dose and increasing the dose stepwise in other animals, until the desired scientific endpoint is reached, or before a moderate degree of suffering is reached, whichever is lowest – this will dictate the maximum dose for the experiment. The effects of each dose will be evaluated before adopting a stepwise approach to higher doses, such that the humane endpoints are not breached.

In all protocols, animals will be weighed and body-scored at least twice weekly, at around 3 days apart, and with increased frequency as the endpoints approach.

Other than in terminally anaesthetised animals, dosing and sampling procedures will be undertaken by a person competent in the relevant technique, in accordance with good practice using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm and are the minimum compatible with the scientific objectives.
The latest procedures that cause the least suffering to mice will be used to replace older, outdated methods. Unless otherwise stated in the protocol, all substances will be administered in accordance with “Refining procedures for the administration of substances by Morton et al Laboratory Animals 2001 35 1-41,” in accordance with Appendix 4.

For protocols that require surgery, procedures will be carried out aseptically and post-operative analgesia will be given after surgical procedures to manage anypain.

If protocols require anaesthesia, this will involve agents and methods suitable for the species as advised by the NVS. Depending on the anaesthetic regime used, animals will be ambulatory within a few minutes to 1hr of the end of anaesthesia. Supplemental heat and analgesia will be provided as advised by the NVS during surgery and recovery. Any animal which has not resumed normal mobility, eating and drinking by the end of the working day of surgery will be killed.

Where the immune status of the animals or a procedure such as irradiation might compromise health, they will be held in a barrier environment and/or given antibiotics to minimise the risk of illness due to microorganisms present naturally in the environment.

If a procedure, such as those that induce diabetes, is likely to cause dehydration over a short period of time, gel formulations, such as hydrogel, may be given to mice to help keep them fully hydrated. These mice will be given wet food or food gels.

For diabetic mice, due to the possibility of increased drinking and urination, cages or bedding will be changed twice weekly, at around 3 days apart, or when excessive soiling has occurred. Mice may also be supplied with 10% sucrose in the drinking water overnight in case hypoglycaemia occurs.

Several breeding and experimental scenarios may arise where mice find themselves individually housed. For example, male mice born without brothers in a litter that are required for breeding or experiments at a later date. Also, during experiments mice are often culled at different times, depending on when the scientific or humane endpoints are met for each mouse, often leaving mice individually housed.

In order to minimise this from occurring, weaning will be managed to avoid singly housed animals wherever possible and mice that are of no scientific interest or are not required for breeding will be culled. In cases where singly housed males are to be kept for experimental or breeding purposes, post- reproductive females will be sought as cage companions.

Where the immune status of the animals might compromise health, they will be held in a barrier environment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best guidance practice published on websites such as NC3Rs and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?
We will ensure to use the most refined methodology by: -

Literature searches.

Checking websites such as NC3Rs and ARRIVE guidelines.

Frequent communication with collaborators in Industry and Academia who have carried out similar work.

Checking with the NVS, NACWO and BSU staff before any procedure is carried so that we can implement these techniques effectively.

138. The role of redox signalling in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Protein tyrosine phosphatase Signalling, Cancer, Redox biology, Biosensor, Immunology

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to increase our understanding of the molecular signals that allow the cells in our bodies to talk to each other and work together, that when deregulated can cause or worsen diseases such as cancer, or promote damage associated with limiting healthspan.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A better understanding the biological mechanisms underpinning human health and the causes of disease will allow us to improve the way we treat disease in the future. It will reveal new strategies or therapies with as few undesirable side-effects as possible.

What outputs do you think you will see at the end of this project?

The expected benefit from this project is that we will gain a better understanding of the complex molecular and cellular mechanisms that underpin a healthy lifespan that - when deregulated - can cause or exacerbate complex diseases such as immuno-deficiencies and cancer, as well as age- related decline. Our findings will be published in open-access

journals. In the long term, the knowledge generated from this project might contribute to the development of more effective drugs.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries are the scientific community and the interested general public who will gain new understanding from our open access publications, presentations and conferences and public engagement activities. In the longer term, the pharmaceutical industry may benefit by exploiting the knowledge generated to develop new therapies. Eventually, society as a whole may benefit from the improved health brought by such interventions.

How will you look to maximise the outputs of this work?

We will publish our findings in open-access journals accessible to all and disseminate our results at international scientific conferences. We will collaborate extensively with other laboratories around the world to maximise the impact of our work. We will make our research accessible to the general public, with the help of our public engagement team.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice, as they are the best understood and most widely used mammalian laboratory animal, with excellent means for generating and interpreting the effects of genetic modifications. Most of the mice will be used at young adult life stage, to study the development of the immune system or tumour development.

Typically, what will be done to an animal used in your project?

The majority of mice will be used for the generation and maintenance of genetically modified strains or for the collection of cells and tissues for analysis after the animals are humanely killed. Some mice will be injected with agents to induce superovulation. Some mice will be given single injections of tumour cells resulting in tumours under their skin. To modify gene expression some animals will be administered gene inducing agents such as doxycycline, either by injection or in their drinking water. The tumours will be monitored for size and mice humanely killed once the tumours reach a pre- determined size. Some animals with tumours may be given pharmacological or therapeutic agents to affect tumour growth. Tumour studies typically last 2-5 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?
The main adverse effect could be a mild and transient discomfort, for example following injection of tumour cells or following surgery to transfer embryos. Tumour bearing mice should not experience clinical signs other than tumour growth under the skin. Should a

palpable tumour not grow within 4 weeks, mice will be killed and excluded from the study. Repeated dosing, orally or by injection, might rarley lead to stress (due to increased handling) or irritation at the injection site. This might be expected to impact <10 mice overall. We will prioritise the least invasive methods. Adverse effects, such as pain, can affect animals undergoing surgery (e.g. embryo transfer/vasectomy), however, analgesics will be administered in consultation with the facility vet. Injections for superovulation could cause transient distress but should not cause lasting harm. All animals will be killed by a quick and humane method at the end of experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of mice will experience sub-threshold or mild severities at worst from breeding procedures and will be maintained in our excellent animal facility. Mice are not expected to show any overt clinical signs due to their genetic modifications. The surgical transfer of embryos to surrogate mice (used to generate new genetic strains) may cause short-lived post-operative pain and discomfort categorised as moderate severity. However, non-surgical transfer methods will be used wherever possible. Tumour-bearing mice may experience moderate severity (<5%), if subjected to repeated (e.g.
>1 week) handling and dosing of pharmacological agents (e.g. twice daily).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Physiological context is important in our research, because we study biological processes that affect tissues and the immune system, as well as cancer. The complexity of these processes cannot be adequately modelled by other means such as tissue culture, purified proteins or computational methods. Thus, we need to use animals, and in order for our data to be relevant to human biology, we need to use mammals rather than non-mammalian species in which these processes are very different. The mouse is the mammalian species most widely used, most amenable to genetic modification and best understood for such research. Thus, we must use tissues or primary cells isolated from mice and research involving experimentation in live mice, such as tumour growth, to achieve the aims of our project.

Which non-animal alternatives did you consider for use in this project?

We use cell lines (2D and 3D cultures)ultures), organoids, and purified proteins widely and wherever possible to study the protein tyrosine phosphatase signalling network and redox biology.

Why were they not suitable?

Tissue culture and purified proteins are very valuable in some aspects of our research. However, there are limits, as some cell types, e.g. from the immune system including T cells, cannot be cultured for long periods, and their protein composition cannot be modified other than by genetic means. Furthermore, tissues and tissue culture experience very different environments, therefore monitoring changes in the cell environment will be more physiologically relevant in tissues or primary cells. To understand this context, experiments on live mice, or using cells and tissues from mice, are the only options. Furthermore, we have found significant differences in the signalling in the same cells in tissue culture compared to grown as 3D tumours. The 3D environment much more closely resembles patient tumours.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have consulted with our Biostatistician, and have built on our previous experience of working with mice to ensure we use the optimal number of animals in order to make reliable scientific conclusions and avoid the unnecessary use of animals beyond those needed. We estimate that for each breeding pair, we will generate an average of 4 offspring (half of females will fall pregnant with an average litter of 8), and use mendelian frequencies of genotypes to calculate the number of pairs to set up for a particular experiment or colony maintenance. Furthermore, we have used pilot studies to help determine the size of experimental groups for tumour studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3R's Experimental Design Assistant to ensure we are considering all relevant aspects of design.

Our work is complemented by tissue culture systems, which can involve using cells from a mouse and growing more cells for our analysis, or using cell lines that are already established. We are also exploiting technical improvements to characterise the immune cells of our animals. This means we can obtain more information from a single animal, reducing the overall number of animals required. For our work with the redox biosensor strain, we plan to harvest multiple tissues/cell types using a specialised preservation technique. This means we will increase the amount of data we can derive from each animal, further reducing the overall number of animals required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will continue to use efficient breeding to ensure we do not over-produce mice. In addition to pilot studies and harvesting multiple tissues from mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Other than for tumour studies, mice will be used for isolation of primary cells and tissues after they have been humanely killed, minimising the pain and distress of animals. The minimum number of animals will always be used that yield meaningful results, and with the lowest possible relevant severity procedure to address a specific question.

We will work in cell lines to evaluate some effects of genetic modifications prior to generating new mouse strains. In new genetically modified mouse strains, we will undertake pilot studies and test isolated primary cells to investigate effects prior to using experimental models that rely on live animals.

Why can’t you use animals that are less sentient?

The mouse is the best model organism to address our aim and objectives, as its physiology and disease processes are sufficiently similar to humans to allow us to draw meaningful conclusions, and because a wide knowledge base and many genetically modified strains and protocols exist that allow comparisons of results between projects and research groups.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our routine refinement methods include added enrichment for breeders, alternative bedding for animals with reduced motility, using established social groups where possible, habituation to handling, and providing food in gel format, additional warmth and more frequent monitoring for mice at increased risk. For established strains, we only take samples from mice from the first litter for genotyping, and we use ear rather than tail samples. We may introduce further refinement methods to protocols or husbandry methods in consultation with animal technicians and veterinary staff.

Stress and suffering of mice undergoing procedures will be minimised by observation and adherence to clear guidelines on clinical signs that trigger the end of an experiment. In rare cases where it will be required that we induce and maintain general anaesthesia, we will use modern anaesthetics and continuous monitoring.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow PREPARE and internal guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through our AWERB liaisons, who keep us informed of NC3Rs seminars and events.

139. Understanding and targeting the inflammatory response

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Inflammation, Immunology, Cytokines, Inflammatory disease, Co-morbidity

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how inflammation starts and develops and inform new treatments to limit inflammation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inflammation is a process by which your body’s immune cells and the things they make protect you from infection and tissue injury. However, too much inflammation or inflammation that last too long (referred to as ‘inappropriate’ inflammation) contributes to the development of some of the most common and devastating diseases in society, such

as Alzheimer's disease, stroke, heart disease, type II diabetes, and occurs in response to infection (such as COVID-19). Some groups of people (e.g. those with other conditions/co-morbidities such as obesity) are more likely to have 'inappropriate' inflammation that can lead to a greater severity of disease and an increased chance of mortality (e.g. seen in obese people with COVID-19), but it is not known why. Targeting 'inappropriate' inflammation with anti-inflammatories (drugs that reduce the damaging inflammation) is commonly used to treat inflammatory disease, but is often insufficient since our understanding of the how inflammatory responses start and develop is incomplete. A more detailed understanding of the inflammatory response is therefore necessary for the identification and development of future effective therapies.

Our work focuses on identifying the fundamental biological processes behind inflammation, providing a greater understanding of their impact in the development of inflammatory disease and revealing new ways to treat these diseases. This work will also aim to understand the impact co-morbidities (i.e. obesity) have in the initiation and development of inflammation, leading to the identification of tailored and more effective therapeutic strategies.

What outputs do you think you will see at the end of this project?

We will achieve a greater understanding of the biological events that promote and sustain inflammation through the identification and characterisation of critical biological mechanisms. We aim to identify signatures (such as blood markers) associated with sustained inflammation and, determine if these are altered when other diseases are present (such as obesity), directing research into the diagnosis of inflammatory disease and the development of strategies to limit inflammation. Our findings will be widely disseminated through publishing scientific papers and participation in conferences. We will make our data available to others to use in their studies. In the long term we hope that our research could provide the basis for new clinical trials to target unwanted/inappropriate inflammation in patients.

Who or what will benefit from these outputs, and how?

The main benefits of this research will be the generation of new knowledge on how inflammation starts and how it can become uncontrolled leading to the development of disease. Since inflammation underpins the development of multiple diseases, our research will benefit preclinical and clinical research on a range of disease disciplines. We aim to identify new biological processes and biomarkers fundamental to inflammation assisting with basic and clinical research into therapeutic approaches to target inflammatory disease. In the short term, our research will benefit other researchers, the pharmaceutical industry, and clinicians studying the development of inflammatory disease. In the long term, our research will help guide the development of future diagnostic tools and therapies to benefit patients that suffer from diseases driven by inappropriate inflammation.

How will you look to maximise the outputs of this work?

We will publish our findings from these studies in respected, open access journals, present our data at leading international conferences, and utilise pre-print servers to maximise the dissemination of our research. We collaborate with other universities, to assist with identification and development/repurposing of effective anti-inflammatories.

Species and numbers of animals expected to be used

- Mice: 1600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult mice in our studies. This includes normal control and sometimes genetically altered mice or those that are obese. The immune system of a mouse is similar to that of a human and it responds in a comparable way to infection, injury, and in disease, and mice are therefore appropriate for this work. Infection, injury and disease can occur at any age, so we will use adult mice to represent the largest percentage of the population.

Typically, what will be done to an animal used in your project?

The main procedure in this project involves the induction of inflammation in mice using established stimuli/agents by giving injections of substances that mimic an infection. These agents will be delivered either through injection (subcutaneously, intraperitoneally or intravenously), orally (oral gavage) or via nasal inhalation. In a typical experiment, these treatments may cause a fever or some sickness-like behaviour in the animals, but this will be monitored closely and kept to a minimum by using the lowest exposures/doses possible. In our experience, mice do tolerate inflammatory agents well and sickness- like behaviour is often short lived. Animals will be humanely killed within a few hours after the injections and tissues taken to assess the inflammatory response. Sometimes we will also use agents to try to inhibit the inflammatory response, which will mean the animals should feel much better. In some experiments we will keep the mice for a bit longer (usually up to 10 days) to give the inflammatory response more time to develop. In a few experiments we might also measure how much food the mice eat and how much they weigh. Food intake and body weight measurements are not invasive or disruptive to the animals and are often monitored to assess well-being. In some circumstances, we will monitor body temperature with a rectal probe as part of monitoring the welfare of the mice. For some experiments we might also use mice that have obesity as this condition has been shown to affect how people respond to infection, injury and disease. Most often, we will make the mice obese by feeding them a diet high in calories, usually one containing a lot of fat as this is how most humans become obese. Sometimes we will use mice that have altered genes, which make them eat a lot and become very overweight. In addition to these procedures, mice will be used in this project for breeding, and for collection of cells and tissues for *in vitro* laboratory-based studies. At the end of all experiments, animals will be humanely killed, and blood and tissues taken to assess the inflammatory response in more detail.

What are the expected impacts and/or adverse effects for the animals during your project?

We will cause an inflammatory reaction in the animals by injecting them with agents that mimic an infection. The animals will experience some sickness and the impact will be similar to what humans experience when sick with an infection and symptoms could include lethargy, fever and reduced appetite. However, the symptoms will usually only last for a few hours before the animals are humanely killed to take tissues for analysis. In those tissues we will then look at markers of inflammation, such as identification of immune cells and the agents that they release. In the experiments where we keep animals for longer the

mice might also have some sickness behaviour but this will tend to be milder. The mice that we use for breeding will not experience any adverse effects.

Feeding mice a high-fat diet leads to weight gain and obesity. Over time, obesity may lead to insulin resistance and low-grade inflammation (similar to that observed in individuals with type 2 diabetes). Together these effects of obesity may cause subtle changes in behaviour (e.g. reduced activity), but are not associated with any lasting suffering or distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold/Mild (30%)

Moderate (70%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Inflammation is a complex response that involves many different tissues and organs that cannot be modelled accurately in *in vitro* systems. An inflammatory response also produces symptoms such as reduced appetite, which is due to an interaction of the immune system with the nervous system and the brain. Thus, the whole body is involved in an inflammatory response and as such whole animals are needed to understand this complexity. The proposed studies could also not be undertaken in lower species because they do not show such similarities to humans including their immune system.

Which non-animal alternatives did you consider for use in this project?

We did consider lower species (e.g. zebra fish at an age before protection) and where appropriate these will be used. The wax moth larvae (Galleria mellonella) was also considered as an infection model, but it lacks some of the key features of the human immune system. We are routinely using *in vitro* models and data from these experiments will help us design our experiments using animals. Many of our *in vivo* studies will use a partial replacement by performing *in vitro* experiments in parallel, reducing the numbers of animals needed.

Why were they not suitable?

These lower species, such as zebrafish, do not always show such similarities to humans including their immune system. Of relevance to our project, they do not have some of the

important molecules that we are interested in, such as mammalian-specific inflammatory mediators (e.g. interleukin-1 alpha; IL-1α), and other inflammatory pathways are known to function differently in lower species (e.g. the inflammasomes). These molecules are implicated with human disease, and so understanding their contribution to inflammation is an important feature of our models. *In vitro* studies do not fully mimic the complexities of the multiple tissue systems and organs involved in an inflammatory response to infections/injury.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used our previous experience of performing experiments of this type to help us decide the best way to answer the questions we are asking while using the minimum number of animals. For example, estimates of animal use is based on i) previous work and experience using the relevant methodologies, the parameters to be studied, and specific mouse models; ii) the scope and objectives of the current project; and iii) careful consideration of experimental design.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Several factors lead to a reduction of animal numbers, including reducing variation (e.g. keeping the environment consistent), good experimental design (including the use of the NC3R's Experimental Design Assistant) and the use of appropriate statistics. In particular, statistical tests will be used to ensure that we use the minimum number of animals possible to reliably interpret our data and also so we can refine our questions to then design the most informative experiments. Whenever we get new data, we will always re-do our calculations in order to make sure we are still using an appropriate animal number to achieve our aims.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will minimise the number of animals bred by using efficient breeding strategies and by using mice of both sexes whenever possible, but for many studies we will obtain animals from commercial breeders. We usually take several tissues from the animals at the end of the experiments for multiple analyses (and sharing of tissue), which often leads to additional scientific questions. Whenever we perform analyses that leads to a large quantity of data (such as RNA-seq to analyse all genes) we will make our data freely available to other groups so they can analyse it to answer their own research questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Species: We will use mice as there are no *in vitro* alternatives that can fully replicate the inflammatory response after infection, tissue injury and disease, and rodents are the lowest species that have most of the important components of inflammation (e.g. IL-1α and inflammasomes).

Models: In some experiments we will also use obese mice as a model of co-morbidity that alters how the immune system responds to infection, injury and disease. Mice will usually be made obese by access to a high-fat diet. Alternatively, we might use mice that have altered genes that make them obese. These models, therefore, do not involve any surgery or painful procedures to induce the obesity.

A key objective of this project licence is to identify the biological events underlying systemic inflammation induced by infection or tissue injury. In some experiments, we aim to reduce inflammation by giving appropriate inhibitors/modulators so the response should be less in these animals.

Measurements: For a lot of studies animals will be humanely killed only after a few hours after induction of inflammation (e.g. 2h). This early time point is a result of a refinement in which for some of our questions we can now assess some important/key mediators/parameters after only 2h. For longer term studies (e.g. up to 10 days) animals will be monitored over time for well-being.

In some studies, we will require a cardiac blood sample followed by perfusion with fixative in order to best preserve the tissue for subsequent analysis. In this situation this will be done under terminal anaesthesia.

Why can’t you use animals that are less sentient?

Our objectives cannot be fully achieved using less sentient animals (such as fish/insects) or with very young (neonate) mice mainly due to differences in their immune system, and adult mice are therefore needed. However, we will use zebrafish whenever possible and perform *in vitro* studies in immune cells before we move to mice. However, zebrafish cannot be used for all studies as they do not have exactly the same immune system as humans (and mice) and the way in which their cells produce some inflammatory molecules can be different. As some of our studies involve keeping animals for up to 10 days terminal anaesthesia cannot be used. For some of the acute studies where mice are humanely killed after 2-6h induction of inflammation, if a second injection/stimulus is required (e.g ATP, a marker of tissue damage) this will be done under terminal anaesthesia as mice are usually humanely killed 15 mins later.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In a significant amount studies, animals will be humanely killed within 2-6h with minimal adverse effects on the mice. We have further refined some protocols and mice can now be

humanely killed at a 2h time point in some studies. We need to keep some animals for longer (up to 24h) as some of our primary outcome measures (e.g. in the blood) will not be elevated as early as 2h. However, we will continue to develop our methods of *ex vivo* analysis and if further outcome measures become apparent, we will refine methods to also allow mice to be humanely killed earlier.

For studies where we want to study sustained inflammation, we will keep animals for longer (e.g. 10 days). However, we will continually assess which are the best outcome measures and where appropriate animals might be humanely killed earlier. In these studies mice will be monitored frequently.

For all studies and at all times, mice will be handled appropriately by trained researchers (e.g. using tube handling for movement in and out of cages) and the use of suitable home cage enrichment.

As there is no surgery in our experiments, post-operative care and pain management is not applicable.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will stay up to date with literature, publications and recommendations from the most appropriate bodies such as the NC3Rs and LASA, as well being informed from communication with the NVS and NIO and developments within the scientific community in general. For example, for refinements involving injections we refer to Morton et al 2001 and https://researchanimaltraining.com/articles/an- introduction-to-the-administration-of-substances/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will at all times aim to implement any advances in techniques that adhere to the 3Rs and improve the welfare of the animals. We will stay up to date with the NC3Rs literature and recommendations as well being informed from communication with the NVS and NIO and the scientific literature in general.

140. Drug Metabolism, Pharmacokinetics and PK/PD of Substances for Drug Discovery and Development

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
pharmacokinetics, pharmacokinetic/pharmacodynamic relationship, concentration-time profile

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary aim of this project is to evaluate what the body does to the substance (pharmacokinetics) and whether the substance has the required effect in the body (Pharmacodynamics).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This licence will focus on developing new medicines for a range of diseases, including immuno- inflammation, respiratory, oncology and pain. Such diseases affect millions of people who are in need of improved, effective treatments to either cure the disease or improve their quality of life.
Substances will be evaluated as they are discovered and developed as potential new medicines. They will be assessed in animals (mice, rats, rabbits) to predict what the

human body does to the substance (pharmacokinetics) and whether the substance has the required effect in the human body (pharmacodynamics). The analysis of the concentrations in the blood and tissues of animals following administration helps us to understand how much of these potential new medicines will be required to be administered to humans to be both effective and safe.

What outputs do you think you will see at the end of this project?

The amount of test substance in the blood over time (the concentration time profile) allows us to determine the rate and extent of absorption from the site of substance administration, distribution throughout the body and the rate of removal and excretion from the body. Selection of substances for further evaluation is based on the potential to reach the target organ/site of action and be retained for sufficient time and at a concentration appropriate for assessment in a subsequent pharmacology (efficacy) study.

The concentration time profile generated in animals is used to predict what will happen to the substance in the human body (absorption, distribution, metabolism and excretion). This type of data, generated early in the research program enables us to mitigate the risk of progressing substances as potential medicines that the body handles poorly, through rapid metabolism or poor absorption. Alongside the animal (pre-clinical) pharmacology data, the pharmacokinetic data we obtain allows us to predict the likely human dose and frequency of dosing required in the clinic.

Who or what will benefit from these outputs, and how?

Pharmacokinetic evaluation of new substances enables a greater understanding of the link between blood and/or plasma concentrations and the effects of these substances in a range of animal models. Subsequent studies benefit from this prior understanding of the concentration time profile through accuracy in dose and formulation prediction and the suitability of substances put forward into additional studies. This reduces the number of animal studies performed at unsuitable doses or with sub-optimal substances. In addition the identification of an appropriate animal species in which new substances have the appropriate exposure will help assist in their safety (toxicological) evaluation and could reduce animal testing with unsuitable dose formulations. Pharmacokinetic data generated in the animal (pre-clinical species) forms part of regulatory submission which is required for progressing substances into evaluation in humans (clinical). These benefits will be ongoing throughtout the lifespan of the Project Licence.

The ultimate benefit will be to the waiting patients. The pharmacokinetic evaluation of potential drug candidates is an important piece of the jigsaw that leads to the discovery, development and marketing of new therapeutic agents for the treatment or prevention of diseases in man. This benefit will be ongoing throughout the lifespan of the Project Licence.

How will you look to maximise the outputs of this work?

Physiologically based pharmacokinetic computer models are routinely built and refined using the information obtained from pharmacokinetic studies for a number of Projects which can lead to a substantial reduction in the need for additional animal experiments. Study data and knowledge gained will be shared within the company and with collaborators and applied to benefit future work. Data and knowledge will also be shared outside the company in the form of posters at scientific conferences and publications in scientific journals

Species and numbers of animals expected to be used

- Mice: 7550
- Rats: 9800
- Rabbits: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice, rats and rabbits will be routinely used on this project since they have developed physiology and organ systems similar enough to humans to perform studies in these species that enable prediction of what will happen to the substance when it is administered to humans in a clinical trial or a patient. In addition adult mice, rats and rabbits align with the ages of animals used in the disease (efficacy) model and non-clinical safety studies. For Regulatory Authorities to give permission to conduct human trials of potential new medicines they require a prediction of dose, concentration and safety profile in humans. Studies conducted under this project are designed to progress substances, with the most appropriate concentration profile, through the development process and enable future characterisation of efficacy and/or toxicity.

Mice and rats are acceptable to Regulatory Authorities for the prediction of human pharmacokinetics, provide reliable pharmacological models to test the effectiveness of substances and are the principal rodent species of choice in safety testing. In certain circumstances the rabbit may be the species of choice (e.g. reproductive toxicity) and therefore an understanding of the pharmacokinetics in this species will be required to aid the study design.

Typically, what will be done to an animal used in your project?

Protocol 1 (Pharmacokinetics): In some cases animals may receive (typically on a single occasion) a substance to alter the physiology prior to substance administration. However, as routine, healthy animals will have substances administered by various routes but typically orally. This could be as either a single or repeat administration. Blood samples will be taken either via a needle or cannula inserted into a blood vessel near the surface of the body (i.e. tail vein for rat or ear for rabbit) or directly via a small puncture wound over the tail vein (rat or mouse) in order to determine the concentration of a substance over a time course. At the end of the study animals will be humanely killed and tissues may be collected to determine the substance concentration in those tissues. Where appropriate the effect of any given substance on the pharmacological response produced will be assessed by measuring substance concentrations and/or markers of treatment effects (i.e. cytokines) in the blood. Animals will be weighed and general health assessed daily throughout the study duration. The duration of an experiment is determined by the type of substance being administered (short or long acting), the frequency of dosing (single or multiple doses) and the number of phases to an experiment (if performing comparative formulations, doses or routes within the same animals).

OR

Protocol 2 (Surgical Cannulation in Rodent with Recovery): Rats and mice will be surgically prepared (under general anaesthesia) with a maximum of 2 implanted venous cannula(e). In addition a laparotomy may be performed and up to 3 cannulae inserted (for alternate dosing routes or sampling of biofluids). A vascular access button may be attached to the venous cannula(e) or the animal placed in a suitable device (e.g. jacket and tether system) to protect the indwelling cannula(e). Peri-operative analgesia is administered to minimise any pain, suffering and distress associated with the surgical procedures. The rats and mice will typically have a minimum of 72h recovery prior to continued use on Protocol 3 or 4.

AND

Protocol 3 (Pharmacokinetics in Surgically Prepared Rodents): Following recovery from surgery, in some cases animals may receive (typically on a single occasion) a substance to alter the physiology (e.g. transporter inhibitor) or a pharmacological tool (e.g. an inflammatory agent) prior to substance administration. However, as routine, healthy animals will have substance(s) administered by various routes but typically intravenously as an infusion. This could be either a single (short duration e.g 1 h or sustained e.g. 48h) or repeat administration. Blood samples will be taken via cannula which has been surgically implanted into a vein in order to determine concentration of a substance over a time course. The concentration of the substance in blood (or plasma/tissue) will be determined. Where appropriate the effect of any given substance on the pharmacological response produced will be assessed by measuring substance levels and/or markers of treatment effects (i.e. cytokines) in the blood. Animals will be weighed and general health assessed daily throughout the study duration. The duration of an experiment is determined by the type of substance being administered (short or long acting), the frequency of dosing (single or multiple doses) and the number of phases to an experiment (if performing comparative formulations, doses or routes within the same animals). At the end of the study animals may be humanely killed and further blood and/or tissues may be collected for additional analysis.

However, if the animals are determined by the Named Veterinary Surgeon to be fit to be kept alive for re-use, they will be maintained under the protocol to undergo further dosing/sampling cycles to investigate the pharmacokinetics of additional substances of interest. Animals may be transferred to protocol 4 for reuse.

OR

Protocol 4 (Pharmacokinetics in Surgically Prepared Rodents Non Recovery): In some cases, prior to surgery, animals may receive (typically on a single occasion) a substance to alter the physiology (e.g. transporter inhibitor) or a pharmacological tool (e.g. an inflammatory agent) prior to substance administration. The animals may undergo surgical cannulation of organs, the appropriate blood vessels and the organs perfused during the experiment. Following surgery the animals will remain under terminal anaesthesia and will have substance(s) administered by various routes but typically as an infusion into a blood vessel. This could be either a short duration e.g administered over less than 5 minutes or sustained infusion e.g. 1 - 7h). Biofluid (e.g. blood, bile, urine) samples will be taken via cannula which has been surgically implanted to determine concentration of a substance over a time course. At the end of the study animals will be humanely killed and further blood and/or tissues may be collected for additional analysis. Animals may occasionally be transferred onto this protocol, from protocol 3.

OR

Protocol 5 (Control Biofluid and/or Tissue Collection): Blood samples may be removed from a superficial vein on a single or serial occasions. Animals may be housed in a metabolism cage (up to 24h duration) to enable collection of control urine/faeces. Where large volume of blood or control organs are required the animal will undergo terminal anaesthesia and the tissues, organs and/or biofluids collected. At the end of the study animals will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse events are not expected with dosing and blood sampling due to the low doses typically administered under this project and refined techniques of blood sampling. Non-specific signs rarely observed include weight loss (on repeat substance administration) discharge from eyes and/or nose, altered coat condition, reduced activity, behavioral or postural changes, reduction in food and water intake, abnormal faeces, abnormal breathing, fur staining, alteration of body temperature, irritation/discoloration/crusts/ulceration of the skin and swelling or masses under the skin. Any adverse events are likely to be transient in nature, with clear signs of improvement within 2 hours of the onset of signs, and throughout the day following dosing. Animals will be monitored and undergo regular observation and action will be taken to minimise adverse effects. This may result in animals being killed to prevent further suffering.

During surgery there is a risk that a blood vessel may snap/shred or display bifurcation (branching) and therefore unsuitable to insert a cannula. In these circumstances the animal will be terminated and used for control tissues/biofluids. In addition there is a risk that the animal may stop breathing under anaesthesia. Post surgery a small amount of temporary weight loss can occur whilst other post operative complications are rare e.g. suture breakage, dryness/dead skin or infection at the surgical site. The vascular button system or harness restrain system may result in mild friction injuries, irritation, inflammation or infection to the area of contact. The development of swellings around the button site may occur however this will have negligible impact on the animals welfare. On rare occasions the presence of indwelling cannula in a blood vessel may lead to unexpected thrombosis, inflammation of the vessel and infection (swelling, redness or discharge at site of wound).

During procedures such as substance administration or blood sampling animals are restrained to avoid injury to themselves and ensure success of procedures. There is a low risk of misdosing or cannula being dislodged. Patency of cannula(e) is maintained by flushing with suitable solution in an aseptic manner. There is a small risk that this flushing procedure may dislodge a clot resulting in the potential death of the animal. This is minimised by regular (weekly) flushing and minimal applied pressure should there be any resistance.

For some studies animals are housed on their own to either avoid post operative complications, if dosed with different substances, if administered at different doses or to collect urine and faeces for substance analysis. Animals are monitored for general signs of stress or discomfort during this time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Experience under previous PK and PK/PD Projects indicates that at least 55% of animals are expected to show no more than mild effects following treatment. Up to 30% of animals will likely, experience a cumulative moderate severity, or at least a period of moderate severity at some point during experiments.

Protocol 1 is moderate however approximately 70% of rats and mice are expected to experience mild severity, approximately 30% of rats and mice will experience moderate severity. Approximately 100% of rabbits are expected to experience mild severity.

Protocol 2 is moderate. All animals will be subjected to surgical procedures, 100% of rats and mice are expected to experience moderate severity .

Protocol 3 is moderate however approximately 70% of rats and mice are expected to experience mild severity, approximately 30% of rats and mice will experience moderate severity.

Protocol 4 is mild with approximately 30% of rats and mice expected to experience mild severity when dosed prior to terminal anaesthesia with 100% of rats and mice progressing to non-recovery severity.

Protocol 5 is mild with approximately 20% of rats, mice and rabbits expected to experience mild severity when sampled for serial control matrix collection with approximately 80% of rats, mice and rabbits to be non-recovery severity as control matrix collected under terminal anaesthesia.

Approximately 5% of the total number of rat and mouse studies conducted under this project are anticipated to be Pharmacological efficacy studies.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?
Preliminary triaging utilising in silico, in vitro and modeling techniques will occur reducing the number of substances from thousands to hundreds, to finally only those demonstrating potential as a new medicine progressing to investigation in animals. These substances need to be tested in animals due to the complexity of the mammalian body and the different interactions between the body and new medicines. Understanding these interactions and hence understanding the concentrations of a substance following administration via the desired route of dosing cannot be achieved without using the 'whole body system' of animals. Without this information the risk of ineffectiveness of a new medicines against a disease or it's potential toxicity would be too high to give to humans.

Which non-animal alternatives did you consider for use in this project?

Whilst in silico, in vitro and modeling methodology is employed for triaging compounds to select those with greatest potential to deliver a suitable clinical profile (i.e. balance between efficacy and concentration) the models are limited as they do not represent an integrated whole body system. There has been much progress with the development of non-animal alternatives such as Quantitative Structure-Activity Relationship (QSAR) models (Review on QSAR modeling. J Anal Pharm Res. 2018;7(2)), they are not yet at a stage where the relevance of the data generated from them for humans is fully understood and accepted as suitable alternatives by Regulatory Authorities. Similarly, experiments using many small pieces of isolated tissues or cells do not yet reproduce the level of complexity and integration of body systems within a living animal such as the ability of cells and organs to continuously communicate. Non animal alternatives are also not yet adequately able to simulate absorption, distribution, metabolism and elimination of medicines throughout the body. Consequently, non-animal alternatives are not yet fully characterised and/or validated to provide confidence to replace data from studies in animals (Ref: Indian J Pharm Sci. 2011 Jan-Feb; 73(1): 1–6; J Pharmacol Toxicol Methods. May-Jun 2013;67(3):203-13).

The company continues to seek alternatives to animal use in research and development to reduce the number of studies requiring the use of animals. However any alternatives must be shown to be reliable, robust and acceptable by government organisations that regulate new medicines for patient use globally.

Why were they not suitable?

In order to generate relevant decision making information from studies conducted under this project they need to use the same experimental animal models to correlate with those studies required by Regulatory Authorities before a potential new medicine can be given to humans. There are currently no non-animal models that are considered acceptable to drug regulatory authorities for this purpose and it is therefore not possible to consider the use of non animal alternatives for this project at this time (J Pharm Pharm Sci 24, 113 - 126, 2021).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

The estimates of animal numbers that are likely to be used over a five year period are based on the experience of similar work and projects previously supported under licence authority within the company. There is an anticipated steady rate of projects likely to require information that cannot be gained from non-animal alternatives. Also considered in these estimates is the likelihood of changes to research priorities as a result of continuing scientific advancements in many areas of science. Because we are familiar with the types of models that are likely to be used and know the resources that we have available we can estimate the number and type of studies that will likely be required over the life cycle of a licence.

We use accepted statistical principles based on the main readouts from each model together with knowledge of the variability of those readouts to inform on animal numbers required per type of study to produce statistically useful information.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whenever possible blood samples will be collected using microsampling technology (reference: nc3rs.org.uk/microsampling). In addition continuous advances in analytical detection sensitivity could enable even smaller blood sample volumes to be accurately taken from an animal and the blood concentration of substance(s) at a single time-point determined. Reducing the volume of blood required per sample enables a serial concentration-time profile to be determined in a single animal rather than using multiple animals to generate a composite profile. Therefore the use of serial blood sampling reduces the number of animals required to generate a pharmacokinetic profile. It could also enable the simultaneous collection of blood to measure pharmacological biomarkers and blood concentration within the same animal. This may lead to a more rapid decision on a series of substances, eliminate the need for additional studies to be performed at a later date or enable termination of a substance earlier in the drug discovery process and a downstream reduction in animal usage.

A pool of scientists are available to provide expertise to assist with the design, conduct and interpretation of the studies. Internal scientific and ethical review of studies ensures that the number of animal studies are minimised. Statistics and study design are optimised to ensure the minimum numbers of animals are used to achieve the aims of the study and project and advice is available and taken from a qualified in-house statistician who provides dedicated support for the project. The use of robust study design principles will be used to maximise the likelihood of generating non-biased experimental results and limit the number of animals needed to generate good quality decision making data.

When investigating the concentration of a substance following administration via different routes, formulation and/or doses the same animal may be used. In doing so the comparisons are made intra rather than inter animal, thereby reducing variability and animal numbers.

Where possible in vitro based assays will be planned so that minimal amount of control tissues are required and, where appropriate, samples of control tissues or body fluids will be collected for use in future investigations to reduce animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Surgically prepared animals typically experience a higher degree of suffering as a result of surgical procedures than that experienced during the course of the rest of the study. Therefore re-use of surgically prepared animals for more than one study significantly reduces the number of animals undergoing a higher degree of suffering. Wherever possible re-use of both surgical and non-surgically prepared animals may be undertaken, under veterinary guidance, where this is considered to be of lower impact than using another animal.

To help minimise experimental variation, studies are conducted in facilities providing an optimal environment suitable for the species, with a limited number of dedicated staff performing the technical procedures, animal care and husbandry. This will help to ensure

that animal group sizes are the smallest possible to achieve the scientific objectives of the study.

Studies conducted at higher doses than typically used in this project may involve ‘staggered starts’ to limit the risk of adverse effects to the animals. Existing blood concentration and in vitro potency data will also be reviewed from similar substances before choosing doses.

Animals will be randomly assigned to experimental groups using a computer-generated random number generation system which will reduce bias in animal allocation that could influence the data generated.

Where appropriate, samples of control tissues or body fluids will be collected for use in future investigations in order to reduce animal use.

Although experimental work authorised by this project is not performed using Good Laboratory Practice (GLP) guidelines it is performed to the general standards of GLP to ensure quality and data integrity.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The work conducted under this Project Licence will evaluate substances as they are discovered and developed, have undergone in silico and in vitro analysis and are deemed of further interest. To help understand how much of these potential new medicines will need to be given to humans to be effective and safe the concentrations in blood, biofluids and/or tissues following administration via an appropriate route of delivery will first need to be investigated in animals.

The doses administered to determine blood, biofluid and/or tissue concentrations are chosen such that the exposure achieved in the animal will have minimal risk of adverse events. The dose route and volumes of administration and the number of blood samples taken will be kept to a minimum to complete the scientific study objectives, whilst aiming to ensure the welfare of the animals is not compromised and that the level of discomfort is kept to a minimum. Non surgically prepared animals will be warmed prior to blood sampling to facilitate successful blood collection. This will be kept to the shortest time possible with an aim to give the smallest impact to the animal. The use of microsampling helps to achieve this aim. Using the tail nick method for blood collection in mice, in conjunction with microsampling, allows for fewer procedures to be carried out; for example, fewer times in a warming cabinet, and fewer punctures are required for blood collection as the fresh scab is gently removed to allow serial bleeds to be carried out from one puncture over a short period of time.

Surgically prepared animal models are used to enable substance to be administered by intravenous infusion to assess the pharmacokinetic profile. In addition serial blood sampling via an indwelling cannula reduces the need for handling and manipulation of the animal thereby reducing any distress and allowing the animal to continue to exhibit normal behaviours during the procedure. Peri-operative care e.g. warm environment, supplementary fluids, supportive food, analgesia, aseptic technique and antibiotics (if required) all contribute to minimise the potential of surgery to have pain, suffering, distress and lasting harm on the animals. The use of vascular access button system to protect the rodent surgically implanted cannula will minimise the need for individual housing of cannulated rats. Duration of surgery, dosing and sampling is kept to a minimum required for individual studies to minimise their impact on the animals whilst ensuring quality decision-making data is obtained. Exploration of the use of vascular access buttons in group housed female mice may minimise the need for individual housing in cannulated mice.

The core study designs are based on internal guidance in order to provide quality decision-making data balancing the need to achieve study objectives while minimising animal use. The core study designs have been used extensively under previous project licences, and in other facilities, and have proved successful in characterising and/or assessing the concentrations of test substances in the body. They are generally in line with those used throughout the pharmaceutical industry.

The combination of activities outlined in this section will ensue that the study objectives are achieved whilst causing the least pain, suffering, distress, or lasting harm to the animals.

Why can’t you use animals that are less sentient?

Rodents are a relevant species as they provide many similarities with the mechanisms, systems and processes involved in human absorption, distribution, metabolism and excretion of a potential new medicine that are not known to be fully active in less sentient species. In addition there is a regulatory requirement to characterise the concentration-time profile of potential new medicines in mammalian species (rodents and non rodents) during the programme of regulatory studies. Preliminary pharmacokinetic studies need to use the same species intended for the efficacy, safety and regulatory programme and accepted by Regulatory Authorities. This is to ensure the outcome of the preliminary studies are likely to be predictive of the outcome of the studies conducted during the regulatory programme. Since findings in animal studies are used to understand the potential concentration, efficacy and safety risk when giving a potential new medicine to humans the experiments conducted under this project will normally be conducted in conscious young adult animals with complex, integrated and well-developed physiological mechanisms and organ systems representing those of patients. Due to the duration of the majority of the models to be used, it is impractical and unethical to keep animals anaesthetised for the duration of the required procedures and sample collection periods.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Experiments described within this project will undergo continual review to ensure that the number and frequency of procedures and necessary harms caused will be kept to the minimum required to achieve the study objective.

Warming cabinets will be used for post-surgery recovery and wet food/mash will be provided to ensure all animals recover as quickly as possible. All animals will be monitored

closely following surgery, dosing and sampling. Where the condition of an animal gives cause for concern, observations will be continued until clear signs of recovery are evident or further action will be taken to ameliorate them.
Additional refinements to the cage environment (e.g. provision of enrichment) and good practice in animal handling will continue to be considered and implemented where practicable throughout the duration of this licence.

During the course of the previous licence, various refinements were implemented including:

Use of "button system" to protect rodent surgically implanted cannula(e) as a replacement to the "harness and tether system". This minimises the time spent singly housed as well as improving body weight gain post surgery.

Use of pulseoximeter for anaesthetic monitoring of rodents during surgical procedures.

Use of nesting material to provide environmental enrichment for rats without compromising regulatory requirements.

Use of additional nesting material as well as paper based nesting material to provide environmental enrichment to mice without compromising regulatory requirements.

Changing the way that mice are restrained for procedures by using a soft (e.g. sponge) rather than a rigid surface.

Handling of mice using tube/tunnel/cupping method.

Where possible the use of an in-house mouse restrainer that enables the mouse to be restrained by the tail but with free body movement.

Acclimatisation of animals to handling for procedures likely to be encountered on study prior to surgery being implemented.

Regular attendance at the scientific and ethical review forum by representatives from research statistics as part of the scientific and ethical review of studies.

Where possible the introduction of enhanced, multilevel caging for group housed rodents. Group housing of rabbits in floor pens in preference to caging to allow habituation and handling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following published documents will advise on experimental design, animal welfare and husbandry during the life cycle of this licence:

NC3Rs - Responsibility in the use of animals in bioscience research: expectations of the major research council and charitable funding bodies (2019).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Company's Named Information Officer (NIO) will help distribute information associated with animal welfare, best practice and 3Rs. The project licence holder and other key personnel who operate under this licence, also regularly attend the Company's internal Animal Welfare and Ethical Review Body (AWERB) meetings, where animal welfare, best practice and 3Rs related information is shared.
Furthermore, regular referral to the NC3Rs website, published literature (including new or revised guidance issued by Regulatory Authorities), and feedback from external conferences, symposia and workshops will ensure that advances in 3Rs are identified. 3Rs matters are highlighted, discussed and action taken to implement within the Company via these forums.

141. Safety, residues and pharmacokinetics of veterinary pharmaceuticals, biologicals, feed additives, feed components and contaminants, and vaccines, including their first use in the target farm animal.

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Safety, Vaccines, Pharmacokinetics, Additives, Residues

Animal types	Life stages
Cattle	juvenile, adult, pregnant, neonate
Sheep	adult, juvenile, neonate, pregnant
Pigs	juvenile, adult, neonate, pregnant
Domestic fowl (Gallus gallus domesticus)	juvenile, adult
Game birds	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to complete a series of individual studies to evaluate safety to the animal, residue safety for the consumer and the pharmacokinetics of existing, novel or generic veterinary medicines, biologicals, feed additives, feed components and contaminants, and vaccines. This may be for early preclinical work which may include first use in the target species or for later clinical studies including reformulation of current pharmaceuticals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to conduct animal studies looking at the safety, residues and pharmacokinetics of a new or existing medicine, biological, feed additive, feed component, contaminant or vaccine before either larger studies are performed, and necessary before any application is submitted for regulatory approval. This minimises the risks to animal health and wellbeing as well as human health risks. Safety and residue tests are a crucial step for new or repurposed pharmaceutical products on their journey to being approved by the appropriate regulating authority (outlined in VICH guidelines GL43 and GL46). During a pharmacokinetic study it's important to understand the metabolism of the therapeutic dose of the product and how it interacts within the target species (Guidance will be sought from VICH GL52 and EMEA/CVMP/133/99).

What outputs do you think you will see at the end of this project?

Multiple scientific reports for the sponsoring companies that will potentially lead to new treatments for animal diseases, and conditions that cause economic and animal losses, together with animal welfare impacts, and human health each year. Our continuing input into fundamental animal health research and scientific papers published in relevant journals. We play an active role in maintaining and updating guidance on animal health and wellbeing and best practise for these types of safety studies.

Who or what will benefit from these outputs, and how?

Animals, pharmaceutical companies, farmers and the wider economy will all benefit from the research carried out. The testing facilities provided may result in new and novel products being brought to market to help alleviate many different animal diseases. Therefore, this benefits the animal's wellbeing and health, farmers see improved yields and pharmaceutical companies see profits by marketing their product. Human health benefits from access to safe food and/or veterinary interventions. These factors combined stimulate and help the wider economy to grow within the UK. We earn income that assists the maintenance and development of our facilities.

How will you look to maximise the outputs of this work?

We will work with companies, institutes and charities to disseminate the study findings, publish research papers, attend relevant conferences and we also play an active role in creating guidelines in this area of research.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 400
- Other birds: No answer provided
- Cattle: 50
- Sheep: 100
- Pigs: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Many of our studies at are conducted in the target species for authorisation and/or support of a veterinary medicine, biological, feedstuff, feed additive or vaccine and such testing is required by the regulatory authorities. There is a policy of checking whether non-animal alternatives are possible, for example by regular visits to the NC3Rs website (http://www.nc3rs.org.uk) and attending relevant conferences. Where there is a validated and appropriate in vitro model then the client would be informed and the in-vivo work refused.

Typically, what will be done to an animal used in your project?

Administration of substances either; in feed or water, orally by gavage, injection (subcutaneous, intramuscular or intravenous), intramammary (via teat canal), intranasally, topically to the skin or via a non-surgically implanted slow release device. Blood may also be taken, cannulas inserted, biopsies of superficial tissues such as hair, fleece, skin or feathers, nasopharyngeal swabbing, cloacal swabbing, faecal sampling and percutaneous secretion sampling (by needle but only once in the last 24 hours of a study) may also be performed. Lactating cows may be dried off.

What are the expected impacts and/or adverse effects for the animals during your project?

Likely adverse effects:

There may be signs of local or systemic treatment intolerance particularly where multiples of normal or proposed dose-rates are used during target animal safety studies. These include:

Local reactions either injection site reactions or site of application reactions (including signs of pain associated with the area, swelling, skin changes)

Systemic reactions to the substance (behavioural changes, mobility changes, feed intake and weight gain changes, organ system changes)

The volume of blood removed could result in anaemia or systemic signs, although this is managed by calculation and reference to guidance on suitable blood volumes that can be safely removed over time

Anaphylaxis following administration of substances Likely incidence:
The substances that have been researched before are likely to have undergone preclinical studies in, for example, rats or mice and most likely the target species already. On occasion, there may be either transient clinical signs or mild lasting clinical signs at normal dose rates, which may be accentuated in higher doses administered in tolerance/safety/residue studies. This is specific to the treatment, its regimen and formulation.

First use in the species carry additional risk as prior experience in e.g. mice, rats or in vitro may not accurately predict the effects in farm species. In addition the product may be in a preliminary formulation. This is specific to the treatment, its regimen and formulation.

Typically pharmaceutical safety studies have groups treated at 1x, 3x and 5x dose-rates and sometimes at repeated intervals (lasting up to 90 days). Depending on the product, there may be clinical signs associated with treatment at the 3x or 5x levels.

Reproductive studies are conducted at up to 3x the recommended maximum dose rate in adult animals including pregnant females. The 3x maximum dose rate could be associated with clinical signs in the adult animal or the offspring.

Vaccines may be tested at up to 10x normal dose-rate.

Repeated blood sampling could result in clinical signs after either a large volume was taken on a single occasion or repeated sampling over a period of time. This is very unlikely to occur as the guidance in the appendices is followed which includes LASA guideline for blood withdrawal.

Anaphylaxis is a rare but possible event.

Measures to prevent, recognise and control occurrence and severity:

Prior knowledge will be reviewed to ensure that doses and dose-rate multiples are unlikely to exceed moderate severity

If they are deemed likely to exceed moderate the work will be declined or the work will be discussed with the Home Office Inspectorate

The protocol will include adverse events that might be seen with the substance or substances together with an assessment of their severity and a cut off limit of moderate

following treatment (excluding in feed or in water treatment where treatment is repeated over a period of days or weeks) animals will be observed at regular intervals (typically hourly) for the first 4 – 6 hours after treatment, then at 24 and 48 hours should any observations approach the predetermined cut offs then a veterinary surgeon or NVS will be consulted and the animal euthanased, treated and/or removed from the study as appropriate. Observation intervals will be decreased if clinical signs indicate this is necessary.

Anaphylaxis is a rare but possible event. To handle this veterinary assistance, treatment and means of euthanasia will be available in the hours after vaccine administration

Dose volumes and blood sample volumes will follow guidance. The main guidance used will be from LASA and is shown in the table below.

Maximum volume of blood samples

Animal Types	Blood volume (ml/kg bodyweight)	Safe single sample volume	Maximum blood sample per 30 day period	Example maximum blood sample volume per 30 days
Sheep	58-64	6 ml/kg	9 ml/kg	Body weight 50kg - 450ml

Cattle	57-62	6 ml/kg	9 ml/kg	Body weight 500kg - 4500ml
Pig	65	6 ml/kg	9 ml/kg	Body weight 50kg - 450ml
Chicken	60	6 ml/kg	9 ml/kg	Body weight 4kg - 36ml

As small a volume as required for the experiment will be withdrawn. Not more than 10 per cent of blood volume will be removed at one time, and less than 15 per cent of blood volume removed in a 30 day period.

Limit Volumes for Substances Dosed (based on LASA guidance)

*: volume will be adjusted depending on actual bodyweight. Licensed veterinary products will be given at the manufacturer's recommended dose rates and volumes (except in protocol 1).Based on aqueous substances i.e. readily absorbable material (NVS advice must be sought if substances are viscous).

Volumes for pigs should be based on those for sheep.

Admin. Route Species	Oral	Subcutaneous	Intramuscular	Intravenous	Intradermal
Sheep (ml/kg bodyweight)	2 (drench) 10 (gavage) 2	2 (50ml per site)	0.1 (5ml per site)	2	0.001
Cattle (ml/kg bodyweight)	2 (drench)	1 (400ml per site)	0.3 (25ml per site)	1	0.002
Birds (average bodyweight 2.5 kg)	-	1 - 2 ml/site*	0.25 ml*	3 - 5 ml*	-

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild and moderate. 75% mild. 25% moderate (see full breakdown in protocols). The maximum expected severity is moderate with any animals that reach this threshold being treated or euthanased as appropriate before they reach the severe threshold.

Animal types	Est. numbers (mild)	Est. numbers (moderate)	Life stages
Cattle	38	12	Adult and Juvenile

Sheep	75	25	Adult and Juvenile
Pigs	75	25	Adult and Juvenile
Birds	750	250	Adult and Juvenile

What will happen to animals at the end of this project?

- Rehomed
- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Veterinary medicines, biologicals, feed additives, components and contaminants, and vaccines must be trialed in the target species for initial safety/tolerance and pharmacokinetic reasons before taking forwards to larger trials or for regulatory submission. Unless otherwise recommended or if there is an established and validated tissue culture model available, the target animal will need to be used in these studies.

Which non-animal alternatives did you consider for use in this project?

N/A.

Why were they not suitable?

N/A.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use a combination of tools to estimate the numbers of animals needed in an individual project. This normally includes the NC3Rs Experimental Design Assistant, VICH and EMA guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used.

Peer-reviewed journals and advice from external peers together with in-house experience and historical data over a number of years is used to ensure that animal numbers are adequate.

We are fully committed to reduction, nonetheless the exact numbers of animals required will vary with the particular study needs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have many years of experience of working with veterinary medicines, biologicals, feed additives and vaccines in the target species. This ensures the minimum number of animals are being used for any particular study. Due to our experience we have highly optimised our processes which enables us to maintain high welfare standards whilst delivering our clients requests. We also utilise the NC3Rs Experimental Design Assistant, VICH and EMA guidelines as well as consulting guidelines set by regulatory bodies and any relevant literature.

For example, pharmacokinetic studies are normally negatively or positively controlled, parallel studies or cross over with a wash out period where the animal is used as its own control.

Expert statisticians will be involved in study design as well as consulting guidelines set by regulatory bodies and any relevant literature to ensure that the minimum number of animals is used that are needed for a valid statistical result.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where appropriate pilot studies are used to establish an appropriate and consistent model that will ensure meaningful results are obtained.

Studies may be exploratory and use small numbers in a standardised design, enrolling further animals one at a time as it is established that the adverse reactions to the drug are mild or moderate and not severe, therefore slowly building up the data to a full set.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species of animals used are the intended target species for each veterinary medicine, biological, feedstuff, feed additive or water additive or vaccine. Regulatory bodies require safety and pharmacokinetic data from the target animal species. The species involved are:

cattle, sheep, pigs, domestic poultry and other farmed avian species (ducks, pheasants, geese).

Models are designed to minimise severity as far as possible to achieve meaningful results. The numbers chosen will normally be within the guidelines set by VICH GL43, GL46, GL52 and EMEA/CVMP/133/99.

Why can't you use animals that are less sentient?

We have to use these animals due to the research being directly related and utilised in real world farm animal and bird environments. However we regularly refine and/or validate existing animal models in support of 3Rs initiatives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We minimise suffering by examining each study plan to identify opportunities to reduce handling by, for example, using experienced and knowledgeable staff, handling and habituating animals to procedures where necessary, meeting or exceeding codes of practice and current guidance or literature suggestions for enrichment.

The animals used are the target species for the veterinary medicines and vaccines on trial. Any models will have welfare at the centre of their design. In addition, animals on these studies will have a heightened level of observations immediately after and in the days following administration of any substance. Our standard level of monitoring is a minimum of twice daily. Frequency of observations are increased on an as needed basis based on animal observations and behaviour. For example, observation frequency would increase to hourly or constant monitoring if necessary. Observations would normally be general health observations but these are supplemented with clinical observations by our NVS (or similar), monitoring of temperature and other parameters as necessary.

If a treatment is to be administered over the course of a number of days then we would aim to administer at the same time daily to allow the animal to become accustomed to the dosing regimen. We may also associate dosing and administration with feeding times as positive reinforcement for the animal

If it is believed an animal is approaching and likely to breach the predetermined severity category then we have a well-established process. This includes seeking veterinary advice from our NVS or another veterinary surgeon, discussions with the NACWOs, PELh, PPLh, PILh and Study Investigator. This group of people decide the best next steps in terms of animal welfare. This could be either, immediate alleviating of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, and increased monitoring if the animal is unlikely to breach the severity limit by the conclusion of the study if appropriate.

If an animal breaches the predetermined severity category for the study then immediate action is taken. This often includes rapid discussions with the NVS, PELh, PPLh and PILh alongside the study investigator. We would also possibly contact an ASRU inspector. The course of action could be immediate alleviation of suffering if irreversible clinical signs via euthanasia, treatment with, for example, analgesics and anti-inflammatories in order to relieve suffering, maintaining and closely monitoring the animal if the scientific need is justified and the end of the study is within a short time frame, this would be agreed by an

ASRU inspector. All decisions are taken on a study by study basis and differs with treatments and species.

We will also continually review our procedures and refine as much as possible with guidance from, for example, VICH, EMA, and other relevant organisations and published literature.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

VICH and EMEA guidelines for best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly reference the NC3Rs website, published literature, attend relevant conferences, and employees are members of The Royal Society of Biology and other relevant organisations.

142. Optimising cardio-pulmonary vascular interventions

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cardiac, Pulmonary, Arteries, Interventions, Monitoring

Animal types	Life stages
Pigs	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop new, and improve existing, interventions in the arteries of the heart and lungs for patients with coronary and pulmonary arterial disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are two major disease types targeted in this application

Pulmonary hypertension (high blood pressure in the lungs) is a common disorder that leads to heart failure and is associated with high morbidity and mortality. Treatments can be both endovascular and medical. Both need to be carefully targeted and closely monitored. Large animal models play an important role in assessing novel treatments and minimally invasive ways of monitoring progress.

Coronary artery disease (furring up of the arteries of the heart) is the most common serious disease of our times, and in the worst affected cases, surgical bypass or angioplasty (balloon and stent) of narrowed vessels is required. When an artery blocks, the resulting heart attack can lead to extensive heart damage and heart failure requiring cardiac support.

Large animal models are required to optimise interventions for these conditions.

What outputs do you think you will see at the end of this project?

The new information generated will include: the feasibility and safety of novel devices to treat coronary artery disease; biological signals that novel therapeutics may prevent graft failure; physiological measurements to support the translation of devices such as pumps to support the circulation; and metrics of reduced pulmonary artery pressure in experimentally induced pulmonary hypertension.
Outputs will include scientific publications, presentations at medical meetings and conferences, higher degrees for researchers, and the development of intellectual property.

Who or what will benefit from these outputs, and how?

In the longer term, patients with pulmonary hypertension, coronary artery disease, heart attacks, heart failure and cardiogenic shock will see an improvement in their treatments.

How will you look to maximise the outputs of this work?

We will collaborate with relevant researchers and experts in the areas under study, publish our findings in peer review journals, disseminate at specialist conferences; and, if successful, seek to commercialise new developments and have them endorsed by regulatory bodies.

Species and numbers of animals expected to be used

- Pigs: 102

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We generally use juvenile pigs, 15-60kg. Their anatomy and physiology are similar to humans. Our devices, techniques, entry points, instruments and skills work well in the pig. Re-design, repurposing or miniaturisation for other animals would delay research. We have a track record in developing and using porcine models over the last 30 years which have proven durable and effective at testing interventions.

Typically, what will be done to an animal used in your project?

A typical experiment will involve general anaesthesia followed by a vascular procedure (an intervention on the blood vessels). This may involve vascular access (insertion of temporary catheters into the circulation), usually via carotid or femoral arteries or large veins, surgery on the vessels themselves, placement of devices, either temporary or

permanent, in or adjacent to the cardio-pulmonary circulation, monitoring, wound closure and recovery. The experiment will usually end with a second, non-recovery, anaesthetic and further study of the effect of the original intervention before killing the animal. The duration may be from one day to one month between the first and the terminal procedure.

The above basic procedure may be augmented by pre-treatment with drugs to create models of clinical conditions, such as monocrotaline, beta-blockers, vasodilators or vasoconstrictors to induce pulmonary hypertension and/or heart failure. We may then give drugs to optimise the interventions, usually given orally in food, or in select cases by subcutaneous injection.

In a few animals, the above will be accompanied by deliberate coronary vessel occlusion and myocardial infarction, implantation of a left ventricular assist device (LVAD) or circulatory support device in or adjacent to the heart (eg in the pericardium [the space around the heart] or great vessels), followed by wound closure, but with a cable tunnelled under the skin to a power source worn in a harness.

What are the expected impacts and/or adverse effects for the animals during your project?

Typically, there will be few adverse effects. About 10% of recovery animals may have wound discomfort at a vascular access site, treated with analgesics. A proportion of those (5%) may have a wound infection, treated with incision, drainage, antibiotics or killing by schedule 1 method. The few animals undergoing myocardial infarction may experience sudden (usually painless, arrhythmic) death in the first few days. Those having induction of pulmonary hypertension may experience shortness of breath, fluid accumulation and lethargy. Those receiving an LVAD may find wearing a backpack uncomfortable. They will be pre-trained to avoid this. A more serious impact may be that the LVAD or the cable may erode or become infected. In such a case the animal will be killed. We plan to install a camera in the pen to ensure there is no prolonged suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Acute studies are non-recovery. The recovery experiments are moderate, and these generally involve a single procedure under general anaesthetic, followed by a period of recovery and killing under a Schedule 1 method. The LVAD experiment will also be moderate because the animal will be trained to wear the harness. We will not progress from 'non-recovery' to 'recovery' until we are convinced it is safe to do so; i.e. until we have shown that an intervention (such as implanted device, or a graft operation), works without complication for at least 3h under anaesthetic. Therefore the exact numbers of animals in each category are (at the time of writing) as yet unknown; but we will only proceed to non-recovery experiments after discussion with the NVS.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

All basic science and bench testing will be complete. This work is designed primarily to test feasibility and safety prior to 'first-in-man' studies.

Which non-animal alternatives did you consider for use in this project?

In the case of devices, all appropriate pre-implantation physical and bench testing will be performed prior to animal work. Biocompatible materials will be used which have previously been tested. In some cases, cadaver testing will be employed, but this is generally neither fully satisfactory nor realistic. In the case of monitoring, only a living being is appropriate. In the case of drugs, they will already have been approved for use or in early phase clinical studies.

Why were they not suitable?

Very often they are suitable, as outlined above, and have already been deployed prior to animal testing, so that animal usage is kept to a minimum.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based upon our group's extensive experience of working with the pig as a model in these fields, under HO Project Licences, over the last 30 years. It is a realistic maximum, but in practice, we usually use fewer animals than this as scientific plans change and grants are (and are not) awarded.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The main method is to ensure that every possible design, engineering, benchtop and computational option has been thoroughly explored before animal testing.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In novel device design, we start with animal cadaveric deployment, after another animal experiment is over. We then progress to a procedure under a single, non-recovery anaesthetic. The next stage is implantation with recovery. By employing intravascular implantable monitors, we can maximise data output from few animals over a prolonged period, without requiring more animals to be killed at intermediate timepoints. In this

licence, we will capture extensive haemodynamic and imaging data to maximise the learning from each animal. For novel device therapy, feasibility, or the next design challenge, may only require one animal in a staged experimental design before the next improvement. If a device fails (such as the left ventricular assist device, LVAD, which is technologically complex), and data collection is incomplete, provided the animal is well, and only under the original anaesthetic, we will replace the faulty device. This will avoid the use of another animal. If the device fails once the animal has recovered, this would be a humane endpoint.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Coronary artery intervention

This model is intended to study new devices and technologies and to test their feasibility and safety in patients with coronary heart disease. Under general anaesthesia, we gain access to the circulation and advance the device via catheter to its target vessel, deploying it and studying the response with suitable monitoring. We then withdraw the catheter, repair the wound and allow the animal to recover. In selected cases, two procedures may be required. After waking from the anaesthetic, the animal usually resumes normal activities immediately and is undistressed.

Coronary artery surgery

In the pig we can perform an operation similar to heart artery (‘bypass’) surgery, which used inpatients with more extensive (multi-vessel) coronary heart disease. Instead of instrumenting animal's heart, we can use the blood vessels in the neck. As above, a second procedure may be required to harvest the blood vessels and study the effect of drug interventions. This is minimalist procedure which avoids the invasive trauma of heart surgery whilst yielding the data we need with minimal distress.

Pulmonary hypertension

In a non-recovery study acute pulmonary hypertension may be induced by intravenous administration of a pulmonary specific vasoconstrictor. Over a 5-10 minute timeframe this increases vascular tone in the pulmonary arterial bed increasing vascular resistance and pulmonary pressure leading to right heart strain. Chronic pulmonary hypertension may be induced by sub-cutaneous or intra-peritoneal ammonisation of monocrotaline. This causes a gradual remodelling of the pulmonary arterial bed that takes 7-30 days to increase vascular resistance and pulmonary pressure leading to right heart strain and heart failure at later timepoints. After waking from the anaesthetic, the animal usually resumes normal activities immediately and is undistressed. As heart failure progresses the animal experiences lethargy and shortness of breath. The use of remote monitoring devices

permits close observation of animal activity and physiology thereby ensuring suffering is minimised while extensive, high value data are collected.

Heart failure

A variant of the ‘coronary intervention’ procedure may be used to induce a heart attack by blocking an artery in the heart for 30-60 minutes. The animal has cardiac monitoring, because heart rhythm disturbances can occur which can be immediately reversed with an electric shock under the anaesthetic. Interventions can then be targeted, for example by inserting a novel pump to support the heart. The function of the heart, and any improvement in it, can be monitored. Alternatively heart failure may be induced by intravenous administration of approved drugs that alters cardiac function (beta blockers, vasodilators, vasoconstrictors). Initial testing of the pump can be performed in the animal without a heart attack, but improvement of cardiac output in heart failure will require the heart failure (heart attack) model. This is a challenging set of experiments and will be performed one by one, with full discussion with the NVS and by close collaboration with the Roslin Institute who have suitable facilities to monitor the animals.

Monitoring

All the above procedures may have remote monitoring. A small device may be left in the circulation which will allow heart rate and vessel and/or interstitial pressures to be monitored and transmitted to a receiver. This will provide lots of data from few animals and avoid unnecessary repeated procedures. It will also allow early identification of deterioration and permit intervention or a humane endpoint.

Why can’t you use animals that are less sentient?

These interventions and devices are intended for clinical use, so the main issue is feasible deployment and correct sizing in an appropriate large animal model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedures are moderate and the main issue is discomfort from the vascular access site in the recovery period. We try and minimise this with surgical suturing techniques and infiltration of slow- release local anaesthetic. Distress is usually minimal, and close observation at least twice a day in the first three days reveals 5-10% animals that require extra analgesic. Experiments involving a heart attack may lead to sudden (arrhythmic, painless) death in the first 48 hours. We will install a CC camera system to monitor that situation. In the few animals that have a large device implanted, especially those requiring a transcutaneous power supply, such as a left ventricular assist device (LVAD), initial implantations will be under non-recovery anaesthetic; and subsequent recovery animals will be in an establishment with an intensive care facility. Experiments with implantable monitors will provide the data required for us to detect early signs of deterioration before suffering takes place.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guiding Principles for Preparing for and Undertaking Aseptic Surgery (https://www.lasa.co.uk/wp- content/uploads/2018/05/Aseptic-Surgery.pdf)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will meet with our NC3Rs Regional Programme Manager to discuss the latest developments in the 3Rs. Attend local and national 3Rs workshops, seminars where applicable. We will consult the NC3Rs website to keep abreast of any new developments (https://www.nc3rs.org.uk/). We have provided detailed information on advances we have made in the 3Rs area to other groups in the UK who are looking to implement these changes locally.

143. Investigating the mechanisms of hypoxic ventilatory control

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

carotid body, HIF, ventilation, hypoxia

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this work is to understand the mechanisms of enhanced ventilatory responses to low oxygen (hypoxia), a process that is mediated by the carotid body.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Oxygen is essential for life and lack of oxygen or hypoxia is associated with many pathologies including stroke, heart attack, peripheral vascular disease, pulmonary hypertension and cancer.

In response to low oxygen or hypoxia, the body mounts various responses to try to adapt to the hypoxic insult such as increased ventilation and red blood production. Hypoxia-inducible factor (HIF) is a master transcription factor that mediates gene expression changes necessary to mount many/most of these adaptive responses to sustained

hypoxia. Previous work has shown that a specific isoform of HIF: HIF-2 is required for the respiratory reflex to low oxygen (hypoxic ventilatory control), both in mediating the increase in ventilation in response to sustained hypoxia (ventilatory acclimatisation) but also in mediating the rapid responses to hypoxia that occur within seconds of hypoxic exposure (acute oxygen sensing).

This project will seek to understand the mechanisms of action of the respiratory reflex to low oxygen (hypoxic ventilatory control) that is mediated by the carotid body, in response to both sustained (ventilatory acclimatisation) and rapid (acute oxygen sensing) exposure to hypoxia. This is important both scientifically, in understanding the mechanisms involved in this signalling pathway (in particular in elucidating the mechanisms of acute oxygen sensing, which remain unknown) as well as biologically, since HIF-2alpha antagonists are clinically licensed for use in treating kidney (and other) cancers and our work shows that these drugs likely have adverse effects on ventilatory control, contraindicating their use in patients (eg with impaired lung function) that rely on hypoxic ventilatory control for adequate oxygenation of tissues.

What outputs do you think you will see at the end of this project?

We aim to obtain the following outputs from this work:

an understanding of the mechanisms of hypoxic ventilatory control (in particular acute oxygen sensing, which are hitherto unknown)

publications in peer-reviewed journals

to better inform the use of the clinically licensed HIF-2alpha antagonist (Belzutifan), which has recently been licensed by the FDA to treat kidney and other cancers yet likely has adverse effects on hypoxic ventilatory control may lead to a novel use of the clinically licensed HIF-2alpha antagonist (Belzutifan) in the treatment of carotid body and related tumours (pheochromocytomas and paragangliomas)

may lead to the development of new drugs targeting respiratory control, relevant to patients eg with impaired lung function such as chronic obstructive pulmonary disease, obstructive sleep apnoea/metabolic disease.

Who or what will benefit from these outputs, and how?

The findings of this proposal will benefit:

the scientific community, in understanding the mechanisms of hypoxic ventilatory control, in particular the mechanisms of acute oxygen sensing

patients being treated with the HIF-2alpha antagonist Belzutifan for kidney and other cancers, in better understanding the adverse effects on respiratory control

patients with cancers of the carotid body, other paraganglia and related adrenal medulla (pheochromocytomas and paragangliomas, PPGLs), in understanding whether the use of HIF-2alpha antagonist Belzutifan extends to these types of cancer
patients with respiratory diseases eg chronic obstructive pulmonary disease (COPD) who rely on hypoxic ventilatory control for adequate oxygenation of their tissues

How will you look to maximise the outputs of this work?

The outputs of this work will be maximised by:

dissemination of results by collaboration with other research groups (both internal and external to the establishment)

oral/poster presentation at conferences and publication in peer-reviewed journals

publications of results in peer-reviewed journals

Species and numbers of animals expected to be used

- Mice: 10,000
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures. Explain why you are using these types of animals and your choice of life stages.

The proposed work requires an animal model which has a carotid body, lungs, brain and nervous system in order to carry out hypoxia induced ventilation. The carotid body is only present in (adult) vertebrates and the mouse is the lowest vertebrate with all the necessary multi-organ systems required to mount a hypoxic ventilatory response. Additionally, genetically modified mouse models already exist for much of the required work. As such, this work will primarily involve the use of adult mice.

Since the carotid body is small (~1000 cells in mice) and difficult to dissociate into cells, we will additionally use carotid bodies from adult/juvenile rats.

Typically, what will be done to an animal used in your project?

Animals will undergo administration of a gene-inducing or deleting agent over a period of typically five days and by oral gavage. They are then acclimatised to hypoxia, or air containing ~10% oxygen (normal air has ~21% oxygen), which is equivalent to oxygen levels at ~5500m altitude. They are then housed for up to 7 days in these conditions, during which their ventilation in response to normal air and acute (5 mins) hypoxia (10% oxygen) will be measured whilst animals remain conscious. At the end of this period, animals will be killed and tissues harvested for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals typically dehydrate and lose ~5-10% of their body weight within the first 48 h of hypoxic exposure; animals usually recover body weight shortly after or 48 h post commencing hypoxic exposure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse: mild (90 %); moderate (10 %) Rats: mild (90 %); moderate (10 %)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this work is to understand how the body adapts to low oxygen (or hypoxia) by increasing ventilation; this process is mediated by the carotid body. Since ventilation is a systemic/multi-organ response involving the lungs, heart, blood, brain, carotid body, nervous tissue and other organs, it is not possible to study this process without the use of animal models. Additionally, the carotid body is present in vertebrates but not lower organisms. Since mice display hypoxic ventilatory responses mediated by the carotid body and many genetically modified mouse lines are already available for this work, they are the ideal model system for this study.

Which non-animal alternatives did you consider for use in this project?

In vitro cell lines that are kept in tissue culture.

Lower organisms including the fruit fly D. melanogaster, the nematode worm C. elegans. These are widely used in research since they are easy to modify genetically.

Computer modelling.

Why were they not suitable?

Cell lines, that is isolated cells that are cultured in the laboratory, are not useful for studying whole body, multi-organ systemic responses such as ventilation, in particular ventilation that is induced by hypoxia and is mediated by the carotid body. However, cell lines will be useful to complement the animal work and to dissect the exact mechanisms behind carotid body Type I cell responses to hypoxia.

Neither D. melanogaster nor C. elegans have carotid bodies or display hypoxic ventilatory responses and are therefore not useful animal models for this proposed work.

Computer modelling cannot be used to simulate breathing responses to hypoxia.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design

studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimations are based on our previous studies into hypoxic ventilatory control. These studies demonstrate that these numbers are sufficient for the studies to be valid.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments were designed using NC3R's Experimental Design Assistant to ensure use of animal numbers are minimised and consistent with the scientific objectives, methods to reduce subjective bias and appropriate statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Number of animals used in this project will be minimised by various strategies including:

use of efficient breeding programmes to ensure that the genetic status of offspring generated are suitable for our experiments

performing pilot studies using small numbers of mice to allow for adjustments to the protocol without unnecessary wastage of mice

sharing of tissue from one mouse between several users (internal and external to the research group) wherever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice (and to a lesser extent rats) will be used for the work proposed in this licence. Hypoxia will be simulated using a normobaric (ie normal pressure or barometric pressure equivalent to pressure at sea level) altitude chamber and ventilation measured using plethysmography.

Why can’t you use animals that are less sentient?

Hypoxic ventilatory responses require the animal to have a cardiopulmonary system, carotid body (only present in vertebrates) and nervous system. Therefore, mice (and rats)

are among the lowest vertebrates to mount hypoxic ventilatory responses to hypoxia which can be used for study.

The carotid body forms post-natally and therefore these studies require the use of adult mice and rats. Additionally, we would like to look at carotid body function/hypoxic ventilatory control during development, thus requiring the use of juvenile and neonatal mice and rats.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Potential refinements to reduce welfare costs to the animals include:

enhanced monitoring, for example, when animals are under hypoxia they will be monitored (including measuring body weights) once daily and animals provided with mash if losing >10% body weight.

training animals where appropriate to reduce stress caused by the experiment

use of conditionally inactivated transgenic animal models to avoid adverse effects of ubiquitous gene deletion in development

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experiments will be performed in accordance with published literature on refining experiments, for example, the NC3R's website, Arrive Guidelines, RSPCA, the 'Handbook of Laboratory Animal Management and Welfare' by Wolfensohn and Lloyd.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through regular attendance to internal welfare meetings and collaboration with colleagues.

144. Development of novel cancer therapeutic agents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, treatment, resistance, toxicity, efficacy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

More than 1 in 3 of us will develop cancer during our lifetime. The aim of this project is to find novel treatments and to determine their properties prior to their evaluation in the clinic.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Current therapies are associated with non-selective side effects and tumours can develop resistance to the drug resulting in the death of the patient. Consequentially, there is an urgent need to develop targeted therapies to each type of cancer.

What outputs do you think you will see at the end of this project?

Publications in peer-reviewed journals.

Compounds or drugs that have efficacy in animal models that could progress to clinical development.

Who or what will benefit from these outputs, and how?
Many of us are likely to develop cancer during our lifetimes. The ultimate output benefit will be to the cancer patient. New therapeutic agents have the potential to improve their prognosis. Thus addressing high unmet clinical need. Current agents are associated with both a a poor efficacy signal and the emergence of side effects. In addition, tumours can develop resistance to pharmacotherapy. In the shorter term, scientific knowledge and understanding of pharmacology of cancer chemotherapeutic agents will be increased and agents will be developed that can have greater efficacy and/or an improved side effect profile.

How will you look to maximise the outputs of this work?

I publish regularly in peer-reviewed journals and present at national and international meetings. I also collaborate with academic groups and both biotech pharmaceutical companies. Thus new knowledge will be disseminated.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The adult mouse is well validated as a model for the development of cancer therapeutic agents. Immunocompromised and immunocompetent mice will be used for the growth of human and mouse tumours respectively.

Typically, what will be done to an animal used in your project?

The majority of mice will bear a tumour, typically on the flank, but also directly into the tissue of origin. Following growth of tumours (2-4 weeks), mice will be treated with chemotherapeutic agents for up to 4 weeks, with blood samples being taken where required.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals are expected to tolerate both the tumour and treatment well. In the minority of cases, tumour burden will result in some weight loss, up to a maximum limit of 20%. Intervention would take place if either the tumour burden or treatment affected animals welfare, typically within 8 hrs of observation of abnormal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We anticipate that the majority of animals will experience moderate severity as a consequence of bearing tumours.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst in vitro systems provide us with important data on the pharmacokinetic (PK) and pharmacodynamic (PD) properties of novel agents, it is imperative for the pharmacological properties to be determined in the intact biological system, e.g. the mouse prior to progression towards the clinic. In vitro systems model parts of the in vivo biological processing of agents, e.g. isolated liver cells to model conversion of the agent to an inactive product or cancer cells to model the activity of the therapeutic agent. However, it has become clear that these data are not sufficient alone to predict effect of these agents in humans. Furthermore, in order to understand the toxicity of these therapeutic agents, an intact biological system is needed to identify and explore unexpected effects on target and non target organs. We would replace animals wherever possible, e.g. numerous biochemical and in vitro cellular assays will be used to select the optimal agents, for progression into in vivo studies.

If we did not use animals for these studies there would be two main consequences: firstly agents with sub-optimal properties would be administered to sick cancer patients, which would be ethically unacceptable and secondly, potentially toxic agents would be administered to patients, who are already unwell as a result of their disease state.

Which non-animal alternatives did you consider for use in this project?

Organoids and other 3D cell culture systems.

Why were they not suitable?

Currently they are poorly predictive of clinical efficacy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on typical study design and number of projects predicted over the next 5 years and underpinned by knowledge gained through 20 years of experience of completing similar studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Extensive previous experience of designing studies of this type.

The models are reproducible, so we are able to use the minimum number of animals.

The minimum number of animals used is also underpinned by an understanding of the variation between animals, with statistician advice sought when needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies are frequently used when developing models and sharing of model information with collaborators to reduce the overall number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In terms of welfare the least invasive model will be used in the first instance. Similarly for administration of therapeutic agents, the least invasive route, e.g. oral, will used where possible. Mice will be monitored closely daily for any adverse effects of treatments.

Why can’t you use animals that are less sentient?

The mouse is used for evaluation of new cancer chemotherapeutic agents as it is well validated both in the scientific literature and by the pharmaceutical industry. Tumours derived from human cell lines can be readily grown in immunocompromised mice and this provides a means of demonstrating proof of concept of the agents of interest. Mice are well established for such procedures, relative to a simpler organism such as the fish, due to the intact immune system (for immunocompetent mice), circulatory system and presence of mammalian organs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continually review our peri- and post- operative care procedures and each of the PPLs learn from each other with respect to procedures and refinements. Our NACWO/NVS/NIO attends regular national meetings and provides us with feedback on learnings.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We focus on best practice guidance published by Workman et al., Br J. Cancer, 2010. In addition, regular literature reviews will be completed to ensure that our work aligns with current best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By regular discussion with the NIO, NACWO and NVS in addition to receiving regular updates from NC3Rs. 3Rs are also an item agenda during our quarterly AWERB meeting.

145. Generation, maintenance and archiving of genetically altered mice

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Disease model, Genetically modified mouse, Embryonic stem cells, Embryo transfer, Cryopreservation

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To generate, breed, distribute and archive genetically altered mice and to supply them for biomedical research.

To develop and implement new technology for the genetic engineering of the mouse.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically modified mice help advance our understanding of normal and pathological biological processes, revealing new targets for drug discovery. They serve as models for human disease, aiding the treatment and prevention of human disease through discovery and development of novel therapies and diagnostic tools.
What outputs do you think you will see at the end of this project?

New insights into the function of genes or the significance of mutations in health and disease

New mouse models of human disease

Refined and more accurate technology

An archive of cryopreserved gametes and embryos

Who or what will benefit from these outputs, and how?

Genetically altered mouse models generated could provide short-term impacts in our understanding of disease biology, the assignment of novel targets for future drug discovery and a basic scientific understanding of normal and pathogenic biology. Long-term impacts would concern the use of the genetically altered mouse models for preclinical drug discovery and novel diagnostic tool development.

With respect to technology development, short-term/medium term benefits would be more predictable and accurate models, reducing the variation in outcome and thus reducing the number of mice that need to be bred and analysed in an experiment. The archive of cryopreserved gametes and embryos has the short-term benefit of avoiding redundant breeding of genetic models when there is no active experimental need for their continued use. Medium term benefits thus amount to a reduction in animal numbers and considerable savings in research costs.

Biomedical research groups focused on understanding biology and treating human disease will benefit from the outputs, offered as a service. The service work carried out under this license will supply mice that will be used on other project licenses that have had their harm-benefit positively assessed by the Home Office. The work on this license will therefore also contribute, indirectly, to the scientific benefits accrued by these other licenses that receive mice from this license.

How will you look to maximise the outputs of this work?

We plan to publish our technical development, both positive and negative, in peer-reviewed journals and at scientific and technical meetings. Genetically altered mouse models that are generated on this license are transferred to end user licenses, and published once the models are fully characterised. We track all models generated to ensure publications result.

Species and numbers of animals expected to be used

- Mice: 28700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages?

Mice are the animal of choice for this project as more is known about their genetic makeup than any other animal and despite appearances, they are genetically very similar to

humans. The mouse can serve as an accurate model of human disease - more often than not, mutations that cause disease in humans, result in similar pathologies when the equivalent mutation is introduced into the mouse.

Embryonic, neonatal and adult life stages will be addressed in this project, as gene mutation can have consequences on all developmental stages of the animal.

Typically, what will be done to an animal used in your project?

Female mice will be hormonally stimulated by two intraperitoneal injections, and sometimes bred with male mice. Mice will be killed and oocytes or preimplantation embryos isolated. Embryos and oocytes will either be cultured and/or genetically manipulated for example by microinjection or electroporation, or oocytes will be used for in vitro fertilization. Female mice will be anaesthetized and embryos surgically implanted. Male mice will be anaesthetized and vasectomized. Both male and female genetically altered mice will be bred to obtain appropriate genotypes and maintained to up to 15 months. Substances may be administered to mice by injection, gavage, or in the drinking water to induce genetic manipulation at a specific time point or developmental stage.

What are the expected impacts and/or adverse effects for the animals during your project?

The mice undergoing hormonal stimulation or induction of a genetic alteration will experience no more than transient discomfort and no lasting harm. Mice undergoing surgical procedures for embryo transfer and vasectomy will experience short-lived post-operative pain and discomfort, which will be ameliorated by the use of appropriate analgesia. The majority of the mice with genetic alteration will be indistinguishable from normal mice, but certain gene mutations could lead to long-lasting mild suffering e.g. behavioural changes, altered immune function, sensory disturbances or weight gain/loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

50% subthreshold

35% mild

15% moderate

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To understand the complexity of biological processes and to model human disease, it is not possible to rely on cell-culture or computer simulations alone. The effects of genetic alteration on a living organism can be essential to understand the complex interactions that occur. For example when trying to understand neurodegeneration, it can be important to study the behaviour of mice, which can only be done using live animals.

Which non-animal alternatives did you consider for use in this project?

We actively pursue the use of stem cells to model human disease in the dish, and apply many technologies for genetic alteration in this system to explore gene function and mutation. In addition, human patient data can provide information about the significance of mutations or the likely role of particular genes.

Why were they not suitable?

Stem cells can be differentiated to mature types of cells, e.g. neurons, heart muscle cells, but the cells produced are immature and more similar to embryonic stage cells. Experimental results obtained with stem cell-derived cells may not be accurate reflections of the situation in adults. Furthermore, certain biological processes cannot be easily modelled in vitro, for example aspects of the immune system or any brain-behaviour studies.

Human patient data is informative but it is an observational science and discoveries cannot be experimentally validated. A model system for experimental manipulation is thus required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Providing this service to the institution over the past 15 years has allowed us to quantify the service need and thus to estimate the number of animals we will require for the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The BVAAWF/FRAME/RSPCA/UFAW Joint Working Group framework guidelines (Altern Lab Anim. 2004 Jun;32 Suppl 1A:373-5) has been used to ensure that the number of animals used for the generation of genetically altered mice is appropriate.

For experimental proof-of-concept work, the ARRIVE2.0 guidelines will be followed and comprehensively reported in resulting publications.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of mice have been reduced by maximizing the efficiency of the various experimental steps. The age, strain and commercial source of mice undergoing hormonal stimulation for the generation of good quality embryos have been optimized to ensure a maximal yield per female mouse. Specifically, female mice at under 28 days of age will be used, as this ensures at least double the yield of embryos when compared with using older mice and in vitro fertilization efficiencies are higher when using oocytes from mice of this age (Kolbe et al., 2015 Lab Animal volume 44, pages 346–349).

Similarly, for the procedures that achieve the genetic manipulation of the embryos, the quality and validation of the stem cells and injection material used has been optimized to reduce the number of embryos that need to be manipulated, which then reduces the number of embryo transfer procedures that need to be performed. Breeding procedures have been optimized to ensure no redundant breeding and the efficient use of the mice generated.

Embryo and mouse production and breeding will be tracked using an online database that helps monitor the efficiency of the experimental work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will predominantly use inbred or hybrid strains of laboratory mice that are of defined genetic background and are not associated with any harmful effects. When mutations need to be generated on a pre-existing disease model, for example a non-obese diabetic model , we will select only established models at the appropriate age before the onset of any pathology, thus avoiding any pain, suffering, distress or lasting harm.

The surgical methods we will perform - embryo transfer and, on occasion, vasectomy - will be performed using the most refined and appropriate aseptic technique. Where appropriate non-surgical alternatives to these procedures will be employed, for example non-surgical embryo transfer when transferring late-stage embryos, or the use of naturally sterile mice.

Why can’t you use animals that are less sentient?

A mammalian model is required for an accurate modelling of many aspects of human health and disease, e.g. immune function, psychiatric/behavioural research, mammary biology etc. Immature life stages cannot always been used as adult stages are necessary to explore biology associated with diseases that manifest later in life.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Surgical procedures will be performed with peri- and post-analgesia, and post-operative care and regular monitoring will be ensured. Surgical vasectomy will be refined by the use of naturally sterile mice. Surgical embryo transfer will be refined by the use of non-surgical techniques, where possible, for later stage preimplantation embryos.

For technology development, gene manipulations that are associated with simple non-invasive read- out e.g. coat colour will be used for proof-of-concept models.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidance and reports from the NC3Rs, norecopa and Laboratory Animal Science Association, including their “Guidelines on Aseptic Surgery”. In addition, we will follow the appropriate newsgroups and publications of the International Society for Transgenic Technologies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are very active in contributing to and attending 3Rs events, both locally, but also nationally e.g. Laboratory Animal Science Association and Internationally e.g. GV-SOLAS (Germany), International Society for Transgenic Technologies Annual Meetings.

146. Role of autophagy during tumourigenesis and tissue homeostasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Tissue health, Cancer, Treatment, Cellular pathways

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall purpose of this project is to investigate how tissue health is maintained by cellular degradation pathways and how they implicate tumour initiation, maintenance and treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding how normal cells in our body function and what goes wrong in diseased cells (e.g. cancer cells) are important to develop better treatment options for various illnesses. This project aims to study one cellular mechanism, known as autophagy, that maintains normal activities of cells but can also be disrupted during disease.

What outputs do you think you will see at the end of this project?

This project aims to better understand how cells maintain their normal function and prevent the onset of disease. The project will also investigate how diseased cells, such as in cancer, can grow uncontrollably and resist therapy. Success of this project will lead to publications and the potential identification of better treatment options.

Who or what will benefit from these outputs, and how?

The proposed studies have a wide range of academic beneficiaries both within the same field and from other disciplines as well as local and external institutions. These are described as follows:

Members of the academic community, particularly those involved in autophagy (a cellular mechanism involved in recycling of material) and cancer research, are a target audience that will directly benefit from outcomes of the proposed work. The project will primarily increase scientific knowledge in these fields. The findings from this study will be disseminated through publications, meetings and seminars, which are expected to take place within the 5 year time period of this study.

The proposed study will also generate valuable and broadly applicable research tools that will be of interest to the wider research/healthcare community. The research tools include a mouse strain that allows temporal or tissue-specific regulation of genes and cancer-initiating cells which have been extensively characterised (genetically and molecularly). On the longer time scale towards the end of this project, we expect that following deposition of generated tools, models and reagents in established and easily accessible repositories there will be lasting impact and availability of these valuable resources for future projects facilitating reproducibility and extension of the work in this field.

Detailed molecular studies of the tumours derived from the animal studies and their relationship to specific genetic mutations involved in human disease have direct clinical impact and can improve treatment strategies and the understanding of survival pathways.

Clinicians interested in cancers (particularly brain cancers) and novel approaches to cancer therapy and personalised treatment will also benefit. This is largely due to the potential of repurposing drugs that can regulate autophagy or key pathways that are regulated by autophagy (identified through our wet lab studies).

In the long term we will partner with pharmaceutical companies to develop and test the benefits of identified autophagy inhibitors in the clinic (potentially beyond the time period of this application).

How will you look to maximise the outputs of this work?

The outputs of this work will be optimised through various ways:

Collaborations with labs that have established expertise in the proposed work (e.g. model generation, methods or data analyses) are currently ongoing as necessary.

Dissemination of research output prior to publication (for e.g. via meetings) is crucial to ensure progress of work and optimal use of methodologies and reagents. Publication of established work will be important to facilitate the research of others and avoid redundancy.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice in our research as they have been extensively utilised and can closely recapitulate human disease. Numerous well characterised mouse models exist to study cancer biology and various forms of disease. Mice will be used at neonatal, juvenile and adult life stages. Neonates will be mainly used in experiments involving intracranial tumour initiation where gene expression is optimal allowing efficient uptake of exogenous agents. Juvenile and adult mice will be used for most experiments involving transgene induction, disease development and drug treatment.

Typically, what will be done to an animal used in your project?

Animals used in this project will undergo injections of substances (through various routes) and will be culled using established humane methods. Typically, animals will be injected with cells (for example cancer-initiating cells) intracranially and monitored for signs of tumour development. These include neurological signs, lethargy, poor grooming, reduced movement and hunched posture.

All experimental animals will be closely monitored for any adverse effects and will be culled immediately upon the onset of harmful phenotypes. Experimental durations will be short terms (around 1 week or less) and up to several months (up to 11 months of age). Animals will be analysed by imaging (under anaesthesia) and their tissues harvested upon culling.

What are the expected impacts and/or adverse effects for the animals during your project?

All methods used in this project will follow established techniques to minimise the impact on the animal’s welfare. Most injections will be conducted under anesthesia and analgesia will be used to reduce any post-surgical pain.

The main adverse effect of this project is tumour formation which will be induced in a way to closely resemble what is observed in the clinic. Mice will be monitored closely for signs indicative of disease formation and will be culled immediately to minimise their suffering. Veterinary surgeons and experienced animal care staff are always available for advice and help since the welfare of the animals is of major concern to us. Despite optimised injection protocols performed by other groups to obtain efficient tumour growth and minimise adverse effects on the animals, there is a potential for some mice to experience sudden death due to cerebral tumour development without prodromal clinical signs. We do not expect this to exceed 5% of the animals injected with tumour-initiating cells (our current injections in neonates resulted in an incidence of ~2% sudden death during >1 month after initial injection). All experimental animals will be culled at the end of the experimental duration.

The majority of substances administered will already be in use in rodents studies and have information on doses and adverse effects available. We will make use of the information. In cases were adverse effects are not known, animals will be closely monitored following treatments in line with advice from local vets.

Imaging techniques are not expected to cause adverse effects other than those associated with anaesthesia. Animals will be closely monitored while undergoing imaging and body temperature will be maintained.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severities will range from moderate to mild for all procedures involving mice in this project, based on previous research 20% animals experience moderate severity and 80% experience mild. Unexpected deaths as a result of surgical intervention will be monitored and appropriately reported.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Various aspect of disease biology, such as tumour microenvironment and metastasis can strongly influence tumour growth and response to treatment in patients. While some of these aspects can be mimicked using in vitro studies using cell culture systems (e.g. anchorage independent growth in soft agar, oxygen and nutrient withdrawal, and transwell migration assays), accurate modelling of tumour growth cannot be recapitulated using non-animal systems. This is especially important when studying cellular processes which are frequently activated under many of the conditions observed in vivo.

Which non-animal alternatives did you consider for use in this project?

Human- and mouse-derived ex vivo tissue investigations and production of long-term cell culture lines, which may ultimately replace some of our in vivo model systems. We have recently considered using patient-derived stem cells to investigate tumour growth pathways.

Why were they not suitable?
The ex vivo models exclude all potential extrinsic factors that influence disease development and are likely only models in complex organisms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate have been derived from previous studies in the lab and based on publications utilising similar proposed models. To stay updated on optimized experimental design, we will regularly seek guidance from biostatistical experts and estimate provided by local animal facility.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will utilise mouse models that ensures highest tumour incidence. Pilot experiments will help optimise the number of mice used and time points. The experimental group size will be determined in order to obtain sufficient numbers of tumours of a measurable size suitable for statistical analysis. We will use genetic systems to introduce genetic alterations (e.g. inhibition and/or activation of cancer- associated pathways) in postnatal animals that avoid the need for breeding thereby reducing mice numbers (breeding of different genetic backgrounds results in variable offspring genotypes some of which are not suitable for experimental use).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will implement efficient breeding procedures and will additionally perform well-designed pilot studies whenever possible to assess the potential for publishable results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen mice to use as they are the animals that are most similar to humans that are readily amenable to genetic modification – this means that, for us, they are the best model to answer our questions about cancer development and therapy. Of specific research importance are cancers of unmet clinical need including aggressive brain tumours. Researchers have developed the most refined models to study brain tumours and patient-derived gliomas are one of the few human cancers for which we can isolate, culture, and genetically manipulate primary cells as well as their genetically "normal" counterparts.

The protocols are designed to generate as much information as possible from as few mice as possible with the least harm possible. They are optimised to obtain efficient tumour formation with minimal surgical intervention and animal discomfort. Anaesthetics are used for any procedures that would be expected to cause temporary discomfort. We are experienced in most of the protocols listed and know them to create minimal suffering. Where we intend to perform a protocol that we are less familiar with, we do so in consultation with the veterinary surgeons so that suffering can be minimised.

Models that use exogenous vectors to introduce genetic alterations will follow minimally-invasive protocols that ensure least discomfort in animals.

Why can’t you use animals that are less sentient?

Tumour development and changes in tissue homeostasis occur over time and require periods ranging from few weeks to months (depending on the model). Therefore, disease progression will require monitoring mature animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any of studies involving surgical or invasive intervention will adopt appropriate pain management and post-operative care.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will stay up to date on best practice guidelines set forth and regularly updated from the NC3Rs website (Guidance on the Operations of ASPA - https://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about the advances in the 3Rs by attending informational events provided locally and provided by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs). Annual 3R-related symposia are also locally organised to help researchers share best practice and contributions to the 3Rs across various disciplines.

147. Experimental therapies in aggressive variants of prostate cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

prostate cancer, small molecule inhibitor, targeted therapies, Patient-derived xenografts, Genetically engineered mouse models

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to use animal models to test the safety and efficacy of experimental therapies for an incurable and common form of prostate cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Early prostate cancer is curable through a combination of local therapies and hormonal therapies. However, several years after treatment, some prostate cancers become progressively more resistant to any treatment and invariably fatal. These cancers are

called "aggressive-variant prostate cancer" (AVPC). There is currently no treatment for this type of prostate cancer. Here we propose to use clinically relevant animal models to test new treatments for AVPC. This will be an essential step for starting clinical trials and eventually improving the life expectancy and the quality of life of these patients.

What outputs do you think you will see at the end of this project?

Our study will allow us to test different therapies in animal models of AVP, and to assess their effects on tumour growth and on key molecular markers. Hence, these studies will provide biological insights into the molecular mechanisms of prostate cancer progression.

We expect to publish at least two peer-reviewed experimental articles deriving from these studies (one per tested compound).

We expect to obtain key information on the safety and efficacy of experimental therapies in clinically relevant animal models of AVP. This information will inform future clinical trials.

Who or what will benefit from these outputs, and how?

In the short term (2-5 years), these studies will provide insights into the molecular pathogenesis of prostate cancer, which will be published in peer-reviewed journals. Hence, beneficiaries of this projects will be other scientists and clinicians working in this field.

In the long term (5-10 years), we hope that the primary beneficiaries of these studies will be patients with incurable prostate cancer. If these studies allow us to identify promising drug candidates, we will work with our clinical collaborators to design clinical trials. Our final goal is to improve the life expectancy and the quality of life of prostate cancer patients.

How will you look to maximise the outputs of this work?

All our data and publications are freely accessible via the University portal. We will deposit all the publications in this portal, and link genomic data to appropriate servers. This will maximise the reach of our discoveries in the scientific community.

We plan to present and discuss the data at different meetings, e.g. the European Society of Medical Oncology congress, the Prostate Cancer Foundation Retreat (the Applicant has been invited to both types of meetings in the past).

We plan to use these data to strengthen our collaborative network, which include leading clinical centres in the UK and abroad. Results will be discussed with these collaborators, and where appropriate we will take steps towards clinical testing and applications.

Species and numbers of animals expected to be used

- Mice: 980

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cancer models based on cell lines are useful for initial screening of drug activity, toxicity and mechanism of action. However, these in vitro models do not recapitulate the clinical complexity of the disease (e.g. they do not account for tumour-microenvironment interactions). Hence, restricting our studies to these in vitro models might not fully elucidate the clinical efficacy of the experimental drugs. In our study, we will be using human and murine prostate cancer cells, implanted into mice. These models provide a platform for finding novel therapies to treat human patients afflicted with prostate cancer. The two strains of mice will be in their adult life stage to accommodate the size of the tumour.

Typically, what will be done to an animal used in your project?

Animals will be injected with prostate cancer cells (sub-cutaneous injection, flank) and monitored for health and tumour growth.

Animals will be randomised to receive different treatments, typically via intra-venous injections. Typically, animals will be maintained for up to 12 weeks and then humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Likely adverse effects will be mainly due to the tumour (possible weight loss, ulceration), while the treatment is expected to have mild side effects. Animals will have surgery to implant tumours just under their skin. During this procedure, the animals will be unconscious (under anaesthesia), and the recovery will be aided by giving animals analgesics and keeping them warm. The level of pain the animal will experience after the surgery will be moderate and short-lasting. There also could be a mild, long-lasting pain that may accompany the tumour growth. Animals will be euthanised at the end of the experiment or when adverse events occur, and the pain, discomfort or suffering are not controllable

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We will be using mice and expected to have moderate severities. 60% of mice will have moderate severities, and 40% will have mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Clinically relevant animal models enable experimental studies that can predict drug efficacy and safety in humans and reveal new information on their pathogenesis. Unlike in vitro models, animal models enable the study of the complex interaction between the tumour and its micro environment. Animal models also enable the study of key pharmacological characteristics of the experimental drug, e.g. its absorption, distribution in different tissues and stability in biological fluids.

For this particular study, we will employ murine cancer models. Mouse modelling has made a significant contribution to the study of prostate development and disease. The reasons for this success include:

the mouse and human genomes share more than 90% of protein-coding genes; most cancer relevant genes are highly conserved in mice and human.

mice are relatively easy to genetically modify; this allows for the generation of immunocompromised models that can host patient-derived xenografts (PDXs), and for the generation of cancer tumour allografts in immunocompetent mice (mice cancer cells implanted in syngeneic mice), which recapitulate key characteristics of the tumour micro-environment. mice have a relatively short gestation time and are small, they are reasonably easy and affordable to house and breed to generate large populations.

It has been demonstrated that murine PDXs and allografts are superior to currently available in vitro models: these systems can accurately predict key features of the human cancers, including efficacy and safety of experimental therapies. Here we propose to use the two complementary models to test our experimental therapies as accurately as possible.

Which non-animal alternatives did you consider for use in this project?

We have considered relevant websites (NC3R, FRAME) to identify alternatives to the use of animals in this specific research project. Considered alternatives included spontaneous tumour models in mammals and tri-dimensional patient-derived cancer cultures. Patient-derived cell lines will be used to perform initial screening of anticancer activity and toxicity. Only the most promising compounds will be then tested in vivo.

Why were they not suitable?

Unfortunately, none of the alternatives proposed allows for reproducible and controllable results and/or for accurate reproduction of a human neoplasm's clinicopathological characteristics. In particular, spontaneous cancer models of NEPC are extremely rare and unpredictable (variable tumour size, growth, and metastatic rate); tri-dimensional cancer cell cultures are promising, but they do not allow for appropriate pharmacokinetic and pharmacodynamic analyses, and there is no definitive evidence that they can predict patient's response to therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In a typical set of experiments, we would test up to 4 experimental drugs in separate experiments with randomisation and appropriate controls. We have planned for pilot studies for each of these treatments. Each pilot study will employ approximately 9 mice (control and 2 doses of the drug). Hence we will need up to 36 mice for pilot studies.

For the main studies, we have calculated that we will need approximately 20 animals per treatment group. This estimate is based on a sample size estimation conducted by our collaborators with bio- statistical expertise; based on the spontaneous variance of PDX tumour weight in prostate cancer models. Since we will need a total of 8 treatment groups (4 control and 4 experimental therapies) the total number of animals for the main studies is 160 (maximum). We anticipate running up to 5 sets of
experiments during the 5 years. When different therapies will be tested at the same time, we will endeavour to use one control group for multiple treatments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will employ the minimum number of animals while ensuring that scientific objectives are met. To this end, we have conducted sample size estimations, which are based on our previous experience in animal research, and on the extensive experience of our collaborators that have generated the in vivo models.

In addition, all the compounds selected for in vivo study will undergo extensive preliminary in vitro tests. Each drug candidate will be screened in a panel of normal and prostate cancer cell lines, to determine: cytotoxicity, effects on cell cycle and apoptosis and reduction of the target gene expression/activity (depending on the proposed mode of action). Compounds will be selected for in vivo studies if they meet the following criteria, based on in vitro experiments: (I) differential toxicity in cancer vs normal cells (at least twice as toxic in cancer vs normal cells); (II) confirmed inhibition and/or silencing of the validated therapeutic target; (III) activity at clinically achievable concentrations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Tumour-bearing animals will be matched by tumour size and randomised to administer treatment vs control drug. We will analyse tissues from previous experiments and from collaborators whenever possible (e.g. to confirm the expression of the target gene before selecting the appropriate in vivo model for our experiments). Data generated by this project will be publicly available. This will reduce the need to repeat experiments in the future.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will employ 2 mice models in which cancer cells are injected under the skin (flank) of a mouse: an immunodeficient mouse model for patient-derived xenograft (human tissue injected in mice) or immune-competent mouse models (murine prostate cancer cells injected in mouse). The flank injection enables tumour monitoring with minimal impact on the animal wellbeing and locomotion. We will follow appropriate guidelines to minimise animal distress by using humane endpoints. Test compounds will undergo extensive testing in vitro to determine efficacy prior to any in vivo studies. Dose rates and route/frequency of administration will be determined from available literature, if available, and from our in vitro studies. For compounds where no in vivo data is available, we will conduct small pilot studies to determine optimum dosing regimes before proceeding to full studies.

Why can’t you use animals that are less sentient?

Whilst most cancer-relevant genes are conserved between mice and humans, this is unfortunately not true for less sentient species. There are several similarities between mouse and human immune system and blood vessels, which are not conserved in other (less sentient) animal models employed in biological research (e.g. C. elegans and Drosophila melanogaster). Moreover, it is not known whether clinically-relevant mammalian prostate tumours can be grown in non-mammalian hosts, for the purposes of this study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will critically evaluate our practices on regular basis and we will constantly seek ways of conducting our research in a manner that will allow us to maximise our scientific output with minimal impact on the animal's welfare. We will apply the refinement loop technique described by other scientists, to improve all aspects of the animal's use. We will identify appropriate parameters to assess the well-being and needs of the animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?
Daily mouse appearance, activity, posture and other signs (including ulceration) will be scored, as recommended (CRUK guidelines: https://www.ncbi.nlm.nih.gov/pubmed/20502460). Administration of substances will be in accordance with best practice guidelines on maximum volumes and frequencies such as those in Wolfensohn and Lloyd (2013) Handbook of laboratory animal management and welfare. 4th Edition. Chichester: John Wiley and Sons. Surgical procedures will be performed in accordance with LASA best practice guidelines on aseptic surgery.

All animals are group-housed in filter top cages within ventilated cabinets (Scantainers) with enrichment such as tunnels, chew sticks and nesting material

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date by reading scientific articles, attending conferences and animal welfare meetings. I will also keep in touch with the named veterinary surgeon and named animal care and welfare officer. We will consult the Named Veterinary Surgeon, Named Animal Care and Welfare Officer and Named Information Officer on improving the experimental design.

148. Role of tumour microenvironment in cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, metastasis, tumour microenvironment, immune cells, immunotherapy

Animal types	Life stages
Mice	adult, pregnant, neonate, embryo, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify new (immuno-)therapeutic targets in metastatic cancers.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Solid cancers, including breast and bowel cancer, that are of main interest for our lab, represent a main cause of death worldwide. Both breast and bowel cancer are among the top 4 more prevalent cancers, still associated with high mortality rates. Current cancer mortality rates are higher than 30/100.000 for breast cancer in female and bowel cancer in males. Indeed, breast cancer, the most common cancer in women in UK, accounts for around 55,500 new cases and around 11,500 breast cancer deaths in the UK every year. Bowel cancer is responsible for around 16,600 deaths, and around 42,900 new people are diagnosed with bowel cancer in the UK every year. The economic costs associated with cancer are obviously huge, and total economic cost of cancer in UK only has been

estimated to be £7.6 billion in lost wages and benefits per year in 2020. A report in 2020 revealed that bowel cancer only costs the UK economy more than £1.7 billion a year. Costs for treatments are also massively impacting the NHS. Chemotherapy costs the NHS an estimated £1.4 billion a year (over £248 million for breast cancer chemotherapy only).

Notably, the treatment of cancer at the primary site is effective in most cancers, and particularly in breast cancer. Unfortunately, treating metastatic cancer remains a huge challenge. Indeed, metastasis represent the main cause of death in cancer and account for more than 90% of cancer-related deaths, highlighting the urgent need for novel therapeutic strategies able to effectively target metastasis.

A better understanding of the basic biology of metastasis is essential to develop new treatments. This study aims to study how different components of the tumour microenvironment (TME) co-operate to create a tumour-supportive environment, and how these tumour-promoting mechanisms can be inhibited to ultimately impair metastasis. A particular focus of this study will be the immune cells, how they support metastatic colonisation and how this support can be impaired to prevent metastasis or stop metastatic growth.

The ultimate goal of our work is the identification of novel and more effective immunotherapeutic targets to benefit a larger cohort of cancer patients, and particularly patients at risk of developing metastasis.

What outputs do you think you will see at the end of this project?

This research programme aims to better understand the interactions occurring between the cells in the tumour microenvironment and the cancer cells. In particular we will focus at the interactions occurring at different stages of metastasis to support metastatic growth and how these interactions can be impaired to prevent metastatic disease or stop metastatic growth.

This research aims to identify new therapeutic targets that will then be tested more in depth in other pre- clinical and clinical studies.

The data generated will be presented at scientific meetings and included in peer-reviewed publications.

Who or what will benefit from these outputs, and how?

I expect that the research outputs generated with this research will lead to scientific publications and therefore be shared to benefit the whole scientific community by the end of this 5-year research programme.

Moreover, the experimental data generated will be routinely presented and discussed at Departmental meetings in the Institute during these 5 years, as well as presented at Cancer conferences. This will help fostering scientific collaborations to accelerate the generation of new knowledge in the field.

How will you look to maximise the outputs of this work?

I have already started several collaborations to help maximising the impact of our work in cancer research, both within the Institute as well as other research Centres in UK.

Moreover, the generation of new scientific data and the possibility to present them at local as well as international conferences will help to integrate our knowledge with others' and get mutual benefits for the progress of our investigation.

Species and numbers of animals expected to be used

- Mice: 8100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We aim to study cancer initiation and progression, with a particular focus on metastasis, the spread of cancer from the primary sites to distant organ. While treatment of cancer at the primary sites has significantly improved life expectancy in patients in most cancer, metastasis still remains largely uncurable, accounting for more than 90% of death in cancer.

A particular focus of this study will be the immune cells within the tumour microenvironment, with the ultimate goal of identifying new immunotherapeutic targets in metastasis.

To study a systemic process involving multiple organs, such as metastatic cancer, a living organism is needed. We will use mice as a model of disease onset and progression as these are the smallest living creatures that can faithfully mimic what is happening in human disease.

We will mainly use adult mice as they will have a fully developed immune system, one of the key features that a tumour 'hijacks' in order to grow and spread.

We will also use mice that have been genetically engineered to develop cancer. The types of mutations introduced into the mice are usually designed to mimic human disease. This is a key requirement to obtain scientific results that will ultimately benefit cancer patients.

We also aim to use in this study inducible genetic mice, where genetic changes can be induced after the administration of a drug. This will allow to switch on or off specific genes that may play a key role in cancer initiation and/or progression.

Typically, what will be done to an animal used in your project?

Breeding: genetically modified mice will be bred under this licence to study the effect of specific molecules in cancer disease. This will include tumour mouse models.

Breeding: genetically modified mice will be bred to study the role of specific molecules in cancer disease. We will also bread tumour-bearing mouse models. Mostly we will be using models where heterozygous females spontaneously develop tumours in the breast. These tumour-bearing animals will be mostly used for tissue collection.

A minority of genetically modified tumour-bearing mice will be administered treatments in order to impair tumour initiation and/or progression.

To generate tumour growth at the primary site, we will also be administering cancer cells to the mice, typically by injecting cells subcutaneously or in the mammary gland once. Occasionally one injection on each flank may be required. These procedures will be done under general anaesthesia. As I have refined injections in the mammary fat-pad without need to expose the mammary gland, we do not expect these administration routes, subcutaneous or fat-pad, to require surgery.

We will also inject cancer cells via a route deemed to promote metastasis, most commonly intravenous injection. Intrasplenic injections to study liver metastasis will also be used. These will be done under anaesthesia. More commonly this procedure will be carried out using a non-surgical image- guided injection of cells into the spleen. Some animals in b), c) and d) will also receive therapy by mouth or by injection and will be monitored for any side effects. These animals may also be monitored by in vivo imaging for disease regression/progression. Animals will be anaesthetised using inhalation anaesthesia for minimally-invasive imaging (typically 30 min - 1 h duration) Most experiments will be finished within a month from the start of the treatment, when the animals will be humanely culled and their tissues collected for analysis.

Treatments, including the use of therapeutic drugs may be administered at any stage via different routes to animals. Doses know not to cause adverse effect to the animals will be used. Where a drug and/or dose is not known we will use a small pilot study to determine a dose that is both well tolerated in the mice while still showing effective results that will support objective.

I have started to use mouse models to study metastatic cancers in 2012 and I have direct experience in using most of the cellular cancer models that I am proposing in this application. I am therefore familiar with the timings of disease progression. In experimental cases where timelines of metastatic lesion appearance are unknown, animals will be closely inspected for any clinical signs or symptoms of disease. Manual health monitoring at this stage may be complemented by imaging modalities where appropriate.

When studying metastasis, in most cases we will focus on early metastasis. Therefore, animals will be usually culled at a stage when they have micro-metastases. At this stage we do not expect the mice to experience any discomfort due to the metastatic growth.

Aged mice: in a small number of experiment (<10% of mice in Protocol 5), aged animals (older than 15 months) may be used. Tumour growth will be induced in this mice by cancer cell administration, typically via intravenous injection, to study lung metastasis. Administration of cancer cells via subcutaneous or orthotopic injections in the mammary gland may also be used.

What are the expected impacts and/or adverse effects for the animals during your project?
No harm or adverse effect is expected from breeding.

Animals should experience no more than transient discomfort due to injections or imaging/anaesthesia. Anaesthesia times will be kept to minimum requirements to ensure fast recovery. Tumour growth and metastasis may cause long lasting mild or short term moderate discomfort including weight loss and short term pain but animals will undergo

daily welfare checks for clinical signs and will be humanely culled to prevent any effects beyond moderate.

In the experiments with aged animals we will use more specific monitoring for aging mice (Wilkinson MJ, et al. Progressing the care, husbandry and management of ageing mice used in scientific studies. Laboratory Animals 2020 54:225-238). Importantly, aged animals will not experience higher degree of severity. More details will be given in Protocol 5.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals are expected to experience mild-to-moderate severities, mainly due to tumour growth at the primary or metastatic site. Mice that will be used for breeding in Protocol 1 are expected to experience only mild severity due to tissue biopsy needed for genotyping.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are essential for studying complex diseases such as cancer; and a requirement for testing pre-clinical and promising scientific therapies that we would hope to translate into patients.

This work in particular aims to study the immune cell response during the metastatic process, in order to understand how the tumour microenvironment supports metastatic initiation and progression, and how this support can be blocked to impair metastasis.

Since metastasis is a systemic disease, involving the entire organism, living animals are required. I will be using mice, as animal model. Mice have a short life span, fast reproductive rate, known genetic background, close genetic and physiological similarities to humans, and recapitulate many aspects of the genesis, progression and clinical course of human cancers. Of particular relevance for this work, extensive literature supports the value of using mice as model system for immunological studies in cancer, thanks to their ability to recapitulate many features of the human immune system. Indeed, research on mice has hugely contributed to our knowledge on cancer and immunology.

Which non-animal alternatives did you consider for use in this project?

We have previously optimised a 3D co-culture system on a scaffold to mimic the metastatic environment in the lung and study inter-cellular interactions between three different cellular components. This system will be instrumental to validate in vitro the role

of molecules influencing the inter-cellular cross-talk that will be identified by in silico analysis.

Moreover, we are currently establishing more 3D in vitro co-cultures and assays, by mainly using tumour spheroids, to assess how the perturbation of inter-cellular interaction affects cancer cell proliferation and invasion in vitro.

Also, in collaboration with other research groups in the Institute, to help answering some of our questions about immune-stromal interactions in cancer, we will be using de-cellularised tissue models they have been recently established.

Why were they not suitable?

In vitro systems to study inter-cellular interactions in cancer have been established and some relevant to our studies (eg. heterotypic 3D co-cultures) will be certainly used.

However, since metastatic cancer is a systemic disease involving multiple organs, these in vitro systems have major limitations when studying the role of the tumour microenvironment. Indeed, these in vitro platforms do not entirely recapitulate the complex and dynamic interactions occurring in cancer, and particularly in metastasis.

This is particularly relevant when studying the role of immune cells, including immune cells derived from the bone marrow and recruited to the tumour site, is needed. The in vitro systems are certainly valuable and we will also use some to refine and reduce the number of mice required in this study. However, the validation of in vitro findings to assess their relevance in metastasis is still necessary to draw biologically relevant conclusions and strongly support the anti- metastatic potential of the new identified therapeutic factors for future clinical studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers in experimental groups are estimates based on the size of the effect that we expect to see between our various test conditions, standard agents and controls (using our own previous data, pilot data and/or that seen in the literature) and individual variability within groups, and will be different for each experiment.

I have based our estimates of animal numbers on previous studies I have performed during my post- doctoral studies where I have used most of the experimental setting I am proposing to use in this application.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments will be carried out following good laboratory practice. All experiments will be designed after careful examination of the literature, with regards to treatment i.e. drug dosage, treatment regime and with the aid of the NC3R's Experimental Design Assistant. Whenever possible use of in vitro assays will reduce the numbers of animal required. Notably, I have previously set-up a 3D co-culture system on a scaffold to mimic the metastatic environment in the lung. Moreover, we are currently optimising in vitro assays by using co-cultures with tumour-spheroids and we are planning to develop similar platforms by using human cancer cell lines and immune cells isolated from human blood.

The combination of these approaches will reduce the number of animals required in our studies, by having the possibility to perform valuable preliminary screening in vitro.

Ultimately, the potential therapeutic targets we will identify in our studies will needed to be tested in vivo. However, the minimum number of animals will be utilised for each experiment performed under this Programme of work while maintaining a reliable and measurable output.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of the experimental setting I will be using in this study have been previously optimised during my post-doctoral studies.

In case new setting, as well as cellular models we have not previously used, are needed. We will refer to existing literature to design small pilot experiments to identify the most suitable setting (i.e. the number of cells to inject, the number of days needed to grow micro-metastasis, etc) for our experimental needs.

To ensure reproducibility of results, standard operating procedures are usually followed to minimize confounding variables such as using animals of the same genetic strain, of similar weight and age. Also, similar housing conditions will be ensured. Importantly, mice will be randomly assigned to different experimental groups, and researchers blinded to test treatment allocations.

Where high skill is required for a procedure (eg. echo-guided intrasplenic injections) we will plan to have the same personnel performing it in the different experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Spontaneous tumour development models - These mice will naturally develop breast cancer so that we can investigate the biology of the developing disease and test our treatments in a model that most closely matches the human disease. Usually these mice

do not develop any pain or discomfort as a consequence of their developing cancers and we will cull the animals before such discomfort occurs due to tumour size.

Metastatic colonisation model - Intravenous or intrasplenic injections will be used to seed the cancer cells at the metastatic sites, in order to study metastatic colonisation and progression. In most cases we are going to study early metastasis and will cull the animals when they have micro-metastases. At this stage we do not expect the mice to experience any discomfort due to the metastatic growth. When case mice growing metastases at later stages are needed, we will terminate the experiment at a time-point where mice are not showing any clinical signs of pain due to the cancer growth. However, the mice will be closely monitored daily and they will be culled if they present clinical signs due to the tumour growth.

Syngeneic tumour implantation (subcutaneous and orthotopic) - Cancer cells will be transplanted to generate primary cancer growth. Orthotopic cancer implants are within the organ of cancer cell origin, while subcutaneous injection of cancer cells will be performed on the side flanks of the mice. I have refined mammary procedure to inject without need for surgical incision. In longer term studies, mice will be monitored with ultrasound or MRI imaging to measure cancer growth. Immunocompromised models - Immunocompromised mouse models will be used to help differentiating the contribution of the innate immune system to the tumour initiation and progression. These animals will be housed in individually ventilated cages to limit pathogen exposure and subclinical disease.

Why can’t you use animals that are less sentient?

To study the dynamics of a systemic disease such as metastatic cancer, and how the disease progression can be altered by using therapies, in vivo models are still necessary.

We will be using mouse models, as less sentient animals often diverge from their similarity to humans genetically. Moreover, as this study aims to identify new immune-therapeutic target, mouse models will be extremely valuable. The choice of mice as model organism is well-supported by literature showing their value as model system for immunological studies in cancer, thanks to their ability to recapitulate many features of the human immune system. Indeed, research on mice has hugely contributed to the development of current immunotherapies that are benefitting millions of cancer patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To limit severity in our cancer models we will:

measure tumours regularly to prevent tumours exceeding the mmaximum authorised size and close monitoring for tumour ulceration and /or impact on nearby tissue that could impaired animal wellbeing and /or long term pain.

determine humane endpoints to minimise severity beyond moderate clinical signs while delivering valid scientific outcomes

use fluorescently labelled cells to image mice for tumour spread and metastasis, as a valuable refinement and reduction approach.

perform pilot studies on orthotopic cancer models when needed, to characterise kinetics of tumour growth and metastasis.

Mice growing a primary tumour as well as mice who undergo experimental procedures such as surgery or injection of tumour cells to generate metastasis, are monitored daily for any adverse effects to avoid suffering at all times.

Notably, I have started working with mouse models of metastatic cancers in 2012 and have extensive experience of working with most of the models I am proposing to use in this application, and I am aware of health problems the mice could develop and can take timely action to minimise suffering, to ensure pain relief is quickly administered whenever necessary. Moreover, we have clear guidelines on humane endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have been following the ARRIVE guidelines when planning the proposed protocols and will follow the most up to date version (ARRIVE guidelines 2.0) published by the NC3Rs.

We will also make use of the Experimental Design Tool (https://eda.nc3rs.org.uk).

Attalla S, et al. Insights from transgenic mouse models of PyMT-induced breast cancer: recapitulating human breast cancer progression in vivo. Oncogene 2021 40:475-491. This work gives clear indication on the MMTV-PyMT mouse model, the main spontaneous model of metastatic breast cancer we will be using.

Morton DB, et al. Refining procedures for the administration of substances. Report of the BVAAWF/FRAME/RSPCA/UFAW Joint Working Group on Refinement. British Veterinary Association Animal Welfare Foundation/Fund for the Replacement of Animals in Medical Experiments/Royal Society for the Prevention of Cruelty to Animals/Universities Federation for Animal Welfare. Laboratory Animals 2001 35:1-41. This work’s guidelines will be closely followed when the administration of substances is required.

Wilkinson MJ, et al. Progressing the care, husbandry and management of ageing mice used in scientific studies. Laboratory Animals 2020 54:225-238. This work gives specific guidelines when working with ageing mice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our team will be using the NC3R's website as a source of current guidelines. In addition, our on-site Veterinarian typically informs all licence holders of new advances in the 3R's. Moreover, we will benefit of an Animal Technician Service on site that will suggest amendments to Procedures, for the benefit of the 3R's.

149. Neural correlates of motor control and their application to Brain-Computer Interfaces

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

brain, movement, neurons, neuroprosthetics, brain-computer interfaces

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how the brain controls a wide range of skilled movements. In parallel, we will apply our findings to develop a novel “brain-computer interface” that enables users to mentally control an external device more naturally.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Movement is how we interact with the world and others. A variety of diseases and neurological injuries partially or completely impair our ability to move. These conditions are very prevalent: as many as one in four people over fifty years of age suffer from a movement disorder. Brain-computer interfaces (BCIs) that control external devices by "reading out" the user’s intent from brain recordings hold great promise to help this large group of patients. But improving these BCIs so they can become widely used in clinics requires improving our understanding of how the brain works. The proposed research will help us understand how different parts of the brain work together to cause movement. In

parallel, we will combine these findings with technological advances to develop BCIs that are more intuitive to control.

What outputs do you think you will see at the end of this project?

The goal of this project is twofold: 1) to learn about how different parts of the brain work together to control movement; 2) to apply these findings to explore new ways of “reading out” someone’s intent from brain recordings and use them in new “brain-computer interfaces” that are easier to control.

As part of our first goal, we will generate new information in the form of datasets and mathematical analyses that will be published in scientific journals and discussed at scientific conferences. These findings will provide better understanding of how groups of neurons from different regions of the brain learn and control our movements.

As part of our second goal, we will provide a comparison of how well a subject’s intended action can be detected from these different regions of the brain. These results, which we will also publish in scientific journals and present at conferences, will inform the design of future "brain-computer interfaces" that enable paralysed individuals to control devices using their thoughts.

Who or what will benefit from these outputs, and how?

In the short term, the scientific community will benefit from the new data and knowledge on how the brain controls movement we will produce. We will seek to further the impact of our work by making the data available to both current and new collaborators.

In the medium term, these results may be useful for the growing number of companies developing on “brain-computer interfaces”, devices that allow paralysed individuals to control computers or robots with their thoughts. These companies may use our results to identify new brain regions to record from and improve the performance of their products. This way, our results could enable better technologies that improve the lives of people with conditions such as stroke or spinal cord injury.

How will you look to maximise the outputs of this work?

Findings will be made available to other scientists through publication in preprint servers and open- access journals, and through presentations at scientific conferences and meetings. Experimental data will be shared with collaborators.

Species and numbers of animals expected to be used

- Mice: 2100
- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

We require the use of an animal model to achieve our two goals: 1) understanding how the brain controls movement and 2) developing a novel “brain-computer interface” that enables (paralysed) users to control an external device with their “thoughts” in a more natural way. We will be using adult rats and mice as both their behaviour and the organisation of their brains are similar to ours, while being a low order animal. Any non-protected animal alternative would be an inadequate model because their brains are too different from the human brain to be able to translate our findings.

Typically, what will be done to an animal used in your project?

During a 1–2 h surgery, we will implant a device that allows "connecting" a mouse to a system that records brain activity during movement. Afterwards, we will train the animal over several experimental sessions to perform a task (typically, daily over one or two weeks depending on the complexity of the task). Our tasks, which are designed to understand how the brain controls movement, include running on a treadmill either spontaneously or following sounds or pleasant odours, as well as picking up treats or using a joystick.

Following this training period, we will carry out a second 1–2 h surgery to make a small window in the skull to gain access to the brain. These mice will then undergo experiments in which we will record brain activity during movement, to understand the relationship between the two. Brain recordings will be typically performed with very fine electrodes that are inserted at the beginning of the session and removed at the end, without causing any harm to the animal, following well-established practices in the field. In some days, mice will control a "brain-computer interface" using these same recordings, e.g., to "mentally" regulate the frequency of a sound and bring it to a target value to receive a reward. The combined duration of these experiments, which will be carried out five times a week, will typically be under one month.

Some of these experiments will require mice to perform many repetitions of a laboratory task, for example to study how a skill is developed over time. To get mice to practice a task many times, we will have to limit their access to fluids while they are in their cage: instead, mice will get a fluid reward after each successful trial in the laboratory. We will ensure that each mouse receives the appropriate amount of fluid every day by giving them an extra volume to achieve a healthy minimum, when necessary.

Answering some of our scientific questions does not need recordings during behaviour. In this case, we will perform brain recordings under anaesthesia from which the animals will not wake up, to minimise suffering.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will have two surgeries to implant a device that allows "connecting" them to the recording system, and to make a small window in the skull, respectively. They are expected to recover quickly and will be given painkillers and post-operative care just like people recovering in hospital.

Neither the behavioural experiments nor the brain recordings will lead to any negative effects. In fact, in order for us to study how the brain controls movement, we need mice to engage in behavioural tasks, which they only do if they are healthy and feel comfortable in the laboratory.

As mentioned above, a subset of all mice will undergo fluid control to get them to practice a given task repeatedly in the laboratory, which is crucial for us to understand how skills are learnt. This is a well- established approach in the field and, even if animals lose a bit of weight early in training, they adjust rapidly to this schedule and go back to their normal weight usually within a week. In the extremely rare occasions in which mice do not recover their weight, they will be culled.

Animals only participating in experiments under anaesthesia will be culled without regaining consciousness and thus will not suffer any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 95 % moderate suffering, due to the implants for behavioural and brain recording. Note that mice will be closely monitored and provided with pain relief before and after surgery, and will be supervised by trained individuals.

Rats: 5 % non-recovery (they will undergo terminal experiments under anaesthesia, so they will not suffer any amount of pain).100 % non-recovery (they will undergo terminal experiments under anaesthesia, so they will not suffer any amount of pain).

All animals will be humanely killed at the end of an experiment.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We require the use of an animal model to understand the complex and unknown ways by which the brain controls movement. Any non-protected animal alternative would be an inadequate model because they do not have a brain that is similar enough to ours.

Which non-animal alternatives did you consider for use in this project?

We have considered the following alternative approaches:

- computer modelling,
- cell cultures and brain slices, and
- non-protected species.

Why were they not suitable?

Computer modelling: Where possible, we will use computational models to test hypotheses before doing experiments on animals. However, scientists do not know enough yet to simulate the entire brain and how it moves our body to answer the questions in this project only using models.

Cell cultures and brain slices: Understanding how the brain controls movement requires recording brain activity during behaviour, to identify the relationship between the two. This cannot be achieved in cell cultures or brain slices since they are not connected to a body.

Non-protected species: These species have brains that are very different from the human brain, and perceive the world and move within it in ways that are very different from ours. Thus, results obtained from non-protected species cannot be used to understand the human brain, which is our ultimate goal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The projected number of animals reflect the number necessary to achieve the scientific objectives outlined in the programme of work described in this application. We have estimated the number of mice and rats based on the anticipated numbers of experiments, the numbers of experimental groups, and the numbers of animals in each group. These estimates are based on the standard number of animals used to show big effects in our field.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We carefully plan all our experiments to minimise the number of animals we need to use to get the most information possible. In many cases, we will record brain activity from the same animal during two phases of a study. This will allow us to maximise the data generated by one animal, thus reducing the overall number of animals needed without increasing the amount of suffering of each individual animal. All experiments will be designed in such a way as to be publishable under the NC3Rs ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will take all reasonable steps to reduce the number of animals used in our project. We will collect as much information as possible from every animal, for example, by making many measurements over different experimental sessions. This will often include the same animal taking part in two phases of a study that are aimed at answering interrelated scientific questions. We will use consistent experimental techniques across studies, thus reducing variability.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and rats are the most suitable models for this type of research because they share close resemblance to human biology, and the way they perceive the world and interact with it is relatively similar to ours. Due to experimental and technical considerations, mice will be used in all the behavioural experiments, and in some experiments under anaesthesia. A subset of the studies under anaesthesia will be performed in rats, given that their bigger brains and bodies make it easier to monitor many areas of their nervous system simultaneously, which will allow us to map the sensorimotor "networks" of the brain more extensively.

All surgeries will be performed during anaesthesia. During these procedures, we will test for effective anaesthesia by assessing the toe pinch reflex, and will administer additional anaesthesia if necessary. Many of our experiments require simultaneously measuring brain activity and behaviour; during them, animals will be closely monitored by trained individuals. Some of the questions we will investigate require that the animals perform many trials during each experimental session. To achieve this, we will restrict their access to water between experiments, and provide liquid rewards after each successful trial. Importantly, we will always ensure that the animals receive at least a daily minimum amount of water that keeps them in good health. Whenever possible, we will perform studies under terminal anaesthesia, to minimise harm to animals.

Overall, animals will be constantly supervised by trained individuals and advice will be sought from the veterinary team if there is any cause for concern. We will use anaesthesia, analgesia, and humane endpoints to limit suffering.

Why can’t you use animals that are less sentient?

Less sentient animals are further apart from human biology. In contrast, mice and rats are also mammals and have brains, nerves, muscles, joints, and sensory receptors that are similar to ours. The way they experience the world and behave are also quite close to the way humans do. We need to work with animals that are fully grown both from a practical perspective and to be able to translate our results to adult humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement measures carried out in this project will include use of anaesthesia and pain-relief medication as well as enrichment of the animal's environment. We will frequently monitor animals, especially after they have received implants, and will increase monitoring

if any adverse effect manifests; depending on the severity of harm, the animal will be treated following a veterinarian's instructions or humanely killed.

Animals taking part in behavioural experiments will first be accustomed to people, to reduce their stress levels. During any such experiment, we will closely watch all animals for any sign of discomfort and distress and either stop the experiment or humanely kill any animals suffering unexpectedly.
Throughout the project, we will continue to look for new ways to refine our experimental protocols and make animals more comfortable.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published best practice guidance for how to design, perform and report experiments to the highest standard including the NC3Rs PREPARE and ARRIVE guidelines, as well as the LASA guidelines for aseptic surgery and administration of substances.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about any advances by reading scientific publications and speaking with colleagues within our own university and elsewhere, including not only other scientists but those directly involved in the care and welfare of animals. We will constantly review our protocols and experimental design to reduce, refine and replace the use of animals. We will also attend the frequent meetings held at our institution on the advances in the 3Rs and their implementation.

150. Oxidative stress and inflammation in retinal degeneration

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
mouse, retinal degeneration, oxidative stress, inflammation, therapy

Animal types	Life stages
Mice	adult, juvenile, aged, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to use mouse models for understanding the development of disease (called pathogenesis) in the following conditions: diabetic retinopathy, age related macular degeneration and retinitis pigmentosa (RP), these are major types of retinal degeneration.

Retinal degeneration refers to retinal cell loss and is a major cause of blindness in the world.

By understanding the diseases, we can develop potential therapeutic strategies for these conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

Retinal degeneration refers to retinal cell loss and is a major cause of blindness in the world. Diabetic retinopathy (DR), age related macular degeneration (AMD) and retinitis pigmentosa (RP) are major types of retinal degeneration. The disease mechanisms of these conditions are not fully understood and there is also no cure for these conditions.

DR is one of the most common complications of diabetes and the leading cause of visual impairment and blindness in the world, affecting 90% of patients with over 20 years duration of diabetes.

AMD is the commonest cause of visual impairment in the developed world.

It is important to undertake this work because oxidative stress and inflammation have been linked to retinal degeneration. By studying the role of oxidative stress and inflammation in mouse retinal degeneration models we hope to generate new insights into the molecular mechanisms underlying the development of retinal degeneration, which will lead to the identification of potential treatments.

What outputs do you think you will see at the end of this project?

The main outputs at the end of this project are expected to be new insights into the functional role of oxidative stress and inflammation in the pathogenesis of retinal degeneration. This may include the identification of novel biomarkers of disease or new drug targets. We will share this with the scientific community via peer-reviewed publications in international scientific journals and presentations in national and international conferences.

Who or what will benefit from these outputs, and how?

The main beneficiaries of the outputs generated in the period of this licence will be other scientists investigating the disease mechanisms of retinal degeneration. The data we report will provide new ideas and insights to advance their studies. The research will also benefit clinical researchers who are investigating the underlying causes of retinal disorders in patients. In addition, our research will also provide important new insights that may advance the work of others in this general area. Our work may also impact on researchers working in the pharmaceutical industry through the identification of potential new biomarkers (i.e. measurable indicators of some biological state of condition) and drug targets that can be exploited to aid disease diagnosis and treatment. There is also likely to be an impact on the third sector as we will seek to interact with relevant charities, such as Fight for Sight and Sight Research UK, as ourwork progresses.

How will you look to maximise the outputs of this work?

The outputs from this work will be maximised through a range of collaborations with other colleagues in the UK and overseas. We will collaborate with experts in a range of omics technologies (these are technologies used to explore the roles, relationships, and actions of the various types of molecules/signal pathways involved in the pathogenesis of retinal degeneration) to ensure that we develop a detailed understanding of molecular changes that are caused by deficits in disease-causing genes/proteins, which may be linked to retinal degeneration.
We will also attend relevant national and international conferences to present the results of our work as it progresses-this will ensure a constant influx of new ideas and scientific critique. This will be complemented by delivery of invited seminars at other institutions and attendance at general scientific meetings to ensure we are interacting with a broad range

of basic, translational, clinical and industrial colleagues. These fora provide an excellent opportunity to also discuss unsuccessful approaches, unexpected findings etc and to limit any duplication of effort. We also interact regularly with colleagues from other disciplines e.g. chemistry and seek to develop new or modified small chemicals to maximise our scientific endeavours.

Collectively, these approaches will ensure that any publications are of the highest quality and impact. Collectively, these approaches will ensure that any publications are of the highest quality and impact.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mouse models to investigate the underlying molecular pathology of retinal degeneration. The primary reason for using mice is the ease of genetic manipulation of this species and the ability to obtain relevant mouse models from appropriate repositories. In addition, there is an extensive literature using this species to investigate underlying causes of retinal disorders. Indeed, the main mouse models used in this work have been shown by our group and others to exhibit many of the key features seen in patients with retinal degeneration. Mice are typically used from three months of age till 15 months.

Typically, what will be done to an animal used in your project?

Typically, genetically altered (GA) or chemically-induced retinal disease mice are culled in a humane schedule 1 procedure and eye samples will be removed for analysis.

Some mice will receive drugs that cause damage to the pancreas and they become diabetic.

In addition, some mice are given treatments designed to improve the condition of the animal either in the diet, through a tube leading down to the stomach (gavage), eye drops, into the peritoneal cavity (intraperitoneal), intravenous or under the skin (subcutaneous) administration that may run for a duration of six weeks (depending on the route).

After treatment, some mice are used in a range of behavioural tests that may run for a duration of a few days. After behavioural/physiological measurements are completed, mice will be humanly culled and tissues will be taken for furtheranalysis.

What are the expected impacts and/or adverse effects for the animals during your project?

The volume and frequency of injections will be used according to local good practice guidelines.

Diet manipulation: some mice may initially show reduced food intake of the altered diet, however, with time their intake increases. To minimise this adverse effect, the introduction of the new diet will be made gradually. Animals are expected to develop high lipid levels in blood. This in turn may increase the risk of atherosclerosis and, in its wake, myocardial infarction, liver failure, stroke, pulmonary embolism.
However, in our experience, these adverse events are very rare (less than 1 in 100 animals). If any animal develops signs indicative of any of the aforementioned syndromes, it will be removed from the study and immediately culled.

Induction of diabetes: we inject a substance that will result in the destruction of pancreatic islet β-cells and the development of diabetic signs including increased drinking of water, frequent urination and reduced weight gain. The impact of these disturbances will be minimised by ensuring access to water at all times and provision of plentiful bedding (changed as often as necessary). Regular monitoring of weight will be carried out. Some animals may develop cataracts, however, this should not prevent them from accessing water or food. If any animal reaches 20% loss of its initial body weight, it will be humanely killed.

Treatment: Mice will be carefully monitored. We predict that the administration of small molecules, gene cells or natural products will decrease the severity of pathology in the treated mice. If there are any potential side effects (i.e. toxicity) caused by those small molecules or natural products, any animal displaying weight loss of 20%, and/or displaying signs of distress, piloerection and hunched posture will be humanely killed.

When work under terminal anaesthesia in involved, the level of anaesthesia will be maintained at sufficient depth for animal to feel no pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most (estimated 80%) expected to be mild; some (estimated 20%) expected to be moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

It is not feasible to produce an adequate model for a functional retina in vitro, and therefore we need to use living models. Animal usage is essential to allow us to examine the effects of disrupting specific genes or dysfunction of physiology on development and progression of retinal degeneration.
Genetically-altered mouse strains are the most frequently used animal model to study the importance of specific genes/proteins for (patho)physiology and to provide appropriate

disease models, and their use in the current project is essential. Where possible, we will complement these studies using cell lines- these are cells that have been maintained in culture for an extended period of time and are not taken from currently live animals. However, the use of animals is essential to achieve the aims of our investigations.

Which non-animal alternatives did you consider for use in this project?

I have used in vitro mammalian cell systems to characterise the functional role of oxidative stress and inflammation. I also have used stem cell model to characterise retinal disease gene function. We will continue to use mammalian cell lines wherever possible to limit animal usage. However, in vitro assays cannot adequately characterise the effects of oxidative damage and consequent inflammation.

Why were they not suitable?

Whilst analysis of cell lines can (and will) provide important complementary information, it is not possible to study higher integrated processes such as visual function using cell-based assays, and simple model organisms (e.g. yeast) lack the required complexity and physiological pathways to allow a detailed understanding of functional roles of oxidative stress and inflammation that can be translated to human physiology.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been estimated based on usage of mouse models over the previous five-year period. I anticipate that similar numbers of these mice will be used over the 5-year period of the project licence (~700 per year).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The proposed methods, experimental designs and methods of analysis of the results have been discussed with statisticians. The design of individual experiments will generally involve factorial designs, which maximise the information obtained from the minimum number of replicates. We will use the least number of animals to provide an adequate description, generally on the basis of previous experience (ours, or from the literature). In terms of the numbers of animals required, based on our previous work we expect 8 mice per analysis/treatment group should be sufficient to obtain the required results (e.g. statistical significance with one-way or two-way analysis of variance, t-test). Clearly, the exact numbers of animals required will vary with the particular experimental design, the estimate of the coefficient of variation, and so on. For the qualitative experiments, the amount of material required will be the minimum necessary to provide an adequate description.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use the same animals in behavioural tests and physiological measurements where this can be achieved without causing undue stress to the animals and without adversely affecting the outcome of experiments. Similarly, we will take any physiological measurements and tissue samples from the same animals, where this is appropriate. We will also carefully monitor all breeding animals to ensure that breeding is timed with the requirement for offspring. These steps will limit/optimise the number of animals used in this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically altered (specific gene disrupted or transgenic gene) and chemically-induced retinal disease models that we have been studying for the last five years. These mice show no obvious clinical signs or reduction in life-span. The experiments we are undertaking are either minimally invasive physiological measurement or extraction of tissue following schedule 1 killing.

These methodologies for this project are designed to minimise any distress to the animals. Some animals may receive treatment with small chemicals or natural products. Animals will be humanely killed at the end of the experiments.

Why can’t you use animals that are less sentient?

Analysis of complex visual function and analysis of development and progression of retinal diseases cannot be done using less sentient species. The mouse has been commonly used to study the pathogenesis of retinal diseases, the phenotypes of mouse retinal diseases reflect the pathologies seen in man.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is a project licence with mild or moderate severity banding, but nevertheless we will seek to implement refinements wherever possible, e.g. ensuing our breeders are at peak age for mating, that they do not have too many litters, that genotyping methods (if required) are the mildest possible.
Animals under study will be closely monitored and housed in social groups with regular health checks. We will use the least invasive route of injection whenever possible; Early end points will be used when scientific goals have been achieved.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs EDA and breeding information.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information from the NIO and review the NC3R website.

151. Mechanisms of mammalian birth defects and inherited metabolic disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Congenital anomalies, embryonic development, neural tube defects, inborn errors of metabolism, therapy

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, embryo, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project uses wild-type and genetic mutant mouse strains to determine the processes in the embryo, fetus and post-natal individual that cause congenital anomalies (birth defects) and inherited disorders of development. The work focuses primarily on neural tube defects (NTDs), other nervous system malformations and inherited metabolic disorders to improve the understanding these disorders and develop new clinical therapies for humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

Approximately, 1 in 20 babies, equating to 8 million births per year are born with severe anatomical malformations (also known as congenital anomalies or birth defects). These anomalies lead to approximately 300,000 deaths each year and are the leading cause of infant mortality in developed countries. Many children with congenital anomalies have physical and/or mental disability and require life-long medical treatment. Considering Neural Tube Defects (NTDs) alone, at least 250,000 pregnancies are affected by this crippling birth defect per year, world-wide. Children with spina bifida are often paralysed from the waist down, lack sensation in the legs, have vertebral deformities, hydrocephalus (water on the brain) and frequent kidney abnormalities. Individuals and their families with birth defects of this type have many challenges to cope with. Moreover, healthcare services incur very significant financial cost in caring for children with birth defects. Unlike most other causes of childhood mortality, congenital malformations have shown no reduction, and are even increasing in prevalence worldwide.

While secondary preventive methods (e.g. termination of pregnancy after prenatal diagnosis) have resulted a reduction in the frequency of children born with severe birth defects in some countries, a key goal is primary prevention. That is, to be able to normalise the development of fetuses with a predisposition to birth defects, enabling the birth of a healthy or minimally disabled child, and so avoid damaging effects in postnatal life. One example in clinical practice is the use of folic acid supplementation, which has significantly reduced the frequency of NTDs. However, it is unlikely that this public health intervention will eradicate NTDs, as many cases appear folic acid-resistant. Hence, new methods are needed to enable more NTDs to be prevented, and to extend primary prevention to other malformations for which there are currently no therapies available. Other disorders to be studied in this project are linked to alteration in Folate One-Carbon Metabolism (FOCM), a network of biochemical reactions that is needed in almost every cell type in the body.
FOCM is associated not only with birth defects such as NTDs but inborn errors of metabolism and other human diseases including cancers, liver disease and age-related cognitive impairment. In this project we focus on the impact of FOCM in NTDs (both as a risk factor and preventive therapy), hydrocephalus and inherited life-limiting metabolic disorders such as Non-Ketotic Hyperglycinemia (NKH).

Optimising preventive approaches for congenital anomalies requires a better understanding of their underlying causes, both genetic and mechanistic. However, understanding the causes of these anomalies in humans is challenging owing to their complex genetics and the possible contribution of non-genetic factors such as diet and environment. Hence, despite the massive accumulation of human genomics data it is not yet possible to explain the cause of anomalies in most individuals. As one means to address this gap in knowledge it is necessary to use mouse models as one of the tools to assess whether identified genetic variants are causal.

What outputs do you think you will see at the end of this project?

The present research programme uses the following genomics advances, to investigate the origin, development and prevention of birth defects:

Gene sequences as tools for identifying where and when a given gene is active in the embryo; Gene targeting methods for creating new mouse strains that either: Lack a given gene function (knockout strain) or Target loss or gain of function of a given gene in a time-dependent or tissue-specific manner (floxed alleles and Cre driver lines); New information

to be generated (and published with open access) will include: Identifying the genetic and environmental basis of congenital anomalies
We and others have identified a large number of genes for NTDs in mice of which some have also proven important in humans. Multi-gene interactions are likely to underlie most NTDs in humans, and have been studied so far only in mice. Altered folate is implicated in several congenital anomalies other than NTDs (e.g. craniofacial, limb, heart) but a direct causal relationship is unclear in many cases.

Our research plans:

New genes and environmental causes of mouse NTDs will be identified through hypothesis-led studies and through modelling of candidate mutations from human genomic studies.

Findings from mice will be extrapolated to human NTDs wherever possible. We are members of two international consortia which are carrying out genetic analysis of human NTDs. Gene-gene and gene-environment interactions will be studied by breeding appropriate mutant mice and assessing development of NTDs.

Mouse models with altered folate metabolism will be assessed to allow evaluation of potential effects in multiple organ systems implicated in human disease.

Determining the embryonic mechanisms that lead from genes to birth defects

The focus of mechanistic studies will be on closure of the neural tube, which is the precursor of the central nervous system in the developing embryo. A great deal of information is known about the three phases of neural tube closure: shaping, bending and fusion. Many critical questions remain: e.g. the molecular, cellular and biomechanical basis of each of these events, and how disturbances lead to development of NTDs.

Shaping of the neural plate will be studied in mice mutant for genes we hypothesise are key to this process, such as those in the planar cell polarity pathway.

Bending and fusion of the neural plate will be assessed by analysis of mice mutant for a variety of genetic pathways and by treating embryos with exogenous agents to disturb specific pathways. Use of advanced cellular imaging is a priority.

The adhesion and fusion of the neural fold tips is the final step in formation of the neural tube and will be analysed using genetic mutant mice and advanced imaging.

Developing new methods for prevention of birth defects

Folic acid supplementation is the only method for primary prevention of NTDs available in clinical practice. Two key questions remain: (i) How does folic acid work in the embryo? (ii) Can treatments be developed to prevent those NTD cases that are ‘resistant’ to folic acid?

Our research plans:

We are addressing the mode of action of folic acid and related molecules through studies of mouse mutant strains that develop NTDs and either respond to folic acid, or are resistant.

Our previous studies of the curly tail (Grhl3 gene) mouse mutant showed that while folic acid is ineffective at preventing the spina bifida, inositol is highly preventive when administered either to the pregnant dam or directly to the embryo. We will further examine the mode of action of inositol and other micronutrients in order to identify the molecular mechanism of prevention in the developing embryo. This work will inform our concurrent human studies, in which we have conducted a pilot clinical trial of inositol to prevent folic acid-resistant NTDs and are now starting a large-scale further trial.

We are increasingly testing other possible methods for prevention of NTDs including the use of nucleotides as an alternative to folic acid, and the possibility that formate may be able to prevent NTDs, including hydrocephalus, that result from FOCM defects.

We also aim to develop therapies which can maximise neurological outcomes for individuals who have spina bifida by administering stem cells, genetic constructs or small molecule medications to them in the womb in order to protect the nerves in their spinal cord.

Developing new methods for treatment of Non-Ketotic Hyperglycinemia

Children affected by NKH (an autosomal recessive inborn error of metabolism) suffer profound developmental delay, neurological signs and premature death. There is currently no effective treatment. We developed mouse models with mutation of the equivalent gene (Gldc), which shows similar metabolic disturbances.

Our research plans:

We are examining the biochemical abnormalities and cellular pathogenic mechanisms in Gldc- deficient embryos and post-natal mice to better inform our knowledge of the human disease.

We will examine potential novel treatments for pre-natal and post-natal aspects of the diseases using small molecule/nutrient supplements and gene therapy. This work has already yielded promising results and may lead directly to clinical translation.

Who or what will benefit from these outputs, and how?

The ultimate goal of our research is to make fundamental discoveries on the causation, mechanisms and prevention and treatment of birth defects. This will: (i) contribute to an advancement of knowledge, through open access publication in the international scientific arena, and (ii) enable translation of scientific advances into improvements in clinical practice. Specific benefits may include:

Increased understanding of human prenatal development. Because we are studying a mammalian system, i.e. mice, there is a high likelihood that the principles emerging from our research will be also applicable to the human situation. Moreover, our research can be directly transferred into studies of human embryonic development through use of the Human Developmental Biology Resource which provides human fetal material for studies of gene expression in relation to congenital disease (www.hdbr.org).

Novel methods for genetic diagnosis and genetic counselling. This clinical application should follow the identification of disease-causing genes in mice, provided the findings are confirmed in human studies. For example, families with a history of NTDs are currently given a recurrence risk, during genetic counselling, that is derived from empirical data: that

is, the population frequency of recurrence. However, if our studies lead to a new genetic test, this could predict much more precisely the risk of recurrence in a further pregnancy for any particular family.

Improved understanding of existing preventive therapies. We are particularly studying folic acid supplementation to prevent NTDs, with the goal of understanding how folic acid normalises brain and spinal cord formation in the embryo. This is an important question as use of folic acid supplements or food fortification is widespread worldwide and now being introduced in the UK. Finding an answer to this question could make it possible in future to target folic acid to specific genetic backgrounds, where there is likely to be a benefit, while seeking alternative treatments for genotypes that are non- responsive to folic acid.

New therapies for prevention of birth defects. Our work arising from mouse studies in which inositol was found to prevent folic acid-resistant NTDs was taken forward to clinical trial. A follow up study is now underway and will be underpinned by mechanistic studies in mouse. This could become a generally prescribed treatment within 5 years if the trial outcome is positive. Our research on additional nutritional interventions could further expand the scope for prevention of NTDs.

New treatments for inborn metabolic disorders. Our work on mouse models for NKH will test novel modes of treatment, such as gene therapy, that could be used clinically in years to come, if proven safe and effective.

How will you look to maximise the outputs of this work?

We will disseminate new knowledge via publication in Open Access journals, on our laboratory website, presentation at national and international conferences and via our ongoing interaction with family and support groups focussed on NTDs and NKH.

We will seek to follow-up potential translational opportunities. For example, our previous identification of a preventive treatment for NTDs in mice has led to clinical trial in the UK and a current international clinical trial. Current translational work on NKH has progressed to pre-clinical studies.

We collaborate extensively with other groups to maximise outputs from analysis of individual embryos/mice. For example, in recent studies we collaborated with groups studying skin, ear and palate development, abnormalities of which co-occur with NTDs in some mouse strains.

Species and numbers of animals expected to be used

- Mice: 45,000
- Rats: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project mainly uses mice, which are used owing to their applicability as a mammalian mode for human development and the conserved effects of genetic mutation. We use mouse strains that carry genetic mutations that predispose to NTDs or other congenital anomalies, or which carry fluorescent reporters that allow imaging or lineage tracing of selected groups of cells. Our work on neural tube closure focuses on early development. Therefore, work is mainly at stages before pain sensation has arisen.

Some genetic mutant mice will be maintained to adulthood (usually as heterozygotes) to be used in breeding and generation of litters for analysis. Pregnant adult mice are culled for collection of embryos. The majority of the work will be under the mild level of severity.

Studies of inborn errors of metabolism requires maintenance of mice to post-natal stages.

Mice that are maintained to post-natal stages will be analysed for experimental outcome, with collection of tissue and blood at the end of the experiment.

Rats are used for production of serum that is used as the medium for culture of mouse embryos at neurulation stages. Adult male rats are used to maximise serum per animal and where possible these are retired breeders that are due to be culled.

Typically, what will be done to an animal used in your project?

Specific details of the experimental approaches and how these relate to Protocols are as follows:

Breeding and genetic typing of mouse strains (including genetically altered)

Breeding colonies of various mouse strains will be maintained and/or obtained from stocks at other designated establishments (Protocol 1). These mice will be either: (i) new or existing models of congenital anomalies that will enable us to extend our analysis of these conditions, and/or (ii) genetically altered mice (e.g. ‘floxed’ gene alleles and Cre recombinase driver lines) that enable us to answer questions about the developmental pathways leading to congenital malformations. Both types of strain are phenotypically normal (with the exception of few strains that exhibit a benign curled tail among heterozygotes), but when intercrossed can yield embryos with phenotypes that will be analysed in the Project.

Strains will be bred (Protocol 1) for four purposes: (1) to maintain the stocks of GA mice; (2) to perform genetic studies to identify the inherited basis of birth defects; (3) to perform studies of gene-gene or gene-environment interactions (by crossing 2 or more different genetic strains) in the origin of birth defects; (4) to provide embryos, fetuses or postnatal offspring for studies on developmental mechanisms of birth defects and other developmental disorders. In many cases, it will be necessary to genetically type the offspring in order to determine their genotype with respect to molecular markers used in the genetic and embryological studies.

Manipulation of embryos in vitro

A variety of embryological analyses will be performed to determine the mechanisms of normal embryonic development and the alterations that result in birth defects. Mouse embryos can grow and develop normally in culture for limited time periods, thereby permitting a variety of research investigations. This is an economical way of conducting experiments since the unit of experimentation is the embryo, not the entire litter. A single

pregnant dam can provide embryos for several different treatment groups, thereby reducing the use of animals overall and reducing the need to perform procedures on conscious animals.

Serum is used as the culture medium for mouse embryos. The serum needs to be prepared in the laboratory by exsanguination via the aorta in preference to the heart, followed by immediate centrifugation of the blood so that clotting occurs in the plasma, without the presence of contaminating red blood cells (Protocol 3). The methods used in preparation of commercially available serum generally do not conform to these requirements, and render the serum toxic to embryos. Hence, we will need to prepare our own serum for culture experiments in this project.

Embryos are typically cultured for a period of 24-48 hours between day 7 and day 11 of gestation. Embryos are not cultured after embryonic day 13.5 (ie, no cultured embryos reach 2/3 of gestation).

Manipulation of embryos in utero

Some studies require that embryos develop for longer periods following a manipulation than is possible with the in vitro system. In addition, for studies of potential therapies it may be necessary to evaluate the effect of maternal administration (e.g. nutrient supplementation/removal). In this case, embryos will be manipulated in utero. Some manipulations of the embryo will be performed on the pregnant female (Protocol 2), by methods including dietary modification, a suitable route such as oral or gavage or via injection or mini-pump implanted subcutaneously using aseptic technique under general anaesthesia. Examples include:

Administration of nutrients such as folic acid or inositol in diet or drinking water.

Conversely, specific nutrients may be withheld by feeding a deficient diet.

Conditional alteration of gene expression may be induced by maternal administration of tamoxifen.

Manipulation of post-natal mice. For mouse models that develop a post-natal onset phenotype, such as the model of NKH (non-ketotic hyperglycinemia) we will administer substances to try to prevent or rescue the phenotype that is found in human patients (metabolic alteration and/or ventriculomegaly) (Protocol 4). Treatments may include dietary modification, oral administration of drugs or injection of substances such as gene therapy vector or drugs (by an appropriate method and volume) or by mini- pump or encapsulated cell pellet implanted subcutaneously using aseptic technique under general anaesthesia.

Neonatal mice (P0-P3) may be administered gene therapy vector by intra-venous and/or intra-cerebral (intra-cerebroventricular) routes in order to achieve transduction of the liver (intra-venous) and brain (intra-cerebral), which are the target organs in NKH. The brain can be readily transduced by AAV at this stage. Mice will then be followed to determine whether the frequency/phenotype of the disorder is altered by the intervention.

In order to identify mice for treatment such as drug administration it may be necessary to genotype pups prior to the stage when they would routinely be marked and genotyped by ear clip. In these circumstances (prior to P7), pups may be marked by toe clip/tail tipped

with the tissue retained for genotyping. This approach will allow avoidance of unnecessary dosing of mice that are not desired genotypes for the study.

Analysis of embryos or post-natal animals after manipulation

A wide range of analytical techniques will be used to measure the effects of the various manipulations in this project. Examples of the types of analysis to be conducted on embryos or tissue following Schedule 1 killing include: Detection of gene expression by in situ hybridisation, immunohistochemistry or histological staining;

Extraction of nucleic acids for transcriptomic or genomic analysis;

Biochemical analysis of homogenates;

Electron microscopy;

Establishment of tissue cultures or organ cultures.

Quantification of metabolites quantified in blood collected under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals produced under the breeding and colony maintenance protocol are not expected to exhibit any harmful phenotype. Some animals may have the potential to develop a harmful phenotype, eg. tumours, neurological signs, after a certain age but in all cases will be killed before reaching that age and before onset of clinical signs, unless moved on to another protocol for a specific purpose (continued use). Animals exhibiting any unexpected harmful phenotypes will be killed (Schedule 1), or in the case of individual animals of particular scientific interest, advice will be sought promptly from the Home Office Inspector. Any animal will be immediately killed by Schedule 1 method if it shows any signs of suffering that are greater than minor and transient or in any way compromises normal behaviour. Advice will be sought from the NACWO and NVS. Humane end points are:

Appearance

Consistent or rapid body weight loss reaching 15% at any time compared with the weight of age- matched mice. In the case of pregnant females, any weight loss over 24 hours. Body weight will also be monitored with reference to Body Condition Score, and culled if BCS is 2 or less – see (Body Condition Scoring; A Rapid and Accurate Method for Assessing Health Status in Mice (Ullman-Cullere & Foltz, Lab. Animal Sci. 49: 319-323, 1999). Under the moderate severity limit, humane end points are listed below and occurence of any three events will be considered the end point:

Piloerect coat showing no improvement over 24 hours
Dehydration and loss of condition showing no improvement over 24 hours

Posture

Hunched appearance showing no improvement over 24 hours

Tremors showing no improvement over 24 hours

Abnormal gait showing no improvement over 24 hours

Paralysis lasting for more than 2 minutes

Repeated episodes of paralysis showing no improvement over 24 hours

Behaviour

Abnormal response to handling impinging on the welfare of the animal (lethargy, extreme hyperactivity)

Unprovoked vocalisation

Persistent head tilt showing no improvement over 24 hours

We will not use mouse strains with overt epilepsy but a few mouse strains experience occasional mild absence-type seizures among homozygous mutant mice. The end point will be occurrence of more than 2 seizures exceeding 30 seconds.

Body Condition Scoring; A Rapid and Accurate Method for Assessing Health Status in Mice (Ullman- Cullere & Foltz, Lab. Animal Sci. 49: 319-323, 1999).

Additional parameters based on Mouse Grimace Scale (https://www.nc3rs.org.uk/sites/default/files/documents/Guidelines/MGS%20Manual.pdf) Non-surgical manipulation of embryos in utero Adverse effects on the embryos may be common in the case of administration of certain teratogenic agents. In these cases, it is the purpose of the study to examine the developmental defects that result from treatment of the pregnant female. The embryos will be removed from the pregnant female and killed (by Schedule 1 method if at E13.5 or older) for further analysis so in general, embryos will not die as a result of their developmental defects. In the majority of experiments embryos are analysed prior to two-thirds of the period of pregnancy. Adverse effects on pregnant females are expected to occur in less than 0.1% of cases. Substances that are identified as having such effects will be used only if a non-toxic alternative cannot be found. Prolonged nutrient deficiency can adversely affect the health of mice and non-pregnant animals on restricted diets are therefore monitored twice weekly (as well as daily by animal facility staff) to identify any signs of distress (see below for humane end-points), at which point mice will be killed by a Schedule 1 method. Pregnant females are examined daily for adverse effects, and adversely affected animals will be killed by a Schedule 1 method.

If multiple injections are required the potential complications include infection, pain, local irritation and chemical peritonitis, formation of fibrous tissue and adhesions within the abdominal cavity, perforation of an abdominal organ or haemorrhage. Repeated administration can result in a cumulative irritant effect and needle-induced damage. Before each injection the mouse will be examined for any adverse effects of the previous injection and the multiple injections will not continue if any are seen and the mouse will be culled by a Schedule 1 method.

Adverse effects of surgery to implant mini-pumps: Hypothermia following surgery to implant mini- pumps or subcutaneous cell pellets will be prevented by keeping mice warm post-operatively, and monitoring until full consciousness is regained. Reopening of wounds following implantation occurs in 1-2% of cases. If this occurs, the mouse will be re-anaesthetised and re-sutured on not more than one occasion or, if in distress, killed by a Schedule 1 method. Infection following implantation of mini-pumps is rare (1-2% of cases).

If wounds show signs of infection (e.g. inflamed or weeping wound site) and/or mice adopt a hunched posture and lose body weight and condition, affected mice will be killed by a Schedule 1 method (see below for humane end-points). Non-specific effects of anaesthesia or surgery to implant mini-pumps occur occasionally (see below for humane end-points). Pain will be controlled during surgery by general anaesthesia, and pre- and post-surgery by analgesics (e.g. meloxicam, buprenorphine) as required, with reference to the Horton and Griffith System as recommended by the NVS.

Interruption of pregnancy may be an occasional effect of implantation of mini-pumps. Since mini- pumps are inserted early in pregnancy, the usual result is death and resorption of embryos, rather than abortion. Animals will not be re-mated as resorption is generally only recognised at the stage when embryos are collected. Mice will be monitored for adverse effects twice daily for the first two days post- operatively, then daily thereafter.

When work under terminal anaesthesia is involved, the level of anaesthesia is maintained at sufficient depth for the animal to feel no pain. Humane end points: Any animal exhibiting changes in clinical condition or behaviour as listed below will be killed by a Schedule 1 method, or as advised by the NVS and/or NACWO.

The protocol for production of serum is conducted under terminal anaesthesia. The animal is monitored for level of anaesthesia. A level suitable for surgery has been reached when whisker twitching has ceased and respirations are regular. The animal should not react to pinching of its feet. Great care is taken to ensure that this level of deep anaesthesia is maintained throughout the procedure. On completion of exsanguination, the diaphragm is perforated and death is confirmed by use of a second Schedule 1 method. Blood is centrifuged immediately to separate the serum and then prepared in the lab for use in embryo culture.

Breeding and maintenance of genetically altered animals with potential for post-natal onset phenotype

This may apply to mice with GA of components of folate metabolism, including the Glycine Cleavage System GA mice (loss of function alleles of Gldc or Amt). Heterozygous breeding stock are unaffected. Homozygous GA offspring are expected to show the following clinical signs:

Death at birth: 20% of mutant pups will die at or before birth due to neural tube defects (anencephaly). Most of the surviving mutant pups are overtly normal up to 4 weeks of age.

Approximately, 30% of mutant pups develop gradual-onset hydrocephalus between 4-8 weeks of age.
Mice that are surviving at 12 weeks of age do not develop further clinical signs.

Offspring will be killed at the onset of clinical signs. Hydrocephalus is recognised by a swelling of the cranium followed by gait problems. These mice will be culled immediately the adverse effects are recognised. For rescue experiments the mice will be monitored and any showing adverse phenotypes will be immediately culled and the remaining mice will be monitored for 12 weeks and considered rescued.

Tail tipping may be necessary to genotype animals early (P0-2) to avoid unnecessary dosing in heterozygous NKH mice. This method of genotyping will therefore allow us to reduce by 50% the number of injections in the NKH model. Any animal that shows adverse effects (monitored as below) will be killed by a schedule 1 method.

Neonatal injection: Pups will be re-warmed, observed for re-initiation of movement and immediately returned to the mother. We will observe to ensure that the mother is attending the pups. Potential complication is needle-induced damage. If pups display signs of ill-health (as listed below). They will be killed by a Schedule 1 method.

Humane end points: Following treatment, any animal exhibiting changes in clinical condition or behaviour as listed below will be killed by a Schedule 1 method, or as advised by the NVS and/or NACWO.

Treatment of post-natal mice is intended to ameliorate phenotypes but has potential to have adverse effects. Prolonged nutrient deficiency can adversely affect the health of mice and animals on restricted diets are monitored twice weekly to identify any signs of distress (see below), at which point mice will be killed by a Schedule 1 method.

If multiple injections are required the potential complications include infection, pain, local irritation and chemical peritonitis, formation of fibrous tissue and adhesions within the abdominal cavity, perforation of an abdominal organ, haemorrhage. Repeated administration can result in a cumulative irritant effect and needle-induced damage. Before each injection the mouse will be examined for any adverse effects of the previous injection and the multiple injections will not continue if any are seen and the mouse will be culled by a Schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild (90% of mice)

Breeding and maintenance of GA mice

Non-surgical manipulation of embryos in utero (diet, drinking water)

Moderate (9% of mice)

Non-surgical manipulation of embryos in utero (e.g. intra-peritoneal injection)

Breeding and maintenance of genetically altered mice with potential for post-natal onset phenotype (e.g. breeding of mice of which a proportion may develop hydrocephalus)

Sub-cutaneous implantation (e.g. mini-pump)

Non-recovery (100% of rats)

Production of serum (for embryo culture or biochemical analysis)

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This research addresses the complex questions of (1) how embryos develop before birth, and what can go wrong leading to congenital anomalies, (2) the effect of inborn errors of metabolism in brain development and how can this be normalised by therapy. This can only be studied properly in whole developing embryos and post-natal mice as current cell and organoid technology cannot replicate the complex morphogenetic movements or multi-system physiology of the developing embryo.

Our ultimate goal is to understand the mechanisms of human embryo development and disease as a contribution to understanding the causes and possible prevention of congenital anomalies and the development of treatment for metabolic disorders. However, experimental analysis of human embryos during early stages of development is not practical or ethical. Instead, we will use a mammalian model, the mouse, in order to gain information of maximum applicability to humans.

Research into congenital anomalies concerns the mechanisms by which the embryo/fetus develops its specific shape and associated function, and the disturbed mechanisms that underlie abnormal shape and function. For example, brain and spinal cord function can develop in a sustainable way only if the neural tube closes during early embryonic development. Hence, an understanding of normal development, and of disturbed development that leads to birth defects, requires analysis of whole mammalian animal embryos. Alternatives that have been considered, and which will be used where possible, include:
Direct studies of humans: although descriptive analysis is possible, hypothesis-testing through experimental analysis is impossible, on practical and ethical grounds. We will use human embryos for some descriptive studies, thereby minimising animal usage.

Tissue/cell culture and organoids: although this can provide useful information on certain specific molecular or cellular phenomena, it cannot mimic the complexity of functioning organs, organ-organ interaction or the entire body. For example, some key genes in our studies (e.g. Gldc, whose mutation causes neural tube defects and NKH) are expressed in cell-type specific manner and not in cultured cells. We use tissue culture (2D and 3D) for cellular studies, where analysis of whole embryos or post- natal tissues is not essential.

Computer simulations: although they can be valuable in extending theoretical approaches to embryonic development, they cannot tell us about real biological situations. We will use computer simulation particularly in our studies of the biomechanics of development and congenital anomalies, where data from embryos will be analysed and simulated electronically.

Which non-animal alternatives did you consider for use in this project?

We have made use of bacteria, C.elegans and fish to investigate metabolic changes arising from mutation of genes of interest in our studies. In some studies we replace the use of live animals by examining human embryos, using tissue culture cells and developing computer simulations.

Why were they not suitable?

Mouse and human embryos undergo a closely regulated developmental process and by using mice we can benefit from the array of genetic and molecular tools available as well as access embryos for imaging. For example, we use mouse genetic models with defects in the same genes as cause the equivalent conditions in humans.

While bacteria and worms can be useful for biochemical analysis, they do not undergo the complex development that occurs in vertebrate embryos. Organ development in lower vertebrates such as fish often does not occur by the same mechanisms as in mammals. In particular, formation of the neural tube (a key area of our studies) takes place by a different mechanism in mammals and fish.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Methods for minimising numbers of animals in this project include:
In vitro whole embryo culture. Embryos are removed from a pregnant female and allocated to experimental and control groups. Hence, we do not need to allocate different dams to different groups (reducing numbers of mice used), and there is less need to manipulate pregnant females. Moreover, recent research (funded by NC3Rs) in our group has shown that rat serum can be diluted for use in cultures without compromising embryo development. This will reduce the number of rats that need to be bled for serum production in future research.

Careful experimental design. For experiments with qualitative outcome (e.g. pattern of gene expression in embryos of differing genotype), 15-20 embryos (from 3-4 pregnant females) are examined per group to ensure reproducibility. Where an outcome is quantitative (e.g. phenotype frequency), a power calculation determines sample size and professional statistical advice is sought where needed. Experiments are designed with reference to the ARRIVE Guidelines.

Mice: Breeding colonies of genetically altered mouse strains are used to reveal how birth defects arise. Each strain is bred for: (i) genetic studies to localise the key genes, and (ii) to produce embryos for studies of how birth defects develop. In some studies, embryos growing in a test tube are supplied with nutrients to determine whether spina bifida can be prevented. Mice that are studied for post-natal rescue of NKH are typically maintained to 12 weeks of age. Around 8000 mice per year will be used overall for breeding and mating to produce embryos and experimental offspring for our research. Experimental design, analysis and reporting will conform to the NC3Rs' ARRIVE guidelines. Breeding schemes and experimental protocols will be designed to ensure use of minimum numbers of mice necessary to generate data with sufficient numbers for fully powered statistical analysis.

Rats: Embryos can be grown in a test tube, to minimise the number of pregnant mice used. Rats are killed to produce serum for the embryo cultures. We have developed methods to allow 50:50 dilution of rat serum with serum-free media. This allows a reduction in the number of rats used in this research.
Around 300 rats per year are killed to produce serum for the embryo cultures.

Careful planning of each experiment will allow the estimations of numbers of mice used. For example, the number of mice used in a project involving genetic experiments, we need to breed up to 8000 genetically altered mice per year, in order to generate the 2000 we require for experiments (see Figure 1). This is because we use multistep genetic crosses, in which usable genotypes are present on average only in 25% of offspring. For example, to generate tissue-specific knockout:

Step 1. b-actinCre x flox/flox → b-actinCre; +/- (50% of offspring usable)

Step 2. b-actinCre; +/- (from Step 1) x flox/flox → flox/- (50% of offspring usable)

Step 3. flox/- (from Step 2) x Pax3Cre; flox/+ → experimental embryos (tissue-specific)

Hence, in this breeding scheme, only 1 in 4 mice from Steps 1 and 2 are usable to generate embryos for analysis in Step 3. On the other hand, wherever possible, we use otherwise unwanted wild type embryos for control experiments, to avoid setting up specific wild type matings.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Careful study design to justify for experimental and control groups, use of randomisation and blinding as well as determining sample size are used to minimise the number of animals used per experiment. This will be consistent with the aims of this project as well as to ensure that the results are useful and prevents waste. Sample size calculation and justification are chosen using the MRC guidance document.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be carried using a small number of animals to test the feasibility of an experimental study to minimise the risk of repeating the experiment or an uninformative under-powered study. For control animals (for example untreated wild type or genetically altered animals) where tissues are collected for analysis, multiple pieces of the tissue will be stored to be used for parallel experiments where equivalent controls are needed therefore reducing the number of control animals used for each experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically altered mice offer the most incisive approach to the analysis of birth defects mechanisms, because:

Mouse genetics is understood almost as well as in humans, offering the best possible means for genetic analysis in a mammal;

Congenital malformations in genetically-predisposed mice closely resemble those in humans, providing excellent models for analysis and for evaluation of preventive treatments;

Transgenic/gene knockout technologies offer a sophisticated route towards studying the effects of genes in particular tissues, or at specific stages;

This research project makes extensive use of genetically modified mouse strains. In most studies, living mice are either heterozygous for the genetic alteration, or only mildly affected homozygotes, so post-natal mice in general will not suffer from abnormalities. Our analysis of congenital malformations will be confined in the great majority of cases to homozygous embryos, which are killed at a developmental stage before the onset of pain sensation.
In the small number of experiments involving living mice (moderate severity protocols), the focus of the study is to test treatment for rescue of the phenotype (e.g. to correct metabolic defect and lower circulating glycine levels in a mouse model of NKH). Animals will be culled immediately if ill health becomes apparent (see Protocols for humane end-points). Animals are housed in IVCs with tubes or cardboard shelters to enrich their environment. We do not intend to pursue any severe protocols.

Why can’t you use animals that are less sentient?

The majority of experiments will indeed involve embryos at stages prior to 2/3 of gestation. Adult pregnant mice will be heterozygous (unaffected) and will be killed by schedule 1 prior to embryo collection.

Mammals or higher vertebrates of equivalent sentience are required for the study of neural tube closure and developmental anomalies of relevance to human malformations.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where possible we will use oral administration of drugs as opposed to injection (e.g. as developed for tamoxifen).

Anaesthetic will be used when tail tipping is necessary for genotyping of neonatal mice. Any mouse that has undergone a procedure will be monitored at increased by research staff as well as on a daily basis by Biological Services staff.

Each new experiment will be pre-planned and discussed with Biological Services staff following submission of a pre-study request form.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will refer to the PREPARE guidelines (Laboratory Animals 2018, Vol. 52(2) 135–141) when planning each new study.

Experiments will be conducted in a manner to enable comprehensive reporting in accordance with the ARRIVE 2.0 guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular discussions will be taken place between researchers and animal technicians to review current and new 3Rs approaches. Latest 3Rs developments will be kept up to date by monthly NC3Rs e- newsletter and attending NC3Rs events and workshops. We will refer to the NC3Rs website https://nc3rs.org.uk/staying-informed-latest-3rs-advances for additional information.

Previous studies (funded by NC3Rs) have allowed reduction in the number of rats required for production of serum. We also developed methodology for oral dosing with tamoxifen that avoids use of injection and we liaised with NC3Rs to broaden knowledge of this approach.

152. Brain mechanisms and interventions which regulate emotional symptoms in psychiatric disorders

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Emotional behaviour, Major depressive disorder, Cognitive impairment, Psychological, Psychopharmacology

Animal types	Life stages
Mice	adult, aged
Rats	neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the brain mechanisms which regulate affective state-induced changes in behaviour and how they are altered in rodent models of psychiatric disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Depression and anxiety are the most prevalent psychiatric disorders affecting modern society and it is currently predicted that more than 20% of people will experience an episode of mental illness in their lifetime. Although both medical and psychological treatments have been developed, little is known about how they interact with brain mechanisms to have their effects. Importantly, the current medical treatments are at best only partially effective and invariably cause side effects. We also currently do not understand why people develop mood disorders or why their prevalence has increased so dramatically with more than 20% the adult population now expected to experience at least

one episode of depression or anxiety. Studies in humans are particularly challenging as it is technically difficult to gain insights into the underlying brain mechanisms which lead to these disorders. Psychiatric disorders are also highly complex influenced by genetics, early life experience and the adult environment and likely arise from a complex interaction between biological and psychological mechanisms. Animal studies carried out in carefully validated animal models can help us understand the neural mechanism which control relevant behaviours under either normal or pathological states and enable us to work out how current treatments alter these. Animal models also play a critical role in early drug development where they are used to help identify new targets for interventions and to establish the potential effectiveness of new medicines. We have developed new, refined methods to study emotional behaviour in rodents which measures similar behavioural changes in animals to those known to contribute to human mood. This has provided us with the opportunity to undertake translational studies which can ultimately help find new targets for treatment.

What outputs do you think you will see at the end of this project?

My research over the past 15 years has led to the development and validation of methods to study affective states in non-human species which are similar to measures made in humans and are also more refined than previous approaches with the main readouts based on reward-motivated behaviour. A major impact from the planned research will be new information about the mechanisms which control emotional behaviour in relation to both normal animals and those which have been treated to model a psychiatric disorder. Our approach enables us to better understand how currently licensed antidepressant drugs affect emotional behaviour, as this remains poorly understood. We anticipate the knowledge gained in the next 5 years will identify potential new targets for treatment and test whether drugs which act on these targets have antidepressant effects. We will also study the relationship between emotional states and cognition so we can better understand how and why mood disorders also affect people’s abilities to concentrate, make decisions and what they learn and remember. Behavioural changes are central to the symptoms of psychiatric disorders and having translational approaches, as we have developed, enables us to model these in non-human species and then combine behaviour with targeted manipulations of the brain to better understand the fundamental biology of emotions and their impacts on behaviour.

This research will generate outputs in the form of scientific publications which will be disseminated to other scientists and doctors through international journals, conference presentations and lectures presented at scientific meetings. These will improve the wider understanding of emotional disorders and will support colleagues working in academia and industry by generating new knowledge which can be used in the development of better treatments.

Through our collaborations with industry, we directly feed into the drug discovery process. Research outputs from this project will support ongoing drug discovery projects with both large and small pharmaceutical companies with active programmes in antidepressant drug development.

Who or what will benefit from these outputs, and how?

In the short-term our main impact will be through knowledge gain. Our working hypothesis is that a psychological phenomenon known as negative affective biases drives the development of mood disorders and is an important target for treatment. Testing this hypothesis, we would anticipate that the 5-year period of this PPL will enable us to better

understand how current antidepressants are acting within the brain and how these impact on this core psychological process to improve mood and also help to explain why the benefits of treatment vary so much between patients. Dependent on the outcomes of this programme, there is the potential for this work to have clinical implications within the subsequent 10-year period particularly as our work has the potential to improve how we use current antidepressant drugs and psychological treatments and impacts will not depend solely on the development of a new drug.

Our collaborative work with our industrial partners will continue under this PPL and we anticipate this will play a key role in the evidence base needed to support the use of psychedelic drugs in psychiatry. As these drugs already have a well-established safety and tolerability profile, translating our outcomes to patient benefit will not require the same timescale as a novel compound and so may even be realised within the 5 years of this PPL.

As some of the planned studies will relate to novel drug targets there will also be longer-term outcomes (10-20 years) where the fundamental biology discovered over the period of this PPL will be taken forward to inform future drug development programmes. There is the potential over these longer time frames to see the outcomes of these studies leading to new medicines and providing the foundation for drug development programmes.

How will you look to maximise the outputs of this work?

Our aim is to always publish all the results from our studies. We utilise pre-registration and support open science using pre-print servers to disseminate completed studies as soon as possible. The methods we have developed and specialist expertise in translational rodent models for psychiatry research also means we have built an excellent network of collaborators in both academia and industry. Importantly, we not only work with other pre-clinical scientists but with clinical colleagues and researchers utilising experimental medicine approaches in healthy volunteers and patients. These networks support our translational approaches and give us routes to disseminating our findings and maximising the impacts for arising outputs.

Our ability to accurately quantify emotional states in non-human species using unbiased and well validated approaches also has implications for studies into animal welfare.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To understand emotion requires a living, conscious animal which can express relevant behaviours which arise from a complex neural network involving multiple brain areas as well as interactions with the environment. This cannot be replicated in an isolated tissue or cell. Psychiatric disorders are linked to early life adversity and stressful life experiences

during development with symptoms usually presenting in early adulthood. To help us model this, we have included some studies where we manipulate the animal from the early post-natal period. Our behavioural tests are then carried out in adolescent or adult animals. Emotional changes are also commonly seen in aged populations and these are likely to involve different underlying biology to those which develop earlier in the lifecourse and so some studies will also work with aged animals.

Our current approaches have been developed in rats and this species has been able to model important aspects of human psychiatric disorders including how environmental and social factors influence their emotional state. Because rats habituate well to human contact, they respond positively to the types of behavioural tests used and generate reliable and reproducible outputs.

We have more recently started to explore if similar behaviours can be quantified in mice and how we can adapt the methods to suit this species so we can capitalise on the genetic tools available for this species and move at least some of our studies to this lower species. Based on our current experience with these species we are anticipating that some of our objectives can be met using mice, but we will also continue to use rats for most of the systemic pharmacology and studies using non-genetic targeted brain manipulations where they yield more reliable data and show less suffering in association with the types of procedures being used.

Typically, what will be done to an animal used in your project?

A typical experiment for animals used in our mild protocol (~50%) involves non-regulated training and testing in reward-based behavioural tests. In combination with these tests animals may be mildly food restricted (not more than 90% free feeding weight) and animals may be treated up to once daily with a test drug or an acute affective state change induced by a social, environmental or drug treatment. The study may continue for up to 12 months with behavioural testing up to once daily and an acute treatment given using a refined method i.e oral dosing in palatable solutions or unrestrained injection, up to 5 times per week. Where we have a drug treatment which cannot be given using a refined method and requires physical restraint, the number of times the treatment can be given is limited to a maximum of 20 administrations, not more than once daily. In some animals up to 6 additional behavioural tests involving exposure to novel environments and tests of reward sensitivity involving individual housing and ingestion of a palatable solution following up to 24hr withholding of food up to twice weekly may be carried out. In some animals (<10%) an additional step involving blood sampling from the tail vein may be carried on up to two occasions or vaginal smears. All animals will be killed at the end of the protocol including by non-schedule 1 methods to enable tissue collection for post-mortem analysis.

The animals used in the moderate protocol will be either animals which have been treated to generate a model of a psychiatric disorder (~30%) or have undergone a surgical intervention with recovery (~20%) to enable direct manipulation or recording from the brain. In a small number of animals (<10%) they will have both induction of a disease model and a single surgical procedure. These animals will then be used in a similar way to those used in the mild protocol experiencing up to once daily treatments with either pharmacological, environmental or social manipulations and up to once daily testing in reward-based behavioural tasks. Animals may also be tested by exposing them to novel environments on up to 6 occasions and a test of reward sensitivity involving up to 24hr food restriction up to twice weekly. In some animals (<10%) an additional step involving blood sampling from the tail vein may be carried on up to two occasions or vaginal smears.

All animals will be killed at the end of the protocol including by non-schedule 1 methods to enable tissue collection for post-mortem analysis.

To induce the disease models we use methods which recapitulate some aspect of a human psychiatric condition with emotional impairments and their associated risk factor. This may include up to 8 weeks of chronic treatment with up to two different interventions e.g. one pharmacological treatment (once daily injection or oral dosing using refined methods) and one environmental manipulation e.g. early life adversity or adolescents stress. The manipulations do not cause any clinical signs and the animals continue to behaviour normally but show specific changes in our specialised tests.

In animals which have had surgical interventions, behavioural testing may be combined with direct infusions of drugs into the brain via previously implanted cannulae (maximum 16 infusions) or intravenous via previously implanted catheters; optical or electrical stimulation of discrete brain regions and/or recording from the brain involving tethering to enable data transfer. The surgical interventions are done during a single general anaesthetic and with post-operative analgesia and management to minimise pain and suffering. Animals recover from the surgery quickly (<6 hours to return to normal eating, drinking and behaviour) and are returned to group housing within 12 hours unless they have received a head mounted device which is not compatible with group housing (<5% of surgeries).

Animals which have undergone a surgical intervention return to behavioural testing after not less than 5 days and only when they are fully healed. Animals may receive additional drug treatments for up to 6 months post-surgery. The animals which undergo surgical interventions do not develop clinical symptoms or show any signs of changes in their wellbeing compared to non-surgical animals following the post-operative recovery period. In a small proportion of animals, we will induce the disease model and then perform a single surgical step so we can investigate specific neural mechanisms which are altered in the disease model relative to control.

For approximately 5% of the animals used in this project, we will need to use aversive training methods. Aversive training methods may include footshocks, airpuff, loud noise or cues which animals will perceive as a threat. For most studies we use an escapable, aversive stimulation and train animal to predict these and so they can learn to avoid the negative outcome. For these studies, the animals may be tested for up to 6 months. Where an inescapable aversive stimulation is needed (maximum 12 stimulations), these will be limited to a maximum of 6 in any test sessions and not more than 2 test sessions at least 24 hours apart. For both types of aversive training methods we may also use acute pharmacological treatments or use these tests in animals which have previously undergone induction of a disease model or a surgical intervention. No animals will experience aversive training methods in combination with both disease model induction and a surgical intervention.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of animals used on this PPL there will be no obvious signs of pain or suffering or abnormal behaviours. Although we will manipulate the animals affective state, this does not change the animal outwardly and are only detected in our specialist assays. The majority of our behavioural testing involves reward-based tasks which are highly enriching and with our handling and habituation protocols designed to reduce adverse

effects, our animals remain easy to handle and actively engage with the experimenter for the duration of the study e.g. up to 12 months behavioural testing).

We use mild food restriction to increase motivation to perform the task for a food reward and to maintain animals at a healthy weight matched to the normal growth curve, but they will experience some hunger for periods of up to 12months.

Animals undergoing induction of a disease-relevant phenotype will experience periods of chronic negative affective state. This is not associated with overt signs of distress or suffering but may be experienced by the animal for up to 6 months.

Animals undergoing surgery will experience some pain from the interventions which will be managed with analgesia and post-operative care and is expected to last no longer than 48 hours with animals returning to normal patterns of behaviour and social housing within 24 hours.

For the studies involving pharmacological and/or psychosocial manipulation, animals may experience transient periods of mild distress caused by the treatment. These will last between ~10 minutes and ~2 hours and will not prevent the animal performing the reward-based tasks. Methods for substance administration have been refined by our group and we use voluntary drug administration in palatable solutions for most studies meaning animals do not require any physical restraint. For rats we can also perform injections using minimal restraint and animals do not develop any sensitisation or aversive behaviours following repeated treatments using this method. Where we do need to restrain the animal, we have limited the number of cumulative experiences. The substances administered are not expected to induce any adverse events. Animals may experience substance administration integrated with behavioural testing for up to 12 months. For studies including aversive stimuli, the type of aversive method and the frequency of simulations are titrated to the individual animals to maintain an active avoidance response. This is done by gradually increasing the intensity and starting with the most refined method. When presented with the cue for the aversive stimuli, animals are able to avoid it happening by performing a specific behavioural response and should therefore avoid the majority of stimulations delivered over the session. Any use of inescapable aversive stimuli will adhere to specified upper limits and will use the least intense stimulus needed to obtain the required behavioural response.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild - Mice ~90%, Rats ~60% Moderate - Mice ~10%, Rats ~40%
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our primary interest is in the control of higher order behaviours which are only expressed in highly developed animal species and therefore cannot be modelled using non-animal methods or in lower animal species.

To achieve the aims of our project we need to be able to undertake direct manipulations of brain function and then quantify the arising behavioural effects.

Which non-animal alternatives did you consider for use in this project?

Computational models of neural networks

Non-regulated model organisms

Humans

Why were they not suitable?

The complexity of the brain and the types of behavioural process we are studying remain poorly understood and therefore computational models cannot deliver the project objectives. Even in the rat brain which has only a fraction of the neurones of the human brain, we are yet to be able to model even relatively simple behaviours and much more empirical data from humans and non-human animals are needed before this approach could be used to achieve the aims of this project. We continue to support this approach and work closely with computational scientists.

Non-regulated model organisms lack the types of emotional and cognitive behaviours which we are studying and do not have the same complexity in their central nervous systems to humans, limiting their use in modelling psychiatric disorders. We are also particularly interested in the integrated role of psychological, environmental and biological factors and these are poorly represented in simpler non- mammalian organisms.

Humans arguably offer the best model for our research but the questions we want to answer require carefully controlled experimental conditions and manipulations which cannot be achieved in humans for either ethical or technical reasons. We are also interested in evaluating novel drug targets and potential new medicines which are not suitable to be tested in humans. Our animal studies are complemented by our own work in healthy human volunteers and patients as well as work from our collaborators who lead programmes involved in both experimental medicine and clinical trials. We also utilise cell or tissue-based methods where possible, and our animal studies are always designed with careful consideration of the available literature and to test carefully developed hypotheses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on our current research funding and the specific objectives defined in those research grants. Each grant is developed with an experiment design annex which details all the planned studies against the programme objectives with their associated sample size estimates. These are all peer reviewed as part of the funding review process. We have also included some animals based on our projected research income and projects which are currently in development or under review with funding bodies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have undertaken meta-analyses of the behavioural methods to provide a reliable estimate of effect size and then used this to design our experiments. Where required, we integrate both the behavioural work and ex vivo studies to maximise the data we can obtained from any one animal and enhance the interpretation of the behavioural studies. For relatively simple studies we can utilise the NC3Rs EDA but where we require more complex designs, we work with local experts in experiment design or our industrial partners who have dedicated statistical support within their organisations.

Depending on the specific objective where possible, we utilise within-subject study designs. This reduces the total numbers of animals as each animal can act as its own control and generate multiple data points which reduced variability. Although this does mean animals may be on protocol for longer or receive more interventions, combined with our refinements, these should not lead to a major increase in cumulative suffering but can dramatically reduce animal numbers.

When we are working with disease models or using chronic manipulations, within-subject designs are not appropriate and for these studies we reduce the numbers of animals by limiting the use of sham or placebo controls and utilise historical data wherever possible. For new interventions or models, we may use a larger number of control groups for our initial studies but can then reduce the numbers for the remaining work and also publish our findings to reduce the need for others to replicate this work.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Spare tissues from all our animals are made available through the tissue sharing network at our institution.

We collaborate with computational neuroscientists to maximise the outputs from our behavioural data.

The same animal may be used across a number of behavioural tasks so we can look at individual phenotypes and understand how changes in one aspect of cognition may impact on another. This avoids the need to use separate cohorts for each behavioural test and also reduces variability and overall numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

My research group has pioneered the development of refined methods to study psychiatric disorders in non-human species. We have developed and validated non-aversive behavioural tests which can be used in combination with disease models or acute manipulations of affective state to provide reliable and reproducible measures of emotional behaviour. We have also developed refined housing, handling and habituation protocols which reduce the animal's baseline stress response meaning we can detect more clinically relevant changes in affective state in our animals and without using overtly stressful manipulations. Whilst our readouts are non-regulated, we do need to use methods which generate changes in affective state (positive and negative) and for some objectives, be able to combine these with ways to directly manipulate the brain mechanisms we think are involved or look at how they interact with disease models.

Approximately 50% of our objectives can be achieved without needing to induce a disease model. We work with normal animals and focus our studies on acute pharmacological and/or environmental manipulations of affective state. We use pharmacological treatments at doses which are not expected to cause overt changes in behaviour but can cause short term changes in affective state including causing transient increases in anxiety but not overt fear or distress. We can be confident that the animals are not experiencing high levels of emotional distress as they continue to look and behave normally and it is only through our specific behavioural tests that the effects are apparent. We need to repeat the treatments over the course of a week to obtain our main readout but minimise the interval to not less than 48hrs and not more than two acute negative state inductions in one week. The same animals may be tested using this approach for up to 12months which enables us to compare different treatment effects within the same animal and reduce the overall numbers needed to achieve the objectives. By using refined methods for substance administration and only mild/transient affective state manipulations
e.g. 10min restraint, we can also limit the cumulative impact on the individual animal.
Approximately 30% of our objectives require the induction of a depression-like phenotype so we can understand the changes in behaviour which arise under these conditions and can also test the efficacy of pharmacological and/or psychosocial treatments. We have selected models which avoid the need for induction of overt damage to the brain or use of aversive conditioning methods. It is important that we can test how different risk factors for emotional disorders impact on the behaviours and underlying brain mechanisms of interest and so we have included disease models which each represent at least one of these known risks e.g. genetics, early life adversity, chronic pharmacology, chronic environmental manipulations or natural ageing. These models do not cause any overt signs of disease and are similar in terms of the cumulative impact of the treatments as defined by our affective state readout. We know from human epidemiology that patients often experience more than one predisposing risk factor and so in some studies our animal model will be generated using one developmental intervention, early life adversity or adolescent manipulation, and one adult intervention. It is important for our objective to be able to test more than one disease model, we can gain greater insights into where common mechanisms are impacted and hence the potential for a treatment to have efficacy across different subpopulations or patients or, where a treatment may be particularly beneficial for one specific risk factor.

Approximately 20% of our objectives focus on the specific brain mechanisms which regulate emotional behaviour and these require models where we use a surgical intervention to enable us to directly manipulate the brain or to permit recording from discrete brain regions. There is no alternative for these study objectives, but they will be performed under a single surgical step to minimise the number of general anaesthetics the animal will experience. Post-operative analgesia refines the experience of the animals, and they return to normal behaviour and social housing within 24 hours. Animals may receive a local manipulation into the brain and/or implantation of a head mounted device to enable us to directly administer drugs to the brain immediately before behavioural testing without the confounding effects of anaesthesia or, to enable recordings of brain activity to be taken. None of the regions targeted are associated with causing any clinical signs. A small number of animals will require single housing to protect their head mounted devices and these will be provided with access to a play pen with other animals to reduce the impact. Recording of the data generated by these devices or methods to enable us to directly manipulate the brain include the use of tethering for optical stimulation or recording or local infusions of pharmacological agents. To reduce any distress caused by these methods, animals are habituated to the methods before the experimental sessions and tethering methods which do not restrict the animals natural behaviours are used.

Whilst most of our objectives can be achieved using animals responses to reward-based behaviours, these methods do not enable us to study how animals respond to aversive events but these are important in terms of the wider understanding of emotional disorders. We have limited the numbers of models where aversive methods are used to ~5% and also developed tests which use mild aversive methods such as air puff and aversive stimuli that are escapable however, to generate some models e.g. fear learning, animals may experience inescapable footshock. These will be limited in number and duration and no animal will experience footshock of an amplitude greater than required to induce moderate, transient distress and a reliable freezing response (maximum 0.8mA, maximum duration 1 sec, repeated not more than 6 times in one session and maximum of 2 sessions at least 24 hours apart).

To manage the cumulative experience of any one animal, we limit the combination of steps as much as possible and so only a small proportion of animals (<10%) will undergo both induction of a disease model and a single surgical step and for these studies, animals will not be tested for more than 6 months post-model induction. Some animals may undergo aversive training methods and induction of a disease model OR a single surgical step but no animal will be experience induction of a disease model, surgical step and aversive training methods.

Why can’t you use animals that are less sentient?

We need animals to be conscious and able to perform a complex behavioural task. It is important that we can mirror as closely as possible the development stages of mood disorders and so some manipulations may use immature life stages, but our readouts require a mature adult brain. The majority of our studies utilise the rat as we have found that these animals habituate well to human handling thus reducing non-specific effects of stress, show rapid and reliable performance in the behavioural tasks and are compatible with our refined methods for substance administration which is required for most of our planned studies. We cannot use a non-mammalian species and mice perform the current tasks less reliably and are more susceptible to stress from the amount of human handling required for the behavioural assays.

Some of our planned objectives require the use of genetically modified animals and for most studies these cannot be carried out in rats and so we use mice but with simplified behavioural tasks more compatible with the species but able to deliver the specific objective of the experiment. The use of mice is limited to these specific objectives, and they are not suitable for the majority of the study objectives. As part of our plans within this project, further tasks develops are planned including home cage tests and automation of our current foraging-based tasks and these will be piloted in mice and may be more compatible with this species as they will require less direct human contact. Dependent on progress, we may be able to use mice for more of the planned objectives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals undergo a minimum of one week's habituation to handling (including tickling in rats) which is combined with rewards to enhance the animal's positive association with human interactions. Non- aversive handling methods are used and animals are housed in enriched cages unless the specific scientific objective requires changes to the home cage environment e.g. for a depression model.

Substance administration will use refined methods with animals trained to take drugs from a syringe in a palatable solution or using modified restraint method which we have shown reduces stress responses by ~50%. Some of the drugs we need to test cannot be administered by these refined methods due to their pharmacokinetics and in these incidences, we will use the most refined within the pharmacokinetic constraints of the compound and also limit the number of treatments and associated use of physical restraint.

Animals undergoing surgical interventions will be given appropriate pain management to reduce the impacts of the surgery and recovery will be carefully managed with continuous monitoring until the animal is fully conscious and at least twice daily checks until the animal is fully recovered and returned to normal housing.

For rats which require individual housing due to head mounted devices or animals which are not being regularly tested in behavioural tasks we will use a play pen for further enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have been leaders in the field of refinements for cognitive and affective neuroscience and utilise our objective methods to quantify emotional state in rodents and disseminate our findings through publications and presentations. Our planned research programme has reduced the use of aversive training methods with most of the scientific objectives being achieved using reward-based behavioural tasks.

I attend regular CPD events and assess and implement refinements which are compatible with our research objective. I attend meetings such as LASA and subject specific conferences. I utilise the NC3Rs adn LASA resources to follow the latest guidance on procedures including surgical approaches, analgesia and methods to recognise and manage suffering and also follow developments in the field of laboratory animal welfare in other countries particularly in Europe.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I attend the annual 3Rs symposium held across the local University network and regularly attend webinars and workshops hosted by the NC3Rs. I attend and contribute to national and international conferences in my field enabling me to keep up with the latest developments and also disseminate outcomes and refinements from our own research programmes.

I am currently leading a programme of work on refinements to the housing, husbandry and habituation of laboratory mice and rats and the advances we make in this area will be incorporated into our psychiatry research and associated models.

153. Regulatory mechanisms of acute myeloid leukemia

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

acute myeloid leukemia, cancer, therapy-resistance, stem cells, drug targets

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This study aims to identify novel ways that blood cells become cancerous and lead to leukemia development. We also aim to understand the characteristics that render many types of leukemia cells resistant to currently approved forms of treatment. We will determine weaknesses within leukemia cells that can be targeted with new treatments. We will identify new treatments for leukemia patients and undergo pre-clinical testing of novel therapies within our mouse models of human leukemia.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Acute myeloid leukemia (AML) is a highly lethal cancer of the blood and bone marrow that has a five- year overall survival rate of approximately 30%. While patients with specific subtypes of AML respond well to current treatments, many patients fail to enter remission following therapy, and these subtypes of AML are classified as therapy-resistant. Whether

an AML patient responds to treatment is highly dependent on the genetic mutations that drive their disease.

All blood cells originate from a population of cells called stem cells. In AML, genetic mutations occur within the stem cell population that result in uncontrolled cellular division of this population and the inability to properly make all of the normal blood cells needed to be healthy. Current research shows that mutations incurred within specific genes of stem cells are strongly associated with therapy- resistance and poor disease outcomes, but the ways that these mutations promote leukemia development and therapy-resistance remain incompletely understood. Using mouse models of human AML, we can identify how cells initiate leukemia and also identify the weaknesses within these leukemia cells that can be targeted with new treatments. The central aim of this project is to understand how genetic mutations found in AML patients lead to initiation of disease, maintenance of disease, and therapy-resistant disease with the aim of identifying novel therapeutic targets to improve AML patient prognoses.

What outputs do you think you will see at the end of this project?

We will develop highly relevant mouse models for the study of therapy-resistant AML, closely modeling human disease. Using these mouse models, we will investigate the role of genetic mutations found in AML patients in driving disease and in driving chemo-resistance. We will use these models to identify novel therapeutic targets for the treatment of therapy-resistant AML. The findings from this project will be presented in multiple publications in top-tier peer-reviewed academic journals, which our research group has a strong track record of doing. These publications will promote the prompt dissemination of new information such that the AML field can learn from our findings and continue to advance the field of AML research with the aim of improving therapies and patient outcomes.

The specific outcomes expected from this PPL include:
Identify specific biological changes that occur prior to the onset of AML to allow for disease initiation in therapy-resistant AML.

Identifying how specific genetic mutations found in AML patients drive disease initiation, maintenance, and therapy-resistance

Establish new mouse models of therapy-resistant AML that accurately model human AML.

Identify novel therapeutic targets for therapy-resistant AML.

Who or what will benefit from these outputs, and how?

The central aim of this project is to understand the mechanisms by which different genetic mutations found in human patient AML promote disease initiation, maintenance, and therapy-resistance such that we can improve therapeutics and prognoses for AML patients.

Basic science: The work proposed in this project will answer many outstanding basic biological questions in the AML field regarding the specific biological changes that occur prior to the onset of AML and how different genetic mutations function to maintain AML disease progression. These data will benefit the AML research community and the chromatin biology community. Furthermore, to address these questions, we are implementing state of the art single-cell genomics technologies using primary mouse leukemia cells that will benefit the basic biology community as a whole.

Translational science and patients: In this project, we will identify potential novel therapeutic targets using our AML mouse models. Results from this project can significantly improve the poor prognosis for patients suffering from therapy-resistant AML as our findings will directly inform the implementation and pre-clinical testing of novel treatments for AML using the information from these screens. Furthermore, we will generate novel therapy-resistant AML mouse models that will be shared as a resource for the AML research community.

Research community: This work will be disseminated through multiple avenues to ensure that there is not a lag in progress made towards the common goal of improving the survival of AML patients. These avenues include, but are not limited to, presentations at local, national, and international conferences, publication in peer-reviewed journals, and inter- and intra-institution collaboration.

How will you look to maximise the outputs of this work?

We plan to maximize the outputs of this work by:

Optimizing experimental design such that multiple scientific questions can be answered in the same animal. This approach reduces the number of animals needed for experiments while adding no additional stress or harm to the animals being used.

Performing experiments using advanced technologies that require a smaller amount of leukemia cells per experiment. This refinement of more traditional approaches allows us to collect many samples to address multiple scientific questions from the same mouse at the experimental endpoint.

Performing preliminary experiments in cultured mammalian cells prior to performing experiments in mice to optimize the conditions in a system that does not require the use of live animals.

Working through intra- and inter-institutional collaborations to ensure that the data are produced in the most robust manner possible and that the best scientists for the research questions posed are involved in experimental planning and data analysis.

Consulting statisticians for experimental planning and data analysis.

Species and numbers of animals expected to be used

- Mice: 20,000 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

The laboratory mouse is the species of choice for the proposed research for two reasons. First, all of the organ systems that we are studying are conserved between mouse and humans, and the physiology of these organs is similar between the organisms. The physiology and environment of intact organs can only be modelled in an intact animal.

Second, the genome (DNA) of the mouse is easily altered, which allows us to recapitulate identical genetic mutations that are seen in human AML patients and to create those mutations in patterns that are relevant to our overall scientific goals.

Adult mice will be used as their physiology most closely parallels human biology.

Typically, what will be done to an animal used in your project?

We will maintain mouse strains by setting up breedings of males and females. These mice will be minimally handled outside of normal care. Pups will be weaned at 21 days of age.

Experimental mice require a series of injections to turn genetic alterations found in AML patients "on". These injections are administered in the lower abdomen and occur at 8-13 weeks of age. Until these injections occur, the mice do not experience any adverse affects of the genetic alterations as the genetic alterations are not expressed (i.e. "off") until the induction agent has been administered.

For bone marrow transplantation models, experimental mice with the genetic alterations that mimic those found in AML patients will then be euthanized at 10-13 weeks old and their bone marrow cells will be collected after euthanasia. These bone marrow cells will be injected into the tail vein in a recipient mouse that has been irradiated to kill its normal bone marrow cells. Giving a normal mouse bone marrow cells with genetic alterations found in AML patients mimics what is observed in AML patients where they only have genetic alterations in bone marrow cells but not in the cells of the rest of their body.

Blood collections will be taken from the tail by forming a venipuncture. Mice will be returned to their cage when blood clotting at the puncture site has been observed.

Mice will develop AML ranging from 1 month to 18 months following induction of mutations depending on the genetic alterations present. Mice will be euthanized for analysis at the first signs of suffering related to disease onset. For some experiments, animals will be euthanized prior to the onset of disease (a pre-disease time-point). These animals will not experience the adverse side effects of developing cancer.

In some instances, prior to the development of AML, mice will receive treatment with drugs or therapeutics that are administered orally or by injection.

What are the expected impacts and/or adverse effects for the animals during your project?

For breeding: Mice may experience a degree of stress 1) when handled when the breeding is initially established and 2) when litters of pups are weaned from their mothers at 21 days of age. Additionally, there is a small incidence when mothers will harm their own pups. In these instances, the pups usually do not survive. Mothers with a history of this will be replaced by different breeding mothers.
For injections (lower abdomen): Mice will experience a degree of stress when restrained for the injection. Mice will also experience mild discomfort during the injection that will alleviate shortly after the injection has been performed.

For injections (tail vein): Mice will experience an elevated degree of stress when restrained for tail vein injections compared to injections performed in the abdomen. Mice will also experience mild discomfort during the injection that will alleviate shortly after the injection has been performed. As cells injected into the tail vein will eventually lead to the

development of AML in these mice, these mice also have the long-term adverse effect of developing cancer. Mice that develop AML will be euthanized when the first signs of suffering associated with disease are observed.

For irradiation of recipient mice: Mice will experience stress during irradiation due to loud noise associated with the machine, a change in environment, and handling necessary to transfer them to the cage used for irradiation and back to their housing cage following irradiation. Because irradiation kills cells that are important to fight potential disease, mice are at a greater risk for developing infections. They will be fed antibiotic food prior to and after irradiation to combat this.

For blood collection: Mice will experience a degree of stress when restrained for the venipuncture. Mice will also experience mild discomfort during the venipuncture that will alleviate shortly after the laceration has been performed.

For the development of AML: Mice that develop AML will show weight loss (up to 20% of total body weight), pale skin and ears, hunching, lethargy, poor body condition, low blood count, less motility, shaking, and/or difficulty breathing. If any of these adverse symptoms are observed, mice will be humanely euthanized as the experimental endpoint is reached.
For treatment with therapeutics: Mice will experience a degree of stress when restrained for the injection. Mice will also experience mild discomfort during the injection that will alleviate shortly after the injection has been performed. Some treatments may produce adverse side effects in mice including lethargy, weight loss, low blood count, and vomiting.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For breeding: Mild (approximately 95-100% of animals)

For injections (lower abdomen): Mild (approximately 95-100% of animals)

For injections (tail vein): Mild (approximately 95-100% of animals)

For irradiation: Mild levels of stress (approximately 90-95% of animals); moderate due to bone marrow failure (5-10%)

For blood collection: Mild (approximately 95-100% of animals)

For the development of AML: Moderate (approximately 95-100% of animals)
For treatment with therapeutics: Mild (approximately 70% of animals), moderate (approximately 30% of animals)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because leukemia is a blood cancer, we must ultimately perform the majority of our experiments in an animal whose blood and organ systems resemble that of human leukemia patients. The physiology and environment of intact organs can only be modeled in an intact animal. All of the organ systems that we are studying are conserved between mouse and humans, and the physiology of these organs is similar between the organisms.

The stem cells that generate all cell types of the blood grow very poorly in culture. These cells and the closely related populations of cells are often the cell types capable of initiating AML development. Because these cells grow poorly in culture and often do not replicate in culture more than a few divisions, we require these cells to be in their natural environment (a mouse) to answer biological questions regarding leukemia initiation, maintenance, and therapy-resistance.

Our research questions focus on biological changes that occur prior to AML onset (initiation), biological changes that occur to maintain AML progression, and biological changes that promote therapy-resistance. Biological questions pertaining to initiation and maintenance of AML require the physiology and cellular environments of an intact blood circulation system and bone marrow niche. Some questions regarding therapy-resistance can be performed in cultured cells which we have implemented in this project, but must ultimately also be tested in an animal with an intact circulatory system and bone marrow niche to be directly relevant to human disease therapy- resistance. When possible, experiments are first performed in cultured cells and then validated using mouse models of AML.

Which non-animal alternatives did you consider for use in this project?

In many instances, we can perform experiments using leukemia cells in culture as preliminary experiments to focus our hypotheses prior to using mice. We have implemented these experiments throughout the project to reduce the number of mice needed to answer our scientific questions.

We have extensive experience in performing functional genetic screens in cultured cells. We perform these screens in cultured cells derived from our AML mouse models when possible prior to validating targets in mice. However, cells isolated from different AML models do not always grow successfully in culture and, in those cases where AML cells fail to grow outside of an animal, the functional genetic screens must be performed in the AML mouse models directly. When cells derived from AML models do grow in culture, we will always perform functional genetic screens in culture and then use our AML mouse models to validate only the most promising targets.

Why were they not suitable?

Because leukemia is a blood cancer, we must ultimately perform the majority of our experiments in an animal whose blood and organ systems resemble that of human leukemia patients. Cultured leukemia cells are suitable for use in preliminary experiments to narrow down our hypotheses such that we reduce the number of mice needed to answer our scientific questions. Unfortunately, certain cells containing combinations of genetic mutations that induce AML in mice, do not successfully grow in culture (just as

certain types of normal blood cells, i.e. stem cells, do not grow well in culture). In these instances, we are unable to perform preliminary experiments using cells in culture for those specific AML models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have a large amount of experience planning experiments with AML mouse models. We have used knowledge from our previous experiments and power calculations to determine the projected mouse numbers needed for the proposed experiments. Details can be found below.

Breeding mice for project:

Breeding cage: 1 male and 1-2 females
Separate pups from mother (weaning): 3 weeks after birth Estimate new born mice: 6 pups/month

We will initially make a total of 20 breeding cages to maintain our 11 genetic strains of mice, but additional strains will most likely be added during the duration of this PPL necessitating additional breeding cages. We therefore estimate 10,000 mice will be used for breeding.

Experimental mice for project:

We initially plan to generate approximately 30 different AML mouse models over a period of 5 years, some based on genetic crossing and some based on bone marrow transplantation. However, this number may increase during the duration of this PPL. For each transplantation based AML model, we need donor mice (who provide a source of bone marrow to initiate leukemia development) and recipient mice (mice who will be the experimental mice for the AML mouse models). We will also assess the biological events that lead to the onset of AML using a pre-disease analysis time point in each of these models. To determine whether these biological events lead to the onset of AML using statistical methods, we will need multiple mice per model per experiment. We will conduct multiple different experiments per AML model to assess the different biological changes that can occur to change cell behavior and lead to AML development.

For these experiments we estimate we will need 7,000 mice over a period of 5 years.

We will perform experiments in cultured cells to identify new gene targets for therapy to treat AML to replace the need for mice. However, the potential targets that we identify from these cultured cell experiments must be validated in mice to demonstrate that the data we collect in cultured AML cells is also true in an animal model of AML. We will also assess ways to pharmacologically target these potential gene targets identified in cultured cells

using different combinations of therapy on our AML models to determine more effective ways to treat patients with AML.

For these experiments we estimate we will need 3,000 mice over a period of 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal usage will be minimized by optimizing experimental design. Animal numbers for each experiment are based on statistical analyses that use existing data to predict the minimum number of animals needed to detect a biological change in an experiment. Where possible, our experiments are designed to test multiple questions in a single animal to reduce the total number of experimental mice used. This includes the implementation of novel single-cell technologies for use in biological assays. For example, we have successfully implemented the ability to profile two biological features (chromatin structure and transcription) from the same single cell rather than profiling chromatin structure and transcription in separate experiments.

Experiments that can be conducted in cultured AML cells that have been derived from AML mouse model leukemias will be used to reduce the number of mice needed - following these experiments, mice are used to validate the data collected in an AML animal model.

Genetic strains of mice that do not have an adverse phenotype when combined in the same animal will be combined when possible to minimize the number of breeding cages necessary to maintain the strains used in this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Power analysis calculations will be used to determine the minimum number of mice needed in an experimental cohort to obtain statistically significant data. Our calculations recommend minimum cohort sizes of 9 mice for each new AML model for survival analyses. Based on data collected for our initial AML models, we will adjust these numbers accordingly.

We will optimize biological assays on disease stage and pre-disease stage mice for use with single-cell technologies or for use with a small number of cells such that multiple experiments can be performed on cells isolated from the same mouse to reduce the total number of mice needed for our experiments.

For genetic strains of mice where the genetic mutations are are not expressed until induced with the administration of an agent, we will keep them as homozygous strains to minimize the number of breeding cages needed. Furthermore, in the case where genetic mutations can be combined in a single mouse without any adverse effects, we will combine multiple strains to reduce the total number of breeding mice needed.

For genetic strains that are not currently in use or infrequently used, we will freeze embryos and sperm and re-derive the strains when needed.

For many experimental cohorts of AML, we use bone marrow transplantation as a method to give donor AML cells to otherwise healthy recipients. In this regard, we can keep fewer breeding cages and ultimately fewer mice harboring the genetic mutations that cause AML. Furthermore, unused donor AML bone marrow cells can be frozen and used as

donor bone marrow at a later date, further reducing the total number of breeding mice needed.

In all AML cohorts, we collect multiple tissues from the same leukemic mouse to maximize the information per mouse. This ultimately reduces the total number of AML mice we generate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using laboratory mice as the species of choice for the proposed experiments during this project as the organ systems that we study are conserved between mice and humans and the physiology of the organs is also very similar. AML is a cancer of the blood, and we therefore must use a model organism with an intact blood and organ system that closely resembles that of human AML patients. Additionally, the mouse genome is easily engineered to have specific genetic mutations that are found in human AML patients. We can easily mutate the mouse genome, or take advantage of the countless mouse strains that are already publicly available that contain genetic mutations of interest, to recapitulate the genetic mutations observed in human AML patients for our studies.

During many of our studies, we will use well-established methods to induce genetic mutations in a small number of mice which will be used as sources of donor bone marrow. These mice will be euthanized and their bone marrow will isolated and injected into otherwise wild type recipient mice (whose normal bone marrow has been depleted using irradiation). These mice will develop leukemia in 1 to 18 months depending on the AML model. During this time, we will monitor mice for signs of leukemia development and euthanize mice when any of the humane endpoints have been reached for further analyses.

Why can’t you use animals that are less sentient?

To study AML, we must use adult mice as this age range most closely resembles the physiological state of human AML patients. In most of our AML models, mice take 1 to 18 months to develop disease which necessitates the use of adult mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimize harm to mice while maintaining the genetic mutations needed for the studies proposed, we will use strains of mice with mutations that are not expressed under normal conditions when possible. These mutations are not induced (or "turned on") until the administration of a drug via injection has been performed. These mutations will only be expressed in experimental mice. Additionally, the mutation will only be present in the bone

marrow of the experimental AML mice and not throughout the entire body. This will prevent unnecessary suffering due to effects of the genetic mutations on parts of the body outside of the bone marrow and blood system.

Mice with genetic mutations that are always expressed with the possibility to cause harm will be kept as heterozygous strains (one normal gene copy and one mutant gene copy). This will minimize the chance that the mice will develop adverse effects. If these genetic mutations are known to cause adverse effects at a specific age, these mice will be euthanized prior to the age range of expected onset of adverse effects.

Prior to injection of AML bone marrow cells into recipient mice, we irradiate the recipient mice to deplete their normal bone marrow. To minimize the chance of infection, we will keep these mice on antibiotic food prior to and two weeks after irradiation. For injection of AML bone marrow cells into recipient mice, we perform a tail vein injection. To refine this technique to minimize harm to mice, we will pre-warm the tails of the mice prior to injection to help increase the visibility of the vein (the vein will rise closer to the surface of the skin improving the success of the injection). Furthermore, in many instances AML bone marrow cells will be mixed with wild type bone marrow cells to increase the success rate of the bone marrow engraftment and minimize the chance of bone marrow failure in recipient mice.

Any drugs that are administered orally will be performed by a skilled animal technician to reduce the chance of mis-dosing. Any animals exhibiting signs of mis-dosing will be euthanized immediately via a Schedule 1 or other approved method on this PPL.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidance provided by the NC3Rs webpage: https://www.nc3rs.org.uk/resource-hubs. Here, there is specific guidance to ensure that researchers manage and implement best practices of Reduction, Replacement, and Refinement. Furthermore, we will review the Animals (Scientific Procedures) Act 1986 to ensure that all UK laws are being properly adhered to.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We plan to follow the guidance provided by the National Center for the Replacement, Refinement and Reduction of Animals in Research as stated on their webpage: https://www.nc3rs.org.uk/staying- informed-latest-3rs-advances. A few examples listed in this guidance that we will follow include subscribing to the quarterly e-newsletter, contacting the local NC3R's Regional Program Manager, and attending NC3Rs events and workshops.

154. Supply of Biospecimens from Rats and Mice

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Blood, Tissue, Drug Discovery, Drug Development

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

T
he Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To provide an efficient and humane supply of blood, body fluids and tissues for use supporting pharmaceutical research and development projects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The provision of reliable high quality blood, body fluids and tissues to support in-vivo (animal) studies which themselves can:

Enable new scientific understanding and identification of novel therapeutic mechanisms.
Facilitate demonstration of crossoveractivity between species.
Aid in selection of appropriate compounds for further evaluation in-vivo. Allow calibration and validation of measuring systems.

These lead to better informed decision making in the drug discovery programme and consequently the use of fewer animals on in-vivo studies.

Supplying blood, tissue or body fluids in-house will also result in improved efficiency of use of animals since we will manage requests from multiple functions and co-ordinate supply of bio specimens to ensure the best use of each animal.

What outputs do you think you will see at the end of this project?

Tissues collected will provide material for use for in-vitro experiments which will support the screening of compounds and understanding of tissue interaction.

A reduction of live animals used due to the ability to utilise in-vitro (Out-side living organism) testing of blood, body fluids and tissues.

Projects supported by this licence will have informed decision making to screen compounds for evidence of potential toxicity.

Publications further down the project lines will occur and there may be publications based upon in-vitro studies utilising tissues collected under the permissions of this licence.

Who or what will benefit from these outputs, and how?

All therapeutic areas will be able to utilise blood, body fluids and tissues from this licence providing invaluable information to projects.

Short term - the ability to use tissue from animals will provide information of possible cell interactions with compounds and aid the optimisation of in-vivo models.

Medium term - enable the more effective use of animals within live project licences by optimising endpoints and analysis.

Long Term - Reduce the numbers of live animals used by optimisation of models and screening of compounds allowing us to reduce the overall harm to animals.

How will you look to maximise the outputs of this work?

All tissue requests will be managed by a centralised team ensuring that any animals are utilised to their full potential.

All scientists will be asked to provide the following prior to any work being approved to commence, this will allow us to ensure 3R's is being considered.

Briefly outline the scientific background to the proposed use of the tissues

What are the specific objectives that you aim to address by using these tissues?

How will the tissues be used to answer this scientific question?
Why can you not achieve this objective without the use of animal tissues?

How will the use of animal tissues be minimised?

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will utilise and Adult Rats and Mice, mice may be genetically modified or humanised which will provide us translatable results to further refine in-vivo experiments. These animals are required to provide tissues for use within in-vitro experiments, enabling us to refine our in-vivo experiments. Genetically altered animals may be required to allow for increased understanding of human disease pathway, drug interaction and assessment of new therapies.

Where Genetically altered rodents are required these may be transferred from project licences authorised to supply such animals to project licences authorised to use them.

Typically, what will be done to an animal used in your project?

Animals will housed socially and given environmental enrichment by way of nesting and tunnels.

Animals will experience the on set of general anaesthesia, this may be via inhalation anaesthesia within a induction chamber or injectable method. Onset will be fast acting and animals will be monitored throughout until termination.

Any procedures will be performed under a terminal anaesthesia therefore the animals will have no pain or distress linked to these.

What are the expected impacts and/or adverse effects for the animals during your project?

Transient pain and distress may occur with the induction of general anaesthesia, once the anaesthesia is maintain no additional adverse effect to the animals are expected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals - Non-recovery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In drug discovery, research programmes rely, in part, on biological materials obtained from human or animal sources to validate and confirm disease; associated pharmacological targets and mechanisms for potential new medicines. Wherever appropriate, biological samples from animals are obtained post mortem (after death); however, for some studies where there is justifying scientific evidence (e.g where lack of oxygen will compromise the usefulness of the tissues, or where a high quality and quantity of blood is required), it is necessary to obtain samples from living animals.

This programme of work supports the replacement of using living animals by enabling the supply of high quality biospecimens which in turn facilitates in vitro investigations where primary cells are needed due to lack of appropriate cells from existing sources or it is not possible to use cell culture techniques.

The provision of high quality blood, body fluids and tissues to support in vitro studies is important to: Advance understanding of biological mechanisms of therapeutic interest.

Demonstrate relevant activity of a receptor in different species.

Aid selection of potential medicines for further evaluation of efficacy in vivo. Investigate potential medicines for evidence of safety problems.
Which non-animal alternatives did you consider for use in this project?

There are a number of promising technologies in development including organoid culture, multicellular organ models and ‘organ on a chip’ approaches which aim to utilise human cells to recreate the physiological functions of organs without using animals.

Why were they not suitable?

These approaches do not offer an alternative to replace blood, blood products, body fluids and tissues in a suitable form for use in in vitro investigations required to support the research and development of new medicines at the present time.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based upon previous use on the last licence. It is expected that the use of mice will increase due to the increasing use of Genetically Modified animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals chosen to supply any single request is minimised by using collection techniques likely to succeed, including taking blood under non-recovery anaesthesia to ensure that a large volume, non-clotted sample can be obtained, negating the need to use more animals than required.

Biospecimen requests will be co-ordinated in order to supply a number of biospecimens from one animal (e.g. whole blood, pancreas, femurs and liver) to a number of requesters for their individual purposes. This should result in improved efficiency of use of animals (i.e. reduce the total number used).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

It is often possible to co-ordinate collection of biospecimens after death maximising the value of each animal. This may include “banking” and freezing blood and tissue samples.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and Mice will be used during this project. Some mice will be genetically altered and others contain human tissues.

All licenced procedures to be performed under the permission of this licence will be under terminal anaesthesia therefore pain and distress will be limited to the induction of anaesthesia.

Why can’t you use animals that are less sentient?

Rats and mice are required for use in this licence due to the absence of suitable replacement of animal tissues for assays. These animals will be terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be handled using non-aversive techniques and socially housed with enriched environments to ensure their needs are met and any stress from non-licenced handling and welfare checks are kept to a minimum. Anaesthetic protocols to be used will be discussed with the Named Veterinary Surgeon to ensure they are most suitable for species and strain, with inhalation anaesthesia protocols being utilised where possible.

All animals requiring procedures to be performed under terminal anaesthesia will be continuously monitored by a competent scientist to ensure surgical depth is maintained thought-out the procedure, this will be performed using toe pinch and monitoring depth of breathing for any abnormalities. Animals will also be maintained for terminal procedures on a warming mat.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Home office Guidelines, AAALAC and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This project licence is driven to ensure the 3Rs are implemented by the use of only terminally anaesthetised animals.

Publications will be regularly checked to ensure we are optimising tissues.

Continuous professional development will be undertaken by all personal licence holders and Project licence holder to ensure 3Rs are considered and best practices implemented.

155. The influence of sleep dynamics on synaptic plasticity across the lifespan

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

sleep, neuroplasticity, in vivo, rodents, dendrites

Animal types	Life stages
Mice	adult, juvenile, aged
Rats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This research project addresses why sleep is important and how it helps our brain function. In particular, the project aims to better understand how sleep influences our ability to process and retain information and how age influences this ability. This project focuses on the basic molecular and cellular mechanisms that are involved and how the different sleep stages (rapid-eye-movement [REM]/dream sleep and non-REM [NREM] sleep) may have a different, but complementary function in this process.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sleep is an integral part of human life and makes up 1/3 of our lives. Sleep disorders are a major societal problem and are associated with a wide range of human conditions. In fact, most brain disorders during development and ageing are associated with some form of sleep disturbance (e.g., insomnia, sleep apnoea, sleep fragmentation). Natural ageing is also accompanied with notable changes in sleep pattern, especially in an increase in

fragmented sleep. This has led to the idea that poor sleep may be both a symptom and a cause of the progression of many brain disorders. Thus, knowing what sleep does to our brain is essential to understand what goes wrong in human conditions where sleep is impaired. We are addressing these questions in animals where the physiology can be investigated and new insights into basic mechanisms can be obtained.

Our research focuses on synapses, the site where two brain cells communicate. The brain displays a remarkable potential for change in response to new experiences in life and those changes occur specifically at synapses, a mechanism termed synaptic plasticity. Sleep and the ability of the brain to express synaptic plasticity vary considerably across the lifespan, with both evident in high amounts during early life and at lesser levels as we age. This further suggests an important link between sleep and the ability of our brain to adapt to environmental changes. Our study will thus provide important insights on the nature of this link and will establish new starting points for future investigations at both the fundamental and the clinical level.

What outputs do you think you will see at the end of this project?

The direct benefit of this project is to increase our fundamental knowledge of the relationship that exists between sleep and brain function. More specifically, the data collected in this research will reveal how different brain areas changes communication during different sleep stages and how this impacts the molecular landscape at synapses.

Our research will also highlight how all those changes vary across age, which is essential information to understand the beneficial role of sleep across the lifespan.

The indirect, more long-term, benefits of this project relate to the potential for clinical applications. This research combines two types of physiological measures: electrical brain activity and large-scale molecular screenings. Brain activity is measured using surface (electroencephalography, EEG) or intracranial electrodes. While EEG is a widely used method in humans, intracranial electrodes are also used in some patients with neurological disorders (e.g., epilepsy). Our research will try to identify electrical biomarkers associated with ageing and memory performance. Our molecular screening will be essential in revealing which cellular functions are recruited during sleep to help the brain to adapt to new experiences. This will open new avenues for therapeutic targets and will have notable implications for brain disorders known to be associated with alteration of sleep and synapses (e.g., autism spectrum disorders, Alzheimer's).

Results from this project will therefore benefit fields in neuroscience and be of interest for anyone who studies the fundamental and clinical aspects of cognitive functions and dysfunctions and how they interact with sleep. We therefore expect to publish our findings in high impact factor journals.

Who or what will benefit from these outputs, and how?

This project will benefit our knowledge at both the fundamental and clinical levels.

In the short-term, the first beneficiaries will be neuroscientists, computational scientists, and clinical researchers in various fields related to this project (e.g., sleep, brain plasticity, memory, development and ageing).
Data from this research will increase our knowledge on the electrical and molecular changes in the sleeping brain related to learning. Importantly, these changes will be compared across ages, an aspect that is often minimised. Our project is also unique as it

will broaden our understanding on the relative contribution of different sleep stages in all those processes.

The data generated during the project will also be of benefit to computational researchers. This is because we will deliver new, large-scale, data to help model the link between specific physiological measures (e.g., brain rhythms), learning and sleep. Current computational models of memory formation do not take into account the impact of sleep, a gap in knowledge our project should fill.

In the long-term, and beyond the end of this project, individuals may benefit. This is because data from our research may identify new targets to diagnose and treat certain brain disorders. Our research will provide brain activity (e.g., EEG) and molecular data that can be linked to ageing and specific pathologies.

How will you look to maximise the outputs of this work?

Results and data will be presented at international and national conferences during the lifetime of the PPL to share ideas with the broader scientific community. These include large conferences in neuroscience and sleep (e.g., Society for Neuroscience; World Sleep, British Neuroscience Association Festival of Neuroscience) and more specialised conferences (e.g., Gordon Conferences, RNA meeting), the latter being particularly helpful to establish new collaborations. Those conferences are also key to discuss negative results and alternative approaches. Negative results will be included in publications when relevant.

Species and numbers of animals expected to be used

- Mice: 1032
- Rats: 228

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The beneficial role of sleep on brain function involves many different brain structures and physiological systems that can only interact when kept intact *in vivo*. Furthermore, sleep states and brain activity, similar to those known to be important for brain function in humans, are only seen in mammals and can therefore not be studied in lower organisms or simplified systems (i.e., *in vitro*). In this context, the combination of a wide range of molecular and genetic tools, as well as available data on the relationship between sleep and brain plasticity, make rodents our model of choice. All methods (physiological measures and behavioural paradigms) we propose to use have been developed and validated in rodent models. This will help ensure the success of our proposed experiments and will also allow us to provide useful information for comparison with already published fundamental and clinical data in this area.

We are proposing to use ‘young’, ‘adult’ and ‘old’ animals in our studies because sleep and the ability of synapses to modify vary greatly with age. This will allow us to understand

which physiological mechanisms are preserved or changed at different ages, and how brain cell communication during sleep is altered with ageing.

Typically, what will be done to an animal used in your project?

Some animals will be used for breeding purposes only.

Most animals (not involved in breeding or pilot experiments) will undergo one or two brain surgeries and after a period of recovery, a behavioural assessment.

All animals will undergo one surgery to place wireless devices to measure the electrical activity of brain cells. The procedure is performed under general anaesthesia, typically lasts less than 1.5 hours and animals recover to normal behaviour in 2 to 3 days.

A subset of animals will also have fibreoptic probes implanted in the brain during the same surgery and will not require an additional incision. The fibreoptic probes are used to either assess or manipulate activity in specific groups of brain cells. Addition of these probes extends the duration of surgery to about 2 hours but the full recovery period of the animals remains the same (i.e. 2 to 3 days). Animals that receive the fibreoptic probes need to undergo a separate injection procedure prior to the surgery. The injection involves the delivery of a substance into the brain and is necessary to allow the fibreoptic probe to work. This more minor procedure is performed under anaesthesia, lasts no more than 1 hour and has a period of recovery of 1-2 days. Finally, animals may be subject to behavioural experiments. These experiments last a maximum of 72 hours during which brain activity is monitored/manipulated in combination with different types of behavioural paradigms such as housing in the enriched environment cage (up to 12 hours), learning a simple task and/or short sleep deprivation (< 6 hours).

A two-week rest period will be allowed between each surgical procedures and the start of behavioural manipulations. Thus, animals that undergo all procedures undertake these across a minimum of 5 weeks, starting with the brain injection and finishing after behavioural manipulations.

Less than half of the animals (38%) will go through all the procedures and the rest will either only receive one surgery for wireless device placement before behavioural experiments (43%) or used for breeding (13%) and pilot experiments (6%)

To minimise stress, animals will be habituated to behavioural and recording set-ups for several days prior to the experimental phase. At the end of the behavioural experiment, animal will be humanely killed (according to the ASPA Code of Practice) for tissue collections.

What are the expected impacts and/or adverse effects for the animals during your project?

The interventions involved in our experiments include breeding of genetically modified mice, monitoring of brain activity using electrodes, imaging/manipulating brain activity using fibre-optic light stimulation, and behavioural experimentations. These are considered as follows:

Breeding is not expected to generate any adverse effects as these have not been observed previously.

Surgical interventions for brain injections and electrodes/optical fiber probe implantations are expected to cause temporary (1-2 days) pain and discomfort post-surgery which will be alleviated by analgesia. This may include irritation at the site of surgery or where the implant is positioned (i.e. head or dorsal flank).

Behavioural manipulations include short term (6 hours) sleep deprivation, simple learning tasks and housing in an enriched environment, none of which is expected to cause any adverse effects. Some stress is expected when animals are first introduced to the behavioural and recording environment, and this will be mitigated by a habituation phase (3-day) prior to the experiments. Sleep deprivation (≤ 6 hrs) has been kept to the minimum required to test our hypothesis. Housing in an enriched environment is known to increase the animal's well-being.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity for the mice and rats used in this licence is expected to be mild to moderate. The cumulative severity has been noted as moderate due to the two surgeries and behavioural experiments. This will be experienced by 80% of mice and 95% of rats. The remaining animals will either be breeders (15% of mice) or included in pilot experiments (5% of mice and 5% of rats) which are expected to experience a cumulative severity of mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sleep is a complex state, involving changes in the entire organism and many physiological parameters (e.g., temperature, hormone levels, and type of brain activity). The interaction of all those factors is necessary to fully express the beneficial role of sleep for brain function. It is therefore necessary to study the mechanisms underlying this role in the intact organism (i.e., *in vivo*).

Which non-animal alternatives did you consider for use in this project?
We have considered using *in vitro* approaches (e.g., brain slices, dissociated neurons) and in silico (e.g., computational models) in our research.

Why were they not suitable?

While questions about sleep function have been in some cases addressed using in vitro or in silico models, those approaches are not appropriate to address the scientific questions in our research that relies on dynamic interactions with environmental stimuli. Simplified models (e.g., in vitro) are also inherently associated with disrupted connections between

brain cells and can therefore not adequately reproduce the complete array of biological interactions and mechanisms investigated in this project. To this date, in vitro approaches using dissociated cells in a petri dish are very limited to study sleep functions and poorly recapitulate brain cells activity found during sleep. The other alternative approaches involving mathematical models are also limited to mimic the complex interaction that exists between the brain and our environment, which is a critical process studied under this project. Thus, there is no feasible alternative that would entirely replace the use of a living animal and would allow the project objectives to be met.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated according to the methods and experimental design for each Objective, the expected magnitude of changes in our measures (based on existing literature and experience from the principal investigator), and the information provided by the commercial suppliers (Jax, MMRRC) on the mouse lines for breeding plans. The number of animals and planning of experiments have been established with advice from our in-house statisticians and with the help of the NC3Rs Experimental Design Assistant tool. Of note, all groups will have an equal number of males and females unless specified otherwise. Although we do not expect to see major sex differences in our measures, some studies suggest that sex, especially hormone fluctuations, may influence the ability of brain connections to change. We thus include gender as a variable across ages when we estimated the numbers of animals in each group.

Pilot experiments with small numbers of animal numbers will inform and refine the methods to obtain physiological and behavioural measures.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used the NC3R's Experimental Design Assistant (EDA) to help with power calculations for group size and strategy for blinding of experiments. Given the number of factors to consider for each experiment, the statistical methods for data analysis were discussed with our in-house statistician, as suggested by the EDA.

We implemented efficient experimental designs to apply statistical analysis that will assess simultaneously the contribution of several factors (e.g., “age”, “experience”, “brain state”) on our output measures without increasing the number of animals for each experiment

To reduce the number of experimental groups, we will use repeated measures to allow within animal comparisons for some outputs measures (e.g., brain activity, memory performance). The use of telemetry approaches allows the recordings of several parameters simultaneously (electrical activity, movement, brain temperature) in the same animal, which also contribute to reduction.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Other aspects that contribute to optimising the number of animals include:

the development of a breeding strategy using online information from transgenic mouse lines suppliers (Jax, MMRRC) and in consultation with the NACWOs and NVS. The use of transgenic mouse lines will allow to optimise the specificity of our physiological measures, which contributes to both reduction and refinement. The inclusion of pilot studies to establish a reproducible behavioural assessment of memory performance in mice and rats. Pilot studies will also be used to optimise the protocol for animal sample collection and processing prior to its application to animals undergoing the combined physiological and behavioural measures. Those pilot studies will also provide extra tissues to compare results in animals without wireless implants, which is important to validate our findings.

At the end of the experiments, brain tissue and other organs will be harvested. Extra tissue will be made available to other researchers within and outside the University of Surrey.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Sleep states and electrical brain activity, similar to those known to be important for brain function in humans, are only seen in mammals and can therefore not be studied in lower organisms or simplified systems (i.e., in vitro). In this context, the combination of a wide range of molecular and genetic tools, as well as available data on the relation between sleep and synaptic plasticity, make rodents our model of choice to address the scientific questions in this research

All the methods and behavioural paradigms we propose to use have been specifically developed and validated in the rodent model for more than three decades. Of note, in vivo electrophysiological recordings have been applied to rodents for more than 70 years. Over this time a number of refinements designed to reduce suffering have been included such as improved surgical techniques and recovery procedures, reduction of the size of the implants, and non-tethered recordings.

Finally, our research group, including the principal investigator, have extensive experience in rodent behaviour and in vivo brain activity monitoring (electrophysiology > 15 years; fiber optic > 8 years). The wireless telemetry system for EEG measures has been used in-house for several years and procedures have been refined to minimise pain and distress to the animal over the years following the advice from the NVS such as peri-operative analgesics regimens and improvement in the telemetry device and electrodes placements.

Why can’t you use animals that are less sentient?

We are interested in the role of sleep stages and specific brain waves during sleep that have only be characterised in mammals. The questions addressed by our study can therefore not be answered in lower organisms such as flies or nematodes, which are alternative models used to address some questions related to sleep. We use animals at different life stages because we want to specifically characterise the similarities and differences in the physiology underlying the relationship between sleep and brain function across the lifespan. Results obtained in one life stage do not necessarily translate to others and this distinction is critical to understanding the role of sleep in brain function across ages.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal purchased from breeders will be acclimatised to their accommodation for at least 7 days prior to the start of any procedures. All animals (purchased or bred in-house) will be familiarised to handling using refined methods such as tunnel or cupping handling.

Animals will be monitored with health checks and score sheets designed for the protocol and ages. The use of anaesthesia and analgesics will be implemented as advised by the NVS to prevent any potential adverse effects, including stress and pain, to the animals.

Old age can be associated with deterioration of general condition and monitoring regimes and health check will be adapted to include signs of age-related diseases so that these subjects can be humanely euthanized. As aged subjects might be more sensitive to temperature fluctuations during anaesthesia, we will consider special recovery heating chambers and parenteral fluid administration or whatever is more appropriate as advised by the NVS for protocols involving surgeries.

To reduce the stress of animals during behavioural manipulations and brain signal recordings, we will habituate the animals to the behavioural and recording cages and devices at least for 3 days prior to the start of the experiments. From the PI’s experience and reports from other labs, rodents habituate well to novel environments, including recording and behavioural arena so we do not anticipate any signs of stress during the habituation period. It has been reported that mice, especially males, can express some aggressive behaviour when put in cage with additional male companions (e.g., enriched environment cage). Any mice that display stress or aggressive behaviour will be excluded from the experiment. Pilot studies will be implemented to reduce the stress of animals during specific behavioural paradigms.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidelines from the NC3Rs and ARRIVE (norecopa # f251b).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The 3Rs are regularly discussed and best practice shared during the BRF user forum at the University of Surrey, which the principal investigator chairs and organises with help from the BRF manager. The principal investigator is also a AWERB member at Surrey and stays informed about on-line sources of information about the 3Rs through subscription to NC3Rs, RSPCA and Norecopa newsletters.

Throughout this PPL, we will review our results regularly and integrate any new knowledge/experience from other publications and collaborative network.

156. Elucidating immune cross-talks in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

immunology, infection, cancer, vaccines, autoimmunity

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The goal of this project is to decipher the mechanisms regulating the balance between tolerance and immunity. In other words, how can we fight and clear pathogens and cancer cells while preserving the integrity of our body?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This is a fundamental project which aims to understand how our immune system works in healthy individual, and how it is dysregulated in the context of cancer and autoimmunity. The ultimate goal is to find new strategies to prime or rebalance the immune system to provide new tools to improve vaccines and immunotherapies.

Indeed, autoimmune disease such as type 1 diabetes have no cure. The pancreas cannot make insulin because the immune system attacks it and destroys the cells that produce insulin. Dysregulation of blood sugar can have dramatic consequences which can lead to coma. As such, a better understanding of the mechanisms regulating autoimmune diseases is crucial.

At the other end of the spectrum, cancer is a disease during which our body is tolerant, which means that our immune system does not eliminate it, the way it would do for an infection. Strategies to reinvigorate the immune system has been successful in some instance to treat cancer, but we need a better understanding of why immune responses are inhibited in cancer to create new therapies.

Finally, our work could have implication in strategies to make vaccines against high-mutating viruses, such as Influenza. Influenza is a respiratory virus which causes the flu. It still results in 28,000 hospitalizations and 7,000 deaths in the UK yearly despite current vaccination scheme. This is of particular importance for younger and elderly people, which are more susceptible to Influenza infection.

The healthcare costs of those diseases are substantial and therefore any advances which could be used to design better treatment and vaccines will have a potential impact on those costs by reducing the number hospitalisations. This can create economic benefits by saving health care costs, to allow healthy ageing but also to boost the UK-based pharmaceutical industry.

What outputs do you think you will see at the end of this project?

The anticipated output of this project are multiple:

- new fundamental understanding of the mechanisms regulating immune responses during infection and vaccination
- new information on immune imbalance in tumours, new mechanisms regulating type I diabetes
- peer-reviewed publications describing our work.

Who or what will benefit from these outputs, and how?

In the short term, the scientific community will likely benefit from our findings. Our work will further our knowledge of immune communication and how it relates to keeping our body protected while efficiently fighting pathogens. Other scientists will be able to use our findings and analyse how it applies to their field of interest. In addition, by unravelling the niches fostering this novel way of communication, our work might provide a new way to think about immune regulation.

In the long term, beyond this project, we hope that our work will help other by providing means to improve therapies such as vaccines and anti-tumour therapies.

Amongst other, inhibiting immune communication during carcinogenesis might provide increased anti-tumour responses and help control tumors.

On the other hand, re-establishing or strengthening negative immune feedbacks based on the findings of this project might help the immune system become tolerant to cells in the pancreas, thereby diminishing the symptoms of type 1 diabetes.

In addition, this work will also advance of the mechanisms underlying cross-protection, which is essential for successful vaccines towards high-mutating viruses such as Influenza.

Overall, we speculate that the work contained in this project will have important clinical impacts, all of which have the potential to significantly improve the health and quality of life of patients across a spectrum of ages and disease types.

Ultimately, the creation of new therapies based on our findings could have a dramatic health and socio- economic impact, as cancer and auto-immune diseases are associated with direct and indirect costs. The economic burden of cancer costs £7.6bn a year in the UK. NHS spending on type 1 diabetes is estimated at £2bn and the overall economic burden evaluated at £3.4bn.

In addition, our work could have impact on vaccine strategies against high mutating viruses such as Influenza. Given the high rate of hospitalisation and death in the UK despite current vaccination scheme, any advances which could be used to design better vaccines will have a potential impact on those costs by reducing the number hospitalisations and the healthcare costs. This can create economic benefits by saving health care costs, to allow healthy ageing but also to boost the UK-based pharmaceutical industry.

How will you look to maximise the outputs of this work?

The outputs of our work will be maximised by collaborating with experts in our field, but also experts in fields complementary to ours. For instance, we often collaborate with clinicians to confirm the relevance of our findings in patients. New knowledge will be communicated as early as possible through platforms such as bioRxiv. We aim to publish in open access journals as much as possible to allow access of our findings to everyone.

Species and numbers of animals expected to be used

- Mice: 34800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Despite the significant differences that exist between mice and humans, decades of basic science using laboratory mice strains have shown that such models not only allow a systematic reductionist approach to identify potential molecular candidates that may be relevant to humans, but also help to reveal general principles that regulate biological systems.The similarity between human and murine immune systems is reflected in homology at a genetic, protein and tissue-organisation level. It is estimated that the percentage of mouse genes without any homolog currently detectable in the human genome is less than 1 %, thus strengthening the validity of using mouse models. Furthermore, since we study the immune system, we cannot use invertebrate animals, as they do not have an immune system. Finally, we will use adult mice in this project, as we are studying the mature immune system.

Typically, what will be done to an animal used in your project?

Typically, control animals or animals that do not express a gene of interest will be transferred with immune cells intravenously, then infected, immunised, or a disease will be induced (cancer or type 1 Diabetes). A biological modifier might be injected by the intravenous or intraperitoneal route and animals will be monitored for a period of time ranging from 1h to 3 months. Mice will then be humanely killed.

Mice with tumours will be monitored closely every other day. We check that their tumour is not too big and does not interfere with their behaviour. We also monitor that they do not suffer by checking the way they move and their social behaviour. Usually, mice will be humanely killed after 1 month.

Mice with type 1 diabetes will be monitored for glucose in their urine. If their glucose is not detected, mice should feel normal. Usually, mice will be humanely killed after 1 month.

Mice that have been infected should feel tired for a week. They may display reduced movements, but they should recover within 10 days.

Mice might be exposed to radiation.

Mice might undergo terminal non-recovery surgery.

Animals will not receive more than 16 injections overall.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice that will get infected, suffering cancer or diabetes might experience signs of ill-health which includes reduced movement, lack of grooming, hunched posture, or weight loss.

In case of immunisation, those are not expected to occur but if they do, they should be very mild and only transient, a few hours. They might experience flu like symptoms.

Where we induce infection, the lowest dose of the pathogen possible to elicit an immune response. However, the animal will still experience the transient symptoms of infection, such as reduced movement and reduced food intake for up to 10 days before recovery.

In case of carcinogenesis and diabetes, we do not expect most mice to display signs of ill-health, and if they do for more than 48h, they will be killed.

In case of irradiation, most mice will experience ill-health but it should be transient and last less than 2 weeks.

Expected severity categories and the proportion of animals in each category, per species.
What are the expected severities and the proportion of animals in each category (per animal type)?

Breeding protocol: 20% mild , 80% subthreshold Experimental protocols: 90% moderate and 10% mild

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The reason we use animals for this project are multiple:

We are studying the immune response to pathogens and disease. There are so far no perfect surrogate techniques that allows us to fully recapitulate the infection or disease state. We need to induce infection and disease in order to be able to study the immune response elicited in these contexts.

The immune response is complex and relies on crosstalk between immune cells and non-immune cells. This crosstalk is orchestrated through the organisation of specific niches which cannot be fully recreated with artificial systems. As such we have to study immune regulation in those niches.

The immune system is spread and circulate throughout the body. This is an inherent feature of the immune system and this is not possible to recreate with other methods.

Which non-animal alternatives did you consider for use in this project?

We considered different types of alternatives:

We will use in vitro or ex vivo models whenever possible to replace, or at least complement in vivo studies. In particular, we will use micro-fabricated devices made of silicone in order to re- create the 3-dimensional component involved in cell migration. Similarly, for some experiments, we will use in vitro methods for tracking real-time migration such as the collagen matrix system. In some cases, we will also use cell culture systems to replace animal tissue in experiments that characterise the biochemical effects of specific signals on T cell migration, activation and functionality. Overall, In vitro techniques and assays can generate important hypotheses regarding the phenomena under study, and we will use them where possible and adequate.

Harnessing human data: using publicly available sequencing data and tumour biopsies.
Why were they not suitable?
in vitro system: while we can and will use those systems in a number of instances, they often don't recapitulate the crosstalk between immune and non-immune cells, which is what we are studying. They also cannot be used to interrogate immune trafficking throughout the body.

harnessing human data: we extensively rely on human data to generate hypothesis and confirm our findings. However, we cannot manipulate humans and human samples in a way that allows us to investigate specific pathways. In addition, we usually cannot keep

live human biopsies long enough to treat with biological modifiers and assess the effect of this treatment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimated the numbers of animals we will need to complete this project based on multiple parameters:

Based on our experience, we have used those models and are familiar with the extend by which immune modifications affect the disease course and outcomes.

Based on the variability of disease course. As for humans, the course of the disease is different for different animals, and we accounted for this in our calculations.

Based on the number of immune perturbations we have to perform. We have designed a list of priority candidates which are the most likely to affect immune regulation and can be manipulated to ameliorate disease.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Appropriate use of statistics and careful experimental design: We are using statistical software to estimate the number of mice we need to analyse the effect of interfering with a given biological pathway, if the effect exists and whether it is robust. We will also use the NC3Rs Experimental design assistant, which will allow us to minimise the number of animals used without compromising our research.

The large numbers of mice for breeding genetically modified mice reflects the use of these mice as donors of immune cells as well as hosts for immune cell transfer or infection.

We will make every effort to minimise random variation and increase uniformity within and between experiments by using age and sex matched mice.

When possible, we will include intrinsic controls to further reduce the numbers of mice required per experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will maximize the use of harvested tissues and cells. For example, immune cells isolated from secondary lymphoid organs from a genetically modified animal may be used as a source of immune cells for in vivo and in vitro experiments. Cells and tissues may be shared by multiple researchers.

Frozen tissues may be archived to permit multi-factorial analysis without additional in vivo experiments (e.g. for using in histology).

We follow best practice in maintaining our colonies to ensure that only those animals needed for our experiments are produced. We also make use of the colony data available to us from the inhouse animal tracking database.

When performing new assays or when we produce a new batch of infectious agent, we will use pilot experiments to determine intra and inter group variations. We will develop in vitro approaches whenever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models: Because of the existence of genetically modified mice, we can analyse the function of a specific cell or gene in a way that is not possible with other vertebrates, making it a model of choice for this programme. For example, some mice strains express fluorescent proteins in specific cells, which allows us to follow them over time and check their location. Also, some mice do not express a specific gene involved in cell communication or cell movement, allowing us to study the relevance of those phenomenon on carcinogenesis or autoimmune diseases.

Tumour induction: We are engrafting mice with tumour cells. We can do this under the skin to mimic melanoma, in the mammary gland to mimic breast cancer, These models generate an immune response which is ineffective, making them the best models to study dysfunctional immune responses and mimic immune responses to cancer in human. Those models have the advantage of being synchronised and do not lead to metastasis.

We will also inject mice with tumour cells intravenously to mimic cancer metastasis to the lung. Indeed, using this route, most cancer cells are trapped in the lung, where they form tumours. This is a commonly used model of metastasis.
We also use models of mice developing spontaneous mammary tumours for their similarity with clinical picture of local growth followed by lung metastasis. Those tumours are detectable by gentle palpation. Lung metastasis can occur with this model, usually after 8 months. We will use models of mice developing skin cancer resembling melanoma in humans. Those tumours develop after topical application of tumour inducing agent. They are visually detectable and lung metastasis usually occurs after 7-9 months.

Overall, we are using well-established models of tumorigenesis that are standard in the field. Both models are the most refined for different purposes. Tumour engraftment models allow for assessment of immune responses without metastasis. The use of spontaneous tumour model will allow us to study how tumours interfere with and subvert the immune system over time to escape it.

Infections: We have carefully chosen Listeria monocytogenes and Influenza as infectious models. Listeria monocytogenes is a bacteria that causes food poisoning and can be fatal for foetuses. The immune response to Listeria monocytogenes is well characterized, and critically relies on the immune cells we study: T cells. Because of its unique intracellular biology that allows Listeria to gain access to the host cell, the study of these responses has served as a paradigm in this context. Furthermore, Listeria-based vaccine are being developed to treat cancer, which makes this model very relevant to our studies. Whenever possible, we will use a more benign strain, such as ActA, but this is not always possible, as this strain is replication incompetent and as such does not fully recapitulate the associated immune response.

Influenza is a virus that causes the flu, a contagious respiratory illness that can be severe for the elderly. The immune response to Influenza is also well characterised and relies on T cells. Influenza mutates very quickly, and as such, flu vaccines usually protect just for a year. We have different strains of Influenza that harbour specific, known mutations, which allows us to mimic how the immune system responds to mutating viruses. The different strains cause similar adverse effects. Their use is important to understand how to generate flu vaccines that could be effective for a longer period.

Immunisation: We aim to use immunisation methods that are well characterised, well tolerated in mice and relevant to human vaccines. We do not expect more than transient discomfort, and they are as such refined methods of immunisation.

Why can’t you use animals that are less sentient?

We are investigating the balance between immunity and tolerance, and for this we need a mature immune system. Therefore we have to use adult mice.

Since disease models and course of infection are long, sometimes weeks or months, we cannot use terminally anaesthetised mice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use genetically modified mouse models in which the genes of interest can be activated or deactivated by compounds to reduce the risk of a genetic modification causing harms. These systems allow manipulation in a more controlled fashion, such restricted in time and/or space.

We will make every effort to minimise the number of procedures per animal. For example, given our extensive experience in immunisation protocols, we will choose precise time points to sample blood, reducing the amount of pain, stress and suffering that the animal is likely to experience.

For immunisation experiments, we will use adjuvants that are effective but cause minimal adverse effects. We will not use adjuvants that can cause ulcerations at the injection site. When possible, we will use the least painful injection method.

The pathogens we will use are in common use and well documented. We will only use sub lethal infection dosage for the primary response. We will increase the dose for the secondary/memory responses, but mice will have developed a strong and efficient memory response and eradicate the pathogen very efficiently. Whenever possible, we will

use less virulent strains. For infected animals, we may provide food on the cage floor if we notice weight loss or reduced movement.

Appropriate aseptic techniques will be used in non-recovery surgical procedures. Animals will be monitored before the surgery to ensure that they are fit for the procedure, during the surgery to confirm that they are deeply anesthetised (sufficiently to feel no pain). Animals will be provided with warmth and fluids during the procedure to ensure that hydration and body temperature are still maintained.

For mice irradiation, we will split of the doses of radiation in 2 separate doses separated by at least 3hours to minimise side effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the NC3R website and the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We use the NC3R website to stay informed about advances.

In addition, we are monitoring for advertised meetings, event, workshops and courses that deal with the 3Rs and the new advances.

We have regular discussions with the NC3R's Regional Manager, the Named Information officer and animal technicians to review current approaches.

157. Provision of an outsourced drug discovery platform for the development of therapeutics for diseases with an inflammatory component.

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Inflammation, Drug discovery, Therapy

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project licence is to provide a service to support the development of novel drugs for diseases with an inflammatory component and that have an unmet clinical need.

As part of this work we will improve and refine animal models of disease to ensure they are fit for purpose and are the most appropriate to answer the scientific question when testing new drugs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite notable progress in the discovery and development of medicines, there is still a significant unmet need in the treatment of inflammatory diseases with 50% of all deaths worldwide attributable to inflammation-related diseases (Furman et al. 2019. Chronic inflammation in the etiology of disease across the life span. Nature Medicine, 25, 1822-1832). Inflammation is when the body produces a response against something that harms it, such as an infection, injury or toxin. In some cases, however, this response itself can have a negative impact on tissues and organs resulting in disease. Both short and long-term inflammation have been found to be key factors underlying the development and progression of disorders such as arthritis, allergic respiratory disease, kidney failure, sepsis and inflammatory bowel disease (IBD).

This project will generate important proof-of-concept data in the development of potential new test agents (drugs) targeting these and other inflammatory disease areas. These studies will generate vital information that cannot be found without the use of animals. All clients that we work with are developing test agents which will hopefully contribute to helping people with various inflammatory diseases.

What outputs do you think you will see at the end of this project?

This project will provide important information that aids the progression of new drugs against inflammatory disease through the drug discovery and development pipeline. The information gathered will enable us to identify the most appropriate treatments to take forward to human clinical trials and enable us to quickly determine which drugs should not be progressed any further.

In addition, this work will increase our knowledge of how new drugs work and will help us to identify changes in the body that occur in response to the drug. We can use this further down the line to monitor responses in humans during clinical trials.

Data from studies under this project may also be used to support patent applications and applications by clients for additional funding. Data produced may also support the design of regulatory studies for clients.

Who or what will benefit from these outputs, and how?

Inflammation is associated with a large number of health conditions, ranging from arthritis and chronic kidney disease to allergy, inflammatory bowel disease, autoimmune disease and sepsis. Current medications, however, can often result in serious short and long-term side effects or may not even be available to certain patient populations. Further work is needed to develop safe and effective medicines for a multitude of inflammatory conditions.

This programme of work is expected to enable us to progress new treatments for inflammatory disorders through the key milestones of drug development. Drugs shown to be effective in this project can be advanced into the clinic for testing in patients where they could significantly improve a patient’s quality of life.

How will you look to maximise the outputs of this work?

All studies are designed such that the outputs from each animal are maximised. Expert knowledge is gathered not only from within the preclinical (animal) team performing the animal studies, but from other teams within our company, or our clients’ companies. This ensures that all relevant work that has been performed in the laboratory is taken into consideration when designing animal studies. The *in vitro* (in the test tube) and bioanalysis

teams at our company are experts at analysing tissue and blood samples collected from animals and they help with details of sample collection and storage to ensure that the samples are collected and stored in the best way possible. They are also experts at working with small samples, particularly small volumes of blood, meaning that they can often analyse lots of different biomarkers (a measurable indicator of a disease state or other physiological state) and test agent levels from each animal. Any tissues resulting from projects that can be utilised by other projects will be made available. Our company has a very comprehensive sample record system which makes it very easy to assess the tissues we have banked and the conditions of how they were collected and stored.

In addition, we will seek expertise from our established networks, to ensure that we make use of any new knowledge or incorporate better methods of performing animal studies. We will also use these networks to provide information and training to others on the models and techniques we use in our research. We will maintain good communication with managers of the animal facilities to ensure that any tissues from animals being killed that are not required for our work can be made available to other researchers if suitable.

Although there are times where we will not be able to share animal model information (for example, where it would put us at a competitive disadvantage), we aim to publish or share our findings wherever possible, such as control data or where notable refinements have been made in a disease model or procedure.

Species and numbers of animals expected to be used

- Mice: 3500
- Rats: 2250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and rats are the most common type of animal used for generating 'models' of inflammatory disease and for the testing of new treatments. These models mimic areas of the disease in order to provide data on which drugs are likely to work well in humans as a treatment. The immune system of both species has been highly studied, meaning that a lot is already known about how their bodies work, and the techniques used to mimic the human diseases are well developed.

Adult rats and mice will be used for the work outlined in this project licence as we want the biology of the animals to be fully developed to better represent the patients we aim to treat.

Typically, what will be done to an animal used in your project?

Most animals will be part of studies that aim to test whether new drugs can prevent the development of or treat an already existing inflammatory disease, whether that be arthritis in the joint, symptoms of allergic asthma or bowel disease. In the majority of experiments inflammatory disease will be induced by either single or repeated administration of an inflammation-inducing agent that results in damage to key organs and cells. In other experiments, where genetically altered animals are used, animals may spontaneously

develop disease as they age or an inflammation-inducing agent will be given to induce disease.

As part of the study, animals will be dosed with drugs over a period of days or months. Dosing will often take place on a daily basis but this may vary depending upon the drug. Drugs will be most commonly given by the intraperitoneal (i.p., into the body cavity), subcutaneous (s.c., under the skin) and oral (by mouth) routes and less frequently by the intravenous (i.v., into a vein) or intranasal (i.n., into the nose) routes. For i.p., s.c. and oral routes, conscious animals will be held securely by a trained researcher and the dose administered. For i.v. dosing, animals will be placed briefly in a specially designed rodent restrainer. The animal may be placed into a specially designed warming cabinet for up to 10 minutes prior to restraint. For i.n. dosing, animals may be briefly anaesthetised to allow the dose to be administered directly into the nostrils.

Blood samples may be collected during some studies to measure levels of the drug or to assess how well the drug is working. Blood samples are usually small in volume and are most often taken from a vein in the tail. Where disease is expected to result in changes in behaviour or movement, animals will undergo tests to assess how well they can coordinate their movements, such as completing tasks by finding a treat, or assessing how much they want to explore a new environment. Sometimes, tests will look at more general movements, such as balance and gait analysis (how the animal walks). Anything administered to induce diseases, such as osteoarthritis, should only cause minor changes in the way the animal moves, only detectable by special tests.

Other procedures such as urine collection may be performed. Urine may be passively collected from lightly held animals or where possible using a water-repellent sand on which animals are placed for a short period of time. Rodents urinate freely and with regularity and samples are subsequently collected.

At the end of experiments, larger volumes of blood may be collected from animals under deep terminal anaesthesia. Here, animals are asleep, unaware of any pain, and do not regain consciousness. The animals will then be humanely killed while still under anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

The most common adverse effects in this project will arise as a result of the generation of the inflammatory disease and this will be dependent on the particular disease model used.

Animals administered bacterial or similar agents to induce significant systemic (involves the whole body) inflammation will likely experience subdued behaviour, mild weight loss and slight diarrhoea. We aim to minimise these effects as much as possible and experiments will typically be kept short (typically 72 hours) when using higher doses of inflammatory agent. Animals are monitored closely for weight loss, activity levels, body condition, posture and pain, and killed promptly if the humane endpoints are reached.

Mice genetically altered to mimic clinical lupus (where the body's immune system attacks its own organs) will exhibit increased levels of protein in the urine as well as urinate more frequently. Other symptoms may include swollen glands and in the case of certain strains, itching and skin lesions.

The induction of renal disease will similarly result in an increased amount of protein in the urine as kidney function declines, but at an early stage this causes no suffering or other clinical signs.

The injection of an arthritis inducing agent into the joint will result in discomfort following injection and may lead to the development of painful joints and reduced mobility. These effects may last up to the end of the study (typically 10 weeks).

Animals in which a respiratory allergy is induced will experience multiple instances of anaesthesia. However, it is expected that all animals will recover uneventfully from the anaesthesia with no lasting harm. Exposure to the allergen may result in transient (short) respiratory discomfort such as nasal rubbing, sneezing or discharge. In some cases, animals may experience an immediate reaction to the allergen, resulting in the brief cessation of breathing. This will, however, occur while under anaesthesia and is expected to resolve quickly. Gentle chest massage is performed to support breathing and normal respiration is restored prior to the recovery of consciousness.

In response to inflammation some animals will lose weight, but weight loss is not expected to exceed 15% of the starting body weight or result in long-term reduced activity. The only exception to this is when studying inflammatory bowel disease (IBD), where animals may lose up to 20% body weight but not show any other signs of suffering. In studies of IBD, animals will be administered an agent i.e., through their drinking water, that causes inflammation to the gut. This results in animals failing to absorb as many nutrients through their food compared to normal, causing weight loss. IBD animals may also experience diarrhoea and some blood in their stools.

The drugs given are not expected to cause lasting harm, although sometimes the animal may lose some body weight while adjusting to them. Blood sampling is not expected to cause any lasting discomfort but animals will experience slight distress due to restraint and transient discomfort from needle insertion.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: Mild 33%

Moderate 67%

Rats: Non-recovery 22%

Mild 20%

Moderate 58%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand the effects of potential drugs in treating disease, the whole "system" must be studied. Animals enable us to mimic the whole biological system, allowing us to study how the immune system interacts with other cells and organs. It is not possible to fully study this in isolated cells and/or organs.

Which non-animal alternatives did you consider for use in this project?

Our company regularly uses a range of *in vitro* (in the test-tube) methods utilising cells to understand how a novel test agent might affect the cellular functioning of those cells. From these experiments we can prioritise test agents and only take forward those that have the desired effect and, therefore, look the most promising for the treatment of inflammatory disorders. However, this does not fully answer the research question and studying the whole animal is still necessary.

Why were they not suitable?

None of the alternatives mentioned can replicate the complete model of the human immune and inflammatory systems which are required to accurately evaluate the impact of a test agent on an inflammatory condition. In addition, cell-based work does not test the effects the body might have on a test agent, for example how it gets into the blood, travels around the body and how it is removed from the body. No alternative is currently available that can replace the need to test potential therapeutics in a live animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have analysed the number of animals used previously on projects and typically how many animals it takes to fulfil each kind of study, using the most up-to-date experimental methods. This was then combined with a prediction of likely demand of future projects over the lifespan of the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have extensive experience in the design of experiments of the types in this project, which has given us confidence in the number of animals required to ensure that no animals are used unnecessarily, but also that the data generated is robust and reliable. We regularly refer to the PREPARE guidelines (https://norecopa.no/PREPARE) and make use of the NC3Rs Experimental Design Assistant (https://nc3rs.org.uk/3rs-advice-project-

licence-applicants-reduction) to ensure that we are using the correct number of animals for every study.

When designing experiments to look at the effect of novel test agents, where the test agent has not previously been dosed before, we look at published literature or client data to determine the variability observed with similar test agents. We can then use the NC3Rs Experimental Design Assistant, or our own in-house developed tool to help determine the most appropriate group size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

If a new disease marker or an inflammatory agent is to be tested or refined, small initial experiments (pilot studies) may be conducted first to make key adjustments before proceeding with the larger experiments. This ensures that the correct number of animals are used when experiments are performed in full.

Data from pilot studies and previous experience are used to ensure that the numbers used are as low as possible, without compromising the reliability of the data. Within our company, a member of the wider team has generated a tool for performing power calculations and can be consulted as necessary to assist with study design. This is regularly compared and checked against similar peer-reviewed versions and adjusted where necessary.

Wherever possible, our *in vivo (*animal) scientists will be blinded to the treatment status of an animal, therefore reducing bias. This enables more reliable information to be gathered from a smaller number of animals. Those who carry out analysis on samples (e.g. blood or tissues) collected during the study are also blind to the treatment status of the animal where possible.

Baseline data (e.g. bodyweight) are recorded and animals are randomly assigned to treatment groups so there is no difference between the groups at the start of the study.

Good planning ensures that within any series of studies we can control for variability that might be introduced by external factors. To limit this variability we use animals of a similar age/weight range, test batches of test agent in the lab first, use the same source of animals and reagents, keep records of all observations made and standardise as many components of an *in vivo* study as is practicable.

Where possible, we will coordinate with other groups to share tissue including post-mortem tissues to reduce overall animal numbers.
Where genetically altered animals are required, these will usually be provided by our internal breeding projects, which will ensure that animals are bred efficiently using as few animals as possible by communicating need with colony managers. Where animals are obtained from external sources, only the number of animals required for the study will be purchased or imported.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals will be housed in a purpose-built, modern and well-equipped facility, that is free of disease- causing organisms such as bacteria, viruses and parasites. They will have access to food, water and items that enhance their environment, such as tunnels, chew sticks and two-storey levels to climb on. Our company staff and the animal care staff are competent in rodent welfare and will ensure that animal suffering is minimised. We aim to house animals in groups to promote normal behaviour. However, aggressive behaviour can occasionally result in animals being singly housed to prevent injury.

Why can't you use animals that are less sentient?

Adult mice are the lowest species of mammal that allow us to adequately study the complexities of human inflammatory diseases. Studies often span weeks to months to look at how disease develops and impacts on the whole organism and how it may be corrected. Therefore, the use of terminal anaesthesia is not a possibility. It is also important that we are able to monitor the behaviour of the animals in a conscious state. This allows us to monitor for adverse reactions to any new test agents administered and also how the disease itself (particularly arthritis and lupus) affects behaviour and movement.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Each project has a dedicated project manager and a team of highly experienced researchers. This enables us to combine years of knowledge and experience and tailor strategies to refine experimental design as well as the procedures themselves in order to minimise harms to the animals. Open and regular communications with other managers throughout the Establishment alongside unit technicians, Named Animal Care and Welfare Officers (NACWOs) and Named Veterinary Surgeons (NVS) further enables relevant and specific care for our studies and to identify any new and better methods that could be utilised.

Animals will be housed in social groups where possible and provided with an enriched environment in order to minimise stress. Animals will be monitored regularly for signs of adverse effects including unexpected inflammation/infection, body weight, activity, responsiveness, condition of coat and posture. Injection sites will be monitored for signs of redness, swelling and infection. Urine samples will be regularly collected, if appropriate, to assess levels of protein in the urine, a biomarker of kidney function. In studies of inflammatory bowel disease where inflammation might cause abdominal pain and discomfort, pain relief may be given when the animals show signs of it (for example, hunching). Should pain relief be required we will consider adding the pain relief to a palatable substance such as Nutella to allow it to be taken voluntarily. Where substances (inflammatory or test agents) are given in the drinking water, other ways of supportive care that don't compromise the experiment will be found, such as dry treats. Where animals are likely to urinate more often due to disease, we will replace the bedding more frequently. Where animals exhibit subdued behaviour, care will be taken to ensure the enrichment in the cage is sufficient to give areas for the animals to rest in a warm environment. This will

include increasing the amount of nesting material available, providing heat pads and mash and/or hydrogel to the cage (if possible).

During studies animal condition and bodyweight is monitored regularly, with body weight recorded prior to each dose administration as a minimum. A scoring system specific to each protocol, where appropriate, will be used to monitor any effects observed either due to repeat dosing or development of the inflammatory condition. Scoring systems will look at factors such as weight loss, piloerection, food and water intake, lesion size and condition, grimace scale, movement and behaviour. This will help us ensure that the condition of each animal is tracked and acted upon as necessary.

All procedures are performed using the smallest needle possible. The lowest volume of blood needed for experiments is determined prior to the study starting to ensure the smallest amount of blood is taken as possible from animals during blood sampling. Water-repellent sand may be used to collect urine passively from animals without the need for restraint. Where possible, animals are regularly handled prior to studies starting to acclimatise animals and reduce their stress during the dosing of agents. Prior to any behavioural testing animals will be acclimatised to the test in order to become familiar with both the operator and environment and minimise stress during testing.

To minimise distress in arthritic mice we will follow measures that include the provision of soft sawdust litter to reduce any irritation on walking, the use of non-tangling nesting material and long nozzles on drinking bottles if movement is impaired. Nutri and hydrogel will also be provided if needed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We use PREPARE guidelines for the planning of studies and follow the latest version (2020) of the ARRIVE guidelines for ultimate reporting of data. LASA (Laboratory Animal Science Association) also has a range of published guidance documents with principles that can be applied to our animal studies which are found at https://www.lasa.co.uk/current_publications/.

Additional documents that we will also refer to when conducting our work include:

Bauman et al. 1994. Pain and distress in laboratory rodents and lagomorphs. FELASA Working Group on Pain and Distress. Lab Animals 28, 97-112. doi: 10.1258/002367794780745308.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

When designing animal studies we consider the appropriate guidelines, including the guidance from The National Centre for the 3Rs (NC3Rs), Laboratory Animal Science Association (LASA), and the PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines. This guidance will influence our study design.

158. Estrogen, obesity and signalling in pulmonary hypertension

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

obesity, sex, estrogens, serotonin, pulmonary arterial hypertension

Animal types	Life stages
Mice	adult, juvenile, aged, embryo, neonate
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine the effects of obesity, the sex hormone estrogen, serotonin and sex on the development of pulmonary arterial hypertension. To discover novel therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Many more women develop pulmonary hypertension although men get it more severely. The sex hormone estrogen, the blood chemical serotonin and other 'bad' chemicals are

associated with this disease of the pulmonary (lung) blood vessels. The cells of these blood vessels tend to grow more quickly and thicken the blood vessels, stopping the blood flowing through them properly. Survival is extremely poor even with existing drugs and new drugs are needed to prolong survival.

What outputs do you think you will see at the end of this project?

Novel clinical trials of new drugs, development of novel therapeutic approaches, publications, presentations at international and national conferences.

Who or what will benefit from these outputs, and how?

Our work will inform patients, clinicians and other scientists of novel potential drugs for PAH. In the short-term scientists and clinicians will benefit from this knowledge and our understanding of how the cells of the lung blood vessels change. In the medium term these studies will encourage the development of proof of concept clinical trials. In the longer term, patients will benefit through novel therapies becoming available if full clinical trials are successful. This group has already contributed to the use of PDE5 inhibitors and endothelin-1 antagonists being used for PAH and two novel drugs in clinical trials at the current time (serotonin and estrogenic inhibitors). Hence this work is worthwhile. We will publish the data so that it can either be used to support clinical trial applications or stop others from investigating a drug further in vivo that would not be effective. It is likely that the research will translate into the clinic within 5-10 years.

Other benefits will be: patents on novel therapies, publications (we have published over 20 high impact papers since the start of our last project licence), at least two products advanced to Phase 1 clinical trials, prevention of approaches which are contraindicated (such as non-selective 5HT antagonists), development of refined surgical procedures (such as intra-tracheal delivery of some new therapies) and influence on public policy (for example our work previously showed that estrogen based contraceptives are contraindicated in women with PAH (Pulm Circ. 2015 Sep;5(3):435-65. doi: 10.1086/682230.).

How will you look to maximise the outputs of this work?

Data (both positive and negative) will be published in relevant journals and presented at national and international meetings. We will collaborate with several national and international clinical and non- clinical collaborators.

Species and numbers of animals expected to be used

- Mice: 5000
- Rats: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The models selected are the gold-standard refined models of PAH with high fidelity outputs using advanced Pressure/Volume loop.

We have selected the models for sound scientific reasons. The chronic hypoxic model: In PAH the blood becomes hypoxic (low in oxygen) as thickening and loss of lung arteries means oxygen is not effectively transferred, from the air we breathe into the airways into the arteries. The addition of an injection of the VEGF antagonist sugen prior to hypoxic exposure refines the model such that vascular occlusive lesions appear similar to those seen in patients. Transgenic mice are studied where the genotype infers or protects against a pulmonary hypertensive phenotype. These allow the study of one gene and its influence on the development of PH. We do not anticipate severe adverse events and would not keep animals should these arise causing suffering. Adult animals will be studied.

There might be instances where we need to singly-house animals for welfare or scientific reasons, such as:-we need to measure individual faecal/urinary output and/or food consumption for a prolonged period of time (i.e., re-grouping would not be feasible)-we have stud males for our breeding program and they fight when kept in social groups. Any animals kept singly-housed will be handled with due care and empathy and will be provided with suitable enrichment. If at any point in time the reasons for keeping animals singly-housed ceases to apply, and if in the opinion of animal care staff and/or NVS, it would be safe to return these animals to a social group (especially possible in the case of females), this will be carried out, always under proper supervision to ensure the regrouping is not detrimental to welfare.

Typically, what will be done to an animal used in your project?

Pulmonary hypertension (PH) will be induced by exposure of adult mice and rats (male and female) to normoxia or hypoxia with or without the VEGF antagonist sugen (up to 6 weeks). Mice with relevant genes either missing or over-expressed will also be studied. The gonads may be removed to assess the effects of sex hormones. The development of PH will be assessed under terminal anaesthesia using haemodynamic measurements. Some animals will be treated with drugs or RNA delivered as appropriate to that drug (e.g. subcutaneous injection, intra-venously, intraperitoneal injection, orally or intra-tracheally). Some animals may undergo a schedule 1 kill after the development of pulmonary hypertension for immuno-histological examination of lungs and heart. 10 animals will be treated per experimental group.

What are the expected impacts and/or adverse effects for the animals during your project?

For haemodynamic measurements, these will be carried out under anaesthesia and the animals will be humanely culled before they wake up. Minimal transient discomfort may occur during the induction of anaesthesia. Ear biopsy is the standard way to examine the genes affected in mice and this may involve only transient pain and mild haemorrhage and will be controlled by local pressure and/or cautery.

For gonadectomy, short term pain from surgery and risk of infection will be controlled by general anaesthesia and analgesia and the use of perioperative antibiotics, as advised by the Named Veterinary Surgeon. Should wound breakdown occur, the advice of the NVS will be sought and wound repair permitted on one occasion, otherwise the animal will be humanly killed by a schedule 1 method.

Oral gavage very rarely causes short term damage to the oesophagus and inhalation or drug administration into the trachea or intraperitoneal injection may induce peritonitis or organ damage. All animals dosed via the tail vein or having bloods removed via the tail vein will be monitored closely for signs of tail damage which occur rarely. After exposure to hypoxia, animals lose body weight within the first few days and demonstrate reduced activity. However, acclimatisation then occurs with animals returning to normal activity and eating behaviour, and they begin to gain weight at a normal rate.

All animals will be closely monitored for any of these adverse effects and animals exhibiting any unexpected harmful phenotypes will be humanely killed by a Schedule 1 method, or advice will be sought from the Home Office.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate (exposure to chronic hypoxia, dosing of drugs, high fat diet and gonadectomy 60%). Mild (breeding of transgenic animals 5-10%). Haemodynamic assessment is a non-recovery procedure.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

PAH is a complex disease which involves changes in pulmonary hemodynamics causing changes in right ventricular function. Hence we need to examine the effects of drugs in the whole animal. In parallel to these studies we can examine isolated lungs, hearts and arteries but these do not allow us to determine the effects that changes in the pulmonary circulation have on heart function and so the whole animal needs to be studied.

Which non-animal alternatives did you consider for use in this project?

We can use primary cells from patients to carry out key experiments. We have considered 3D cultures. There are no pulmonary arteries-on-a-chip technologies available at the moment but we could consider these in the future.

Why were they not suitable?

Whilst cells from patients are useful to confirm some key observations, the disease is rare and hence availability of these cells is very rare and so we can only carry out a few key experiments on them. Pulmonary cells are extremely specialised and so there are no alternative cells to these. The 3D co- cultures have a hypoxic core and they are non-reproduceable. In addition, the blood vessels in the lungs and heart have a dynamic

interaction in our bodies and we can only examine this in a whole animal. The cellular work will, however, inform and justify the direction of our animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers have been estimated based on numbers calculated for studies already funded by the BHF and MRC. 10% extra has been included to repeat selected experiments or they may be used if other funding applications are successful.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The n values for studies are calculated using a power calculation. Otherwise, we will use the NC3R's experimental design assistant or previous experience (ours, or from the literature) to select sample sizes. If additional animals are required to provide tissue for cell culture or tissue harvest for e.g. RNAseq analysis, these may be added to each group according to power calculations dictated by previous experiments that give statistically significant results. If we are in any doubt we consult our Institute statistician for advice. The animals will be kept under procedure for the minimum required time and drugs administered for the minimum required length of time as suggested by the literature or previous studies. We will always choose the appropriate control which will be strain, age and sex- matched. Where hypoxia is used, control normoxic groups will be studied. We harvest and retain tissue from all experimental animals and this can be reused for pilot experiments to e.g. look at distribution of a new potential target in the lung or heart prior to considering in vivo studies. Lungs can also be preserved for years for future studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will harvest, preserve and save tissue from the animals under procedure to be used for new pilot studies and to share amongst other projects and researchers. Blood sampling over time can be carried out sequentially in the same animal to reduce the number of animals required to obtain sequential data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models selected are the gold-standard refined models of PAH which mimic the clinical situation most closely. The chronic hypoxic model: In PAH the blood becomes hypoxic (low in oxygen) as thickening and loss of lung arteries means oxygen is not effectively transferred, from the air we breathe into the airways into the arteries. The addition of an injection of the VEGF antagonist sugen prior to hypoxic exposure refines the model such that vascular occlusive lesions appear similar to those seen in patients. Transgenic mice are studied where the genotype infers or protects against a pulmonary hypertensive phenotype. These allow the study of one gene and its influence on the development of PAH. None of these models develop disease so severely that the animals suffer pain or death. All invasive haemodynamic measurements are done under anaesthesia such that the animal does not wake up after the measurements. All researchers are highly trained, licenced and experienced and we are supported by trained veterinarians.

Why can’t you use animals that are less sentient?

All invasive procedures are done under terminal anaesthesia such that the animal does not wake up after the measurements. The exception is gonadectomy and this needs to be carried out in adult animals so that we can study adult sex hormonal effects.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is a project licence with a moderate severity banding, but nevertheless we will seek to implement refinements wherever possible, e.g., ensuring our breeders are at peak age for mating, that they do not have too many litters, that genotyping methods (if required) are the mildest possible, etc. Appropriate anaesthesia is always implemented. Animals that undergo sequential blood sampling by the tail vein are trained to enter a warming chamber to ensure dilation of blood vessels. For gonadectomy, post-operative pain management is implemented. Wherever possible we will also replace frequent dosing by using slow-release drug eluting sub-cutaneous pellets as an alternative.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs, EDA and breeding information.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information from the NIO and review the NC3Rs website.

159. Improving therapies for blood cancers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Therapy, Paediatrics, Leukaemia, Central nervous system

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This programme of work aims to identify new drug targets and treatments that may be less toxic and better at killing leukaemia and other blood cancers, especially those that have spread to sites outside the bone marrow, such as the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Childhood leukaemia is the commonest childhood cancer. Although cure rates are good, treatment is prolonged and toxic. Cancer is the leading cause of death for children aged 1-

14 years and despite improvements in survival, leukaemia still accounts for about a quarter of these deaths. Current leukaemia therapy involves the use of intensive multi-agent chemotherapy lasting 2-3 years. Even if cured, many survivors have significant treatment side-effects resulting in late mortality, reduced academic achievement, poor quality of life and accompanying health and societal impacts. The commonest long-term effects are adverse neurological (brain) outcomes seen in 20-40% of patients with leukaemia. This is because current treatment for childhood leukaemia involves intensive brain- directed chemotherapy to prevent the disease returning at this site. Treatment is delivered by up to 26 spinal taps with direct injection of chemotherapy into the spinal fluid around the brain. This is often done under general anaesthetic. This treatment causes many short term (e.g fits) and long-term side- effects (e.g. problems with learning and memory). It is also unpleasant for patients and is very expensive for the NHS. There is an urgent need to develop more effective, and less-toxic, treatments for childhood leukaemia and related blood cancers.

What outputs do you think you will see at the end of this project?

This project aims to discover new ways to treat blood cancer. These results will be made available to doctors and scientists by publishing in high-quality journals.

Who or what will benefit from these outputs, and how?

The results of this project will benefit patients with blood cancer by developing kinder and more effective treatments

They may also benefit the NHS by reducing the costs of treatment

They may also benefit wider society as more children with leukaemia will be cured enabling them to grow up and become effective contributors to society

How will you look to maximise the outputs of this work?

The results of this work will be discussed at scientific meetings with other experts in the field. Any scientific data from the experiments will be made available to other scientists after they have been published. We will collaborate with other researchers and will share our knowledge and expertise as much as possible.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In our previous work we have shown that if we give mice acute lymphoblastic leukaemia (the commonest cancer in children) then the leukaemia cells grow and spread around the body in a very similar way to patients. Our previous work using these mice with leukaemia has already discovered some important genes that might be responsible for keeping the

leukaemia cells alive. We have shown that the genes we discovered in mice are also important in patients with leukaemia. This means that mice are a very good "model system" for studying how leukaemia spreads to organs outside the bone marrow and how it survives in these new environments. We use young mice (usually 6-8 weeks old) in these experiments because leukaemia is most commonly seen in children. In some experiments we will use older (up to 12 months old) or younger (newborn) mice to allow us to look at the differences between leukaemia in babies, children and adults. Understanding these differences will allow us to develop more personalised treatments for patients.

Typically, what will be done to an animal used in your project?

The project covers a broad range of techniques, but 80% of the time we will use immunodeficient mice injected with human leukaemia cells (called xenograft experiments) and 20% of the time we will use genetically altered mice that develop leukaemia due to the genetic mutations they carry (called genetically altered (GA) mice).

For xenograft experiments the majority of mice will be injected with human leukaemia cells into a vein in their tail (80%) - this is relatively painless and quick. For more delicate samples (such as those taken directly from patients - 20% of cases) they may be put under anaesthetic to allow injection of the leukaemia cells directly into the bone marrow using a fine needle inserted into the leg bone - they will be given painkillers to relieve any discomfort which usually lasts less than a day. The leukaemia cells grow in the mice and spread around the body. The mice have regular health checks and may undergo blood tests/scans/other imaging to look at how fast the leukaemia is growing. These tests are usually done once a week or less. After 4-6 weeks the mice usually start to appear unwell. At this point we will humanely kill the mice to prevent suffering.

For our GA mice experiments (20%) the mice will develop leukaemia at a certain age or when we switch on the faulty gene. The mice have regular health checks and may undergo blood tests/scans/other imaging to look at how fast the leukaemia is growing. These tests are usually done once a week or less. After 2-6 weeks the mice usually start to appear unwell. At this point we will humanely kill the mice to prevent suffering.

For 50% of the mice we will try out new treatments to see if they can get rid of the leukaemia or slow its growth. Treatments can be given by injection or by mouth or added to drinking water or food and generally will last up to 4 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Leukaemia causes:

Low blood counts (anaemia) -causing reduced activity and tiredness - this lasts 1-2 weeks on average

Increased risks of infection (although infections are rare because we keep the mice in specialised sterile caging to protect them)
Weight loss - this is seen in the last 1-2 weeks of the illness

Small tumour formation can occur throughout the body (e.g in lymph nodes, liver and spleen) in the later stages of the disease.

Treatments may also cause side-effects such as loss of appetite, diarrhoea, weight loss or fur loss.

Injection of leukaemia cells directly into the bone marrow can cause discomfort which usually lasts less than a day and is helped by painkillers.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity (causing no more than momentary discomfort) - 50%

Moderate severity (discomfort lasting no longer than 72 hours on any occasion) - 50%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To develop new drugs we need to understand how leukaemia cells adapt to different environments within the body. We are currently unable to recreate these complex biological environments (comprising multiple different cell types, nutrients and blood supply) in test-tubes or tissue culture flasks. By using mouse models, we can not only identify molecules responsible for leukaemic spread or therapy resistance but also modify the leukaemia cells using genetic approaches and/or test new drugs to see if this can be overcome. These are essential to develop new clinic-ready therapies for patients with leukaemia and other blood cancers.

Which non-animal alternatives did you consider for use in this project?

All preliminary work (such as testing whether drugs kill leukaemia cells and what dose to use) will be done in the lab with cells grown in culture, before moving on to experiments in mice. Since we need to study cells taken directly from different sites around the body we have two alternatives - animal models or patient samples taken from the bone marrow and the spinal fluid.

Why were they not suitable?

Cell culture: Our central aim is to understand how leukaemic cells adapt to different environments within the body. We are currently unable to recreate these complex biological environments (comprising multiple different cell types, supporting matrix, nutrients and blood supply) accurately in test-tubes or tissue culture flasks.

Patient samples: Patient material is often very limited and generally does not survive or grow once outside the body. We cannot test experimental therapies directly in humans and cannot genetically alter leukaemia cells and inject them into patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have used statistical methods to determine that I will require around 8-10 mice per experimental group and typically experiments will compare 3 or 4 groups. Based on our current funded work and planned future work we will require 1200 mice per year to perform our research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have used both expertise from statisticians and also the NC3Rs' Experimental Design Assistant. Blood sampling and non-invasive imaging techniques (for example MRI) will be carried out for studies to obtain as much data from a smaller number of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

I will employ the most efficient breeding strategy at all times. Ongoing monitoring of a given cohort (mouse group) allows experiments to be stopped as soon as there is enough data (information), thus minimising suffering whilst obtaining meaningful and publishable results. For any new treatments we will always treat a small pilot cohort to estimate the effect size before performing the full experiment. When possible control mouse cohorts can be shared across studies, to reduce mouse numbers required for individual studies. We always maximise all the information we get from each mouse. During the experiment blood sampling and non-invasive imaging techniques will be carried out to obtain as much data from a smaller number of animals. At the end of the experiment we will analyse as many tissues as possible per mouse by harvesting brain, spleen, bone marrow, cerebrospinal fluid (CSF) and blood and sharing this tissue between different members of our research group working on different projects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a variety of mouse models in this project. The models have been developed to be more susceptible to human leukaemia and therefore we can study them without having to expose the mice to harmful irradiation. Other models have fluorescent markers that allow more straightforward investigation of processes within the organ(s) of interest using imaging without the need for additional invasive procedures. All these models were developed to cause the least pain, suffering or distress possible while providing us with valuable data on the disease of interest.

Why can't you use animals that are less sentient?

Mice are still sufficiently closely related to human beings to adequately represent the human condition, whereas other model organisms more distantly related would not replicate the disease sufficiently (on a genetic and disease characteristics level). Most of these experiments will be done on young mice, as we are studying childhood blood cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal monitoring, post-operative care, and pain management are an important part of all the procedures within the project. The need to minimise suffering is always considered when planning experiments. None of our experiments exceed a moderate severity level. All mice on experimental procedures will be frequently monitored (minimum 1 x weekly, increased to daily as needed) and humanely culled when exhibiting signs of altered health status and/or tumour burden or another specified endpoint is reached. We have developed, and successfully used, a stringent distress scoring system that allows an immediate identification of mice with adverse effects. Wherever possible we will use minipumps to deliver drugs to overcome the need for daily injections, therefore reducing the stress of repeated procedures. All researchers working on this project will undergo specific training in monitoring leukaemia development and health status in our models. We will refer to the literature for adverse effects of a new agent and when a genetic cohort is given a treatment for the first time, studies with a pilot-sized group will be carried out and closely monitored before extending to a larger cohort. All animals are housed in a dedicated facility proactive with environmental enrichment and the use of anaesthesia and analgesia under guidance from the named vet is routine practice. To minimise infections immunocompromised mice, will be housed in barrier caging under sterile conditions and handled in a Class 2 cabinet. Post-mortems are carried out to investigate any unexpected deaths.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?
For all studies we will refer to the Guidelines for the welfare and use of animals in cancer research (Workman et al, 2010) and ensure best working practice. We consult the NC3Rs guidelines and monitor refinement when practice advances are published (https://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All our work observes government guidelines we adopt new guidance as soon as these are recommended. We are also actively involved in our establishments 3Rs Day, and there are a number of Culture of Care events organized throughout the year to ensure everyone

stays up to date with current guidelines. I will also check the following website: https://www.nc3rs.org.uk/ monthly for updates and will address any updates at our weekly lab meeting and disseminate this information to all personal licence holders working on the project.

160. Provision of Biological Materials and Research Animals

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunology, Diagnostic, Disease prevention, Vaccine development

Animal types	Life stages
Cattle	juvenile, adult, neonate, pregnant
Sheep	juvenile, adult, pregnant, neonate
Pigs	juvenile, adult, neonate, pregnant
Geese	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This Project Licence aims to provide scientists with biological reagents (blood and blood products) and neonatal animals of a known health status to support the research of the establishment and programs of research at other collaborating establishments and institutes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding immune responses greatly aids in the development of vaccines and other interventions that can help prevent or minimise disease and thus improve animal health, welfare and productivity.
There are animal diseases that are difficult to diagnose and prevent and there are new, emerging diseases of livestock which science needs to understand in order to treat and prevent.

In the investigation of disease and the development of vaccines and other beneficial interventions, occasionally scientists may require small volumes of normal blood for purposes other than those defined in their own Project Licences. Additionally, some completely lab-based scientists may not have a Project Licence as they do not work in the whole animal. This may be allowed under the conditions of this licence provided the cost/benefit analysis for the procedure is deemed to be of sufficient merit by the Animal Welfare and Ethical Review Body (AWERB) and the procedure does not exceed the Home Office guidance on minimal severity protocols.

Surgical delivery of new-borns allows production of Specific Pathogen Free (SPF) animals, where disease risk and variability due to pathogens is eliminated. Scientists whose Project Licences cover the procedures they will perform on animals of a known pathogen exposure usually do not have surgical delivery on their own Project Licence.

What outputs do you think you will see at the end of this project?

This project will provide support to researchers working to promote livestock and one health through increased understanding of animal immune responses. This will aid the development of diagnostic tests, preventative and treatment strategies. Researchers are encouraged to publish study findings with the knowledge gained being shared through collaborations, publications and conferences.

The production of animals by surgical derivation is required to produce animals that have no exposure to pathogens which could cause disease and variation. This allows study of immune responses to a particular challenge, and the pathology resulting from it, without the potentially confounding or confusing effects of intercurrent acquired infections.

Who or what will benefit from these outputs, and how?

This Project Licence allows for the provision of blood products for use by scientists at the Establishment or other organisations (universities, hospitals and research institutes). This will benefit the development of diagnostic tests, preventative and treatment strategies to improve livestock health. Benefits may also be applied to a One health concept and improve human health.

For example, goose blood is utilised for clinical and surveillance purposes to test ruminants and other wild and managed animals (hare, grouse) for Louping ill, for clinical and surveillance purposes. Louping ill (LI) is a viral disease (Louping ill virus, LIV) transmitted by sheep ticks (Ixodes ricinus) and has been recorded for more than 200 years in Britain in sheep flocks. Louping ill virus (LIV) is mainly detected in sheep, cattle, red grouse and ticks in upland areas of the British Isles, particularly in Scotland, Cumbria, Wales, Devon and Ireland. It has also been detected in a range of other animal species, including goats, dogs, pigs, horses, deer, llamas, alpacas and mountain hares and, occasionally, in human. This test is of national importance with the establishment being the only one providing it.

Goose blood is also used as a feed source to maintain poultry red mite colonies. Artificial rearing of colonies aids the development of vaccines against this serious health and welfare concern of the poultry industry.

The blood samples are crucial to the development of novel vectors for vaccine delivery in sheep. Currently, we use these vectors in pre-clinical cell culture studies and the blood samples provide a source of appropriate primary cells for culture. We expect these vaccine delivery vectors to lead to improved future vaccines for controlling infectious diseases in sheep and cattle. Improved disease control will reduce economic losses due to disease and alleviate the animal suffering caused by those diseases. Reduction in disease of farmed animals also reduces the environmental impact of farming.

Whole blood donation may be used in *in vitro* cell culture immunological assays. Sheep and cattle blood is required to isolate and grow the potentially zoonotic bacteria Anaplasma phagocytophilum, the cause of Tick Borne Fever. This is a tick-transmitted disease widespread in northern Europe and the UK causing severe disease in ruminants and other mammals, including humans.

The production of SPF animals by caesarean derivation is required to produce animals with no maternal antibodies for use in studies under a subsequent Project Licence, and on occasions for studies where animals of seronegative status, for specific antibodies, are required to comply with either Pharmacopeia guidelines or specific study requirements.

In some cases SPF animals are required for both safety and efficacy testing of veterinary products. Some of the studies required for the regulatory submission for new products need to be carried out in the most naïve category of animals in which the product may be used in the field. A seronegative animal is generally considered to be the most naïve animal. In some cases it is possible to source antibody negative animals for particular diseases from the field which can then be reared conventionally, which removes the need for caesarian-derived SPF animals. However, for ubiquitous organisms and in the case of endemic disease, it is often not possible to find animals in the field which are seronegative, as all will have been exposed to the organism, in the environment or the dam's colostrum. In such instances, SPF animals are required.

Where possible, colostrum-deprived animals can be substituted in place of caesarian-derived animals and this is done under a different Project Licence.

How will you look to maximise the outputs of this work?

Publications and knowledge exchange is encouraged from the research groups benefitting from this licence. Data is provided to commercial clients to develop new bioactives used in the treatment and prevention of disease.

Serosurveillance, using goose blood to detect LIV, is generally used to identify pastures where possible tick exposure might be likely therefore avoiding exposure not only to LIV but also to other tick borne diseases and to monitor disease prevalence in grouse moors.

Species and numbers of animals expected to be used

- Cattle: 100
- Sheep: 200
- Pigs: 120
- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mature healthy animals are the only suitable source for blood products required. The animals are selected based on cell types and blood properties specific to the disease being investigated.

The production of SPF animals provides a naive animal model that is not affected by passive immunity nor variability due to exposure to a pathogen.

Typically, what will be done to an animal used in your project?

The animals of farmed species are kept in a natural farm environment, indoors or outdoors, in company, and the majority will be used to provide small blood samples at specified, relatively infrequent, intervals. Frequency and volume of blood taken will follow local welfare guidelines. Animals will restrained by normal farm practice and blood withdrawn by experienced, trained PIL holders. Other than mild discomfort associated with needle-prick there should be no adverse effects and the Severity is Mild. The procedure is quick and animals are returned to their group.

Animals kept alive at the end of procedures will be returned to stock, under the care of a veterinary surgeon with knowledge of the lifetime experience of the animal, who has determined that the animal has been fully restored to health.

Full term dams (sheep, pigs) will undergo general anaesthesia to allow surgical delivery of offspring. The dam will not regain consciousness and will be euthansed.

What are the expected impacts and/or adverse effects for the animals during your project?

All blood sampling procedures on the licence are of mild severity and no adverse effects, other than mild discomfort from the needle-prick are expected. This will be of a brief time duration in the majority of animals.

Each subsequent blood sample is a reuse and then animals are returned to stock (kept alive at the establishment). This information is kept on a database. Some animals are humanely euthanased for reasons of age or prevailing circumstances.

In the case of surgical derived offspring, the donor dam is euthanased at the end of the surgery without regaining consciousness.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

This Project Licence would allow a number of farmed species (sheep, pigs and cattle) to be blood sampled and returned to stock and is expected to be of mild severity for all animals. (90% of all project animals)

For the delivery by Caesarian section under general anaesthetic (sheep, pigs) of infection-free offspring this is considered Non-recovery for all animals (10% of all project animals).

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Blood can only be obtained from the actual animal. Currently, different species are required on this licence depending on the proposed use of the blood products e.g avian blood is required for haemagglutination-inhibition assays. Some donors are chosen as the animal is the natural host of the disease being investigated. The subsequent scientific work is generally lab-based and often provides a platform for *in vitro* work replacing the infection of the live animal.

Live neonatal animals, in the numbers required, can only presently be obtained from an adult female animal.

Which non-animal alternatives did you consider for use in this project?

Scientists at the establishment endeavour to use alternatives to live animals and blood supplied will often be used in *in vitro* models.

Attempts at developing alternative serological assays, such as ELISA, have been unsuccessful and currently using goose blood in Hemagglutination-inhibition assays (HIA) is the only assay available for Louping ill virus (LIV) surveillance and disease diagnosis in the UK.

Where possible, colostrum-deprived animals can be substituted in place of caesarian-derived animals and this is done under a different Project Licence.

In some cases it is possible to source antibody negative animals for particular diseases from the field which can then be reared conventionally, which removes the need for caesarian-derived SPF animals.

Why were they not suitable?

Many immunological assays require specific cells from within the blood to cause a detectable reaction with the pathogen.

Where it is impossible to confirm an animal has not been exposed to a disease, as in the presence of a ubiquitous pathogen or where no diagnostic test exists, it may be necessary to produce an animal of known health status, under these circumstances.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on the historical frequency that samples are requested and the need to rotate animals to ensure sample frequency is acceptable to local guidance.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to the surgical delivery of gnotobiotic and SPF animals, a biometrician will review and advise on the number of neonates required for each experiment. Pregnant animals are, where possible, scanned in advance using ultrasound to determine the number of foetuses. The number of dams used is kept to a minimum by using dams with high numbers of foetuses.

The use of SPF lambs provides reduced experimental variation than would lambs in standard housing, thereby providing a refinement to the experiment and reducing experimental group size and contributing to the goals of the 3Rs.

Use of SPF or gnotobiotic caesarian-derived animals can actually reduce the overall number of animals used, since it is not uncommon for conventional vaccine studies to collapse because of seroconversion in the negative control group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All proposed procedures to be carried out under the authority of this licence are assessed by the AWERB of the Institute. Requests for these materials and animals are co-ordinated so that the minimum number of animals are required.

The minimum number of each species required for blood sampling are kept so that the limitations on frequency and volume are not exceeded while normal demand is met.

Although the blood samples are essential for our research, many of the research groups require them only periodically and it would not be cost effective to maintain sole-access animals for each group. By accessing samples through this project, this spreads availability over a wide range of research projects, thereby reducing the number of animals required. If every research lab maintained their own group of sheep and cattle, there would be significantly more animals required overall.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species chosen are those required by the scientists for their particular projects and are often the natural hosts of the disease under study. Trained statisticians are available to provide independent advice on experimental design. All projects require approval by the AWERB, which includes a biometrician.

Trained, experienced, licenced staff are used to collect the blood samples. Training records are audited. Excellent farm animal handling facilities are on site. Stockmen assist with correct restraint and report any concerns regarding competency of phlebotomist.

Gnotobiotic and SPF surgical deliveries, to produce animals of known health status, are performed by trained, experienced, licensed Veterinary Surgeons, under general anaesthesia. These are non- recovery procedures.

Why can’t you use animals that are less sentient?

Healthy, mature animals are the most suited to donate blood.

Dams undergoing surgical delivery are terminally anaesthetised and performed as a non-recovery procedure.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal technicians are trained and experienced in animal restraint. The regular blood donors become accustomed to the minor procedures and experience minimal stress. Animal technicians monitor the animals at regular intervals and seek veterinary attention for any animals of concern.

The delivery of SPF animals has been developed and refined over the years to ensure good anaesthetic and aseptic technique.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Percie du Sert, N., Hurst, V., Ahluwalia, A. et al. The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research. BMC Vet Res 16, 242 (2020). https://doi.org/10.1186/s12917-020-02451-y

Guidance from NC3Rs and Norecopa will be followed.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs, Norecopa and LASA Website. The Establishment 3Rs Group.
Relevant training courses and communication with colleagues working in the field.

161. Effects of Anaesthetic and Other Related Agents on Organ Injury and Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Anaesthetic, Organ injury, Cancer, Molecular mechanism, Therapy

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile
Rats	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to investigate the impacts of anaesthetic and other related agents on organ injury and cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The early findings of studies we have been doing over a few years are promising but more studies are needed in order to develop our ideas to benefit patients. This project focuses on four different areas with the aim of improving patient outcomes:

Kidney ischaemia-reperfusion injury

Kidney transplantation

Hypoxic-ischaemic encephalopathy (HIE) caused by a shortage of oxygen during birth leading to brain injury

Use of anaesthetics in cancersurgery

Firstly, acute kidney injury (AKI) remains a formidable medical challenge worldwide. AKI has become the focus of intense epidemiologic, clinical, translational, and basic science research. This focus is well-deserved given an incidence of 21.6% for all hospitalized adults worldwide, mortality of 23.9%, and an association with the progression of chronic kidney disease (CKD) to end-stage renal disease (ESRD). AKI has numerous etiologies that all result in similar structural and functional outcomes. It is increasingly recognized that AKI is a major contributor to the development of CKD. CKD affects approximately 10% of the world's population and places a significant burden on economy, society and healthcare worldwide. Acute kidney injury caused by ischaemia-reperfusion injury is a significant clinical problem in cardiovascular surgical procedures and kidney transplantation. With more surgical procedures being performed within an aging population, the incidence of acute kidney injury associated with ischaemia-reperfusion after surgery is increasing; this has a high rate of mortality and morbidity. Furthermore, the cost of managing patients with these complications is a huge burden on the NHS. Therefore, investigating the new underlying molecular mechanisms of kidney ischaemia-reperfusion injury and developing novel therapeutic strategies to protect the kidneys are urgently needed.

Secondly, more than 9,000 people in the UK need an organ transplant to save or improve the quality of their lives; most are awaiting kidneys. In 2007, more than 6,000 patients were on the waiting list for kidney transplantation. Donor organs are highly precious resources, but transplants can fail completely or not function as well as they should. Our research will look at new ways of reducing transplant failure and our findings could be extended to all organ transplantation where similar conditions apply. Kidney transplantation is the best treatment for patients with end-stage kidney failure and gives the best results, good quality of life and cost savings when compared with other treatments such as dialysis. There is a severe shortage of donated kidneys and efforts are being made to increase availability by extending the range of people who can donate organs, including non-living donors. Our previous research has shown that the use of the new anesthetic gas xenon before, during or after organ removal and transplant can greatly improve chances of successful transplantation.

Thirdly, HIE is a devastating condition caused by a shortage of oxygen at birth and remains a major cause of sudden death and long-term nerve disease in infants and children even in the developed world. This type of brain injury is currently seen in between 1 and 6 per 1,000 live births in the developed world with approximately 30% of infants who survive developing life-long conditions including cerebral palsy, learning disabilities, epilepsy and mental retardation. The financial and emotional cost of caring for those affected by HIE is considerable due to the severity and lifelong nature of the handicap. In addition, it is common for legal action to be taken by families of those affected, with claims costing the NHS about £300m a year and in 2006, it was estimated that there were outstanding claims of £5 billion for HIE related cases. There are currently limited methods that can be used to reduce the likelihood of HIE related brain injury, so it is a major priority to develop new methods.

Finally, cancer is a major public health problem in the world causing disease and death. Despite better treatments for cancer over recent decades, the chances of cancer coming back after surgery are still high. It has been accepted that surgery itself can lead to cancer spreading to other parts of the body. The effect of anaesthetics has not been thoroughly investigated, despite some studies indicating that the choice of anaesthesia could lead to better patient outcomes after surgery. Some recent studies we have done in the laboratory have led us to believe that there are clear reasons for this at the small scale.

What outputs do you think you will see at the end of this project?

The major benefits expected to be obtained from this project are in new information on some of the most commonly used anaesthetic agents and pain relief medicines. While most of this work is still in the basic science field, much of the information will be useful to other researchers and an important knowledge source for clinicians in relation to their work. We hope to publish our work in well-respected scientific journals. The impact of our research outputs are as follows:

Kidney ischaemia-reperfusion injury

Acute kidney injury (AKI) such as ischaemia-reperfusion injury remains a formidable medical challenge worldwide. Unfortunately, no effective treatment strategies are available due to an insufficient understanding of the underlying mechanisms. If our research outcome is positive, large animal studies and clinical trials can be initiated subsequently for enhancing patient recovery.

Kidney transplantation

As a mainstream therapeutic method, kidney transplantation has drastically transformed the health quality of patients suffering from end-stage renal failure. Success in renal transplantation is promoted by introduction of powerful immuno-suppressive medication. However, the long-term outcome of the transplanted kidney is still far from ideal. A high priority in kidney transplantation research, therefore, lies in the development of reno-protective strategy, which confers a long-term benefit in graft survival. We have been working in developing novel renoprotective strategy against early graft injury and later graft lost and this will ultimately enhance the recipient survival and increase the number and quality of donor organs.

Neonatal brain injury

Perinatal hypoxic-ischaemic brain damage due to lack of oxygen to the brain during birth remains a major cause of mortality and morbidity. It is crucial that strategies are developed to minimise the long- term neurological sequelae of fetal hypoxia-ischaemia during birth. Our research will lead to development of novel neuroprotective therapies against neonatal hypoxic-ischaemic encephalopathy, which will reduce the impact of this injury on the neonates.

Surgery, anesthetics and cancer

Cancer remains the leading cause of death worldwide. Surgical resection is a commonly used method for patients with solid tumors. However, tumor metastasis after cancer surgery often occurs, which is mainly responsible for deaths in cancer patients. Our research will improve the understanding of the molecular mechanisms of tumor growth,

angiogenesis, metastasis and chemo-resistance and more importantly, the factors which promote cancer recurrence after surgery.

Who or what will benefit from these outputs, and how?

Our research will be published once completed, and available to other researchers working on similar themes. The way that many of these anaesthetic agents work is through known routes in the body, which may lead to ideas on the possible actions of similar drugs. Other researchers may use our findings to identify other drugs which give useful results. In the longer term, many of the anaesthetics we use may be able to be used for a wider range of patients, including the most vulnerable. For example, if one anaesthetic is found to increase spread of certain cancers, planning the best treatment for patients could take this into account. It may be possible to change practices in operating theatres and hospitals to improve outcomes in future.

Additionally, recent findings suggest that Argon may have great protective benefits, with the added bonus of being an extremely cheap commodity. Xenon is currently undergoing clinical trials for the protection of the nervous system in newborns, a research field our group has been involved in and published data on. There is very little published data on Argon, so any findings from our research would greatly increase knowledge of how this agent works.

How will you look to maximise the outputs of this work?

The proposed projects are likely to be published in highly respected scientific journals and we will present our research data in the national and international conferences for promoting the dissemination of new knowledge to the general public.

Species and numbers of animals expected to be used

- Mice: 3500
- Rats: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project hopes to develop and test a range of interventions in different patients' illness, especially anaesthetic agents. If these proposed inventions or strategies are effective, then they can be introduced to clinical practice for patients' benefits. As most people will be exposed to anaesthetic agents at least once in their lives, research into the true potential of these drugs to cause any lasting benefits or harm need to be carefully considered. This project aims to determine in a number of scenarios which anaesthetic agent may be the most appropriate to use to reduce adverse outcomes for patients.

Mice and rats are used for different protocols in this PPL (mice for kidney ischaemia-reperfusion injury, rats for transplantation, both mice and rats can be used for neonatal asphyxia study and SCID and nude mice for cancer study). Different life stages will be chosen to simulate the disease or injury occurring in humans. For examples, neonatal

asphyxia in rats/mice is used to need to mimic hypoxia events in early life in humans, so specific postnatal days are chosen to correspond to specific ages in human. Rodents share highly similar mammalian anatomy, physiology and immune system with human. Laboratory rodents are inbred with fast reproduction rate and identical genetic background, allowing experiments to be completed within relatively short period of time with very good reproducibility. Genetic modification is easier in mice and rats will allow easier surgical manoeuvre.

Typically, what will be done to an animal used in your project?

The protocol number and major procedures to be performed on animals under this licence are:

1: Renal Ischaemia
Pre-treatment of pharmacological agents or hypoxia. Under general anaesthesia, laparotomy with or without clamping of renal pedicle or Laparotomy with unilateral clamping of one renal pedicle (maximum time 45 minutes) combined with unilateral nephrectomy of the second kidney (to prevent compensation) or laparotomy to clamp renal pedicle vasculature bilaterally (maximum time 25 minutes).

2: Kidney Donor

Pre-treatment of pharmacological agents or hypoxia. Under general anaesthesia, unilateral nephrectomy and harvest kidney graft.

3: Kidney Transplantation

Under general anaesthesia, A kidney organ that has been harvested from a donor animal in protocol 2 will be used for transplant. Unilateral nephrectomy is performed in the recipient animal, followed by single kidney transplant with end-to-end anastomosis of renal artery, vein and ureter, followed by removal of second kidney. Post-treatment of pharmacological agents.

4: Perinatal asphyxia in dam

Pre-treatment of pharmacological agents. Dam will then be killed by schedule 1 method and laparotomy performed following confirmation of death. One uterine horn is clamped for a periods of time to induce hypoxia and placed in temperature controlled saline for period ranging from 5 to 30mins. Foeti in remaining horn are delivered via caesarean section for immediate resuscitation.

5: Perinatal asphyxia in pups

Pups come from harvest of uteri of gravid dams in Protocol 4. Animals after delivery (at any age) will be exposed to hypoxia (8% O2) in a purposely built hypoxic chamber for up to 2 hours. After a period of approximately 6 weeks, animals will undergo any of the behavioural studies.

11: Cancer growth, metastasis, diagnosis and therapy for solid cancer model

NSG or SCID mice will undergo injection implantation of a cell suspension of cancer cells under anaesthesia, such as A549 and Caco-2, either subcutaneously, or via tail vein or

intraarterially (surgical exposure of carotid artery). Anaesthesia is then maintained for up to 2 hours. Vehicle control will be administered in some animals.

12: Cancer growth, metastasis, diagnosis and anaesthetics for leukaemia model

Animals will undergo implantation of a cell suspension of cancer cells through tail vein injection or be given injection of chemicals. Animals are treated with anaesthetics agents. Anti-cancer drugs (e.g. Cytarabine Ara C) are given to mice intravenously or intraperitonially.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of adverse effects associated with this license are mild in nature and are not expected to be seen, such as following simple anaesthetic gas exposure. Some adverse effects may be seen following surgical procedures and if cancer or leukaemia are brought about in the animal, but we will follow strict sterile techniques and check animals daily so that adverse effects should be rare. We have detailed instructions for the care and monitoring of animals and animals will be humanely killed if they show an symptoms unexpected severity. Actual severity will be recorded for each individual animal to allow us to closely monitor the progression of each protocol and ensure close tracking of animal welfare, as well as experimenter competence.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All procedures are either mild or moderate severity. All animals (100% of mice or rats which undergoing these procedures) will experience the severity level. All animals will be killed after experiments in a humane manner.

1: Renal Ischaemia
Severity category: Moderate
Percentage of mice or rats undergoing this severity: 100%

2: Kidney Donor
Severity category: Moderate
Percentage of mice or rats undergoing this severity: 100%

3: Kidney Transplantation
Severity category: Moderate
Percentage of mice or rats undergoing this severity: 100%

4: Perinatal asphyxia in dam
Severity category: Moderate
Percentage of mice or rats undergoing this severity: 100%

5: Perinatal asphyxia in pups
Severity category: Moderate
Percentage of mice or rats undergoing this severity: 100%

6: Standard Superovulation
Severity category: Mild
Percentage of mice undergoing this severity: 100%

7: Standard Generation of founders
Severity category: Mild
Percentage of mice undergoing this severity: 100%

8: Standard ICL Embryo recipients
Severity category: Moderate
Percentage of mice undergoing this severity: 100%

9: Standard Vasectomy
Severity category: Moderate
Percentage of mice undergoing this severity: 100%

10: Standard ICL Breeding and maintenance of GA animals
Severity category: Mild
Percentage of mice undergoing this severity: 100%

11: Cancer growth, metastasis, diagnosis and therapy for solid cancer model Severity category: Moderate
Percentage of mice undergoing this severity: 50-100%

12: Cancer growth, metastasis, diagnosis and anaesthetics for leukaemia model Severity category: Moderate
Percentage of mice undergoing this severity: 50-100%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We have considered whether we could avoid using animals, but there are no alternatives which can reproduce the whole body responses that we will be investigating. Active efforts have been made to achieve the best replacement, refinement and reduction procedures possible, with advice from the NVS and NACWO.

Which non-animal alternatives did you consider for use in this project?

Extensive laboratory work will be carried out before beginning experiments with animals to work out the best dose levels for the substances we are investigating.

A number of resources (such as the European Union Reference Laboratory for alternatives to animal testing) were looked at during our planning stages to see if there were any different ways of doing this research but due to the nature of this work, none were suitable.

Why were they not suitable?

Due to the complex nature of the systems studied, such as nerve damage or organ inflammation, a whole animal is needed. As our studies address clinical issues it is necessary to observe whole body responses to any given treatments as well as to ensure no unexpected side-effects occur in animals. Wherever possible, studies of drugs will be carried out in the laboratory rather than on animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical analysis will be used to establish the minimum number of animals needed for meaningful results. The design of our experiments and analysis of the results have been and will be further discussed as projects progress. We will aim throughout to keep numbers of animals to the minimum necessary for our studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We carried out extensive work in the laboratory first to help us identify the most realistic treatments to investigate in our animal work, for example live imaging, along with statistical calculations. Careful management of breeding in order to provide pregnant females and ‘sham’ pregnancies with which to compare these, will ensure that no animals are bred unnecessarily.
We aim to get the maximum amount of information from the minimum number of animals.

The ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines will be followed throughout the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be carried out to optimise the number of animals. Laboratory studies, such as growing cells in dishes, will be used to establish the mechanisms whenever it is possible.

Sharing of animal tissues will be actively considered based on the availability of tissues in other research groups. Breeding will be carefully controlled.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models used for this project are listed below:

Rodent kidney ischaemia-reperfusion injury model

Acute kidney injury caused by ischaemia-reperfusion injury is a significant clinical problem in cardiovascular surgical procedures. We use the rodent model of ischaemia-reperfusion injury to investigate the underlying molecular mechanisms and protective strategies. The surgery is performed under general aneasthesia and analgesia is provided to reduce the pain and suffering. The animals are monitored on the daily basis after surgery to ensure adverse effects are minimized.

Rodent kidney transplantation model (donor and recipient)

The rodent kidney transplantation model is used to assess the protective effects of proposed therapeutic strategies. For the donor surgery, we have considerable experience of single kidney removal. Stress to the kidney donor is reduced by carrying out much of the experimental treatment on the kidneys after they have been removed from the body. This reduces the degree of handling and treatment for donor animals. For the recipient surgery, we conduct the artery, vein and ureteral anastomosis under general anesthesia. In addition, analgesia will be provided to reduce the pain. The animals are monitored on the daily basis after surgery to ensure adverse effects are minimized.

Rodent neonatal brain hypoxia model
This rodent model involving both mothers and newborns will be carried out to investigate the treatment methods on the neonatal brain hypoxia injury. All treatments given will be chosen to give the least stress possible to the mothers. Weighing pups and handling procedures will be reduced as much as possible, usually only three times during the first week so as not to stress the mothers and to ensure there is no rejection of surrogate pups. All animals used for evaluation of the nervous system, such as in a water maze, will be checked beforehand to ensure there is no physical defect which may affect their ability to perform behavioral tests, such as swimming.

Animal tumor xenograft model

The tumor xenograft model is used to investigate the cancer development and treatment strategy. It is necessary to use nude mice for our cancer studies, and they are prone to infection. These animals will be carefully monitored and when measuring tumour development using imaging techniques, will only be used for one of the methods of imaging. Limits on the number of sessions for each individual will be set to minimise stress.

Why can’t you use animals that are less sentient?

Laboratory rats and mice provide ideal animal models for biomedical research and comparative medicine studies because they have many similarities to humans in terms of anatomy and physiology. The use of rodents also provides advantages related to the

wealth of genetic information available to scientists. The identification of genes responsible for organ injury and cancer provides an excellent example of the utility of rodent for studying human organ injury and cancer, and their treatment strategy. Using comparative genomic techniques, identification of a gene responsible in the rodent allows the equivalent gene to be identified in human. Rats are the preferred rodent model for cardiovascular and transplantation surgery where their larger size is an advantage, especially for facilitating surgical procedures and other types of testing after surgery. The rodents are commonly used for behavioral studies because they are much more social than other animals and their behavior better mimic behavior seen in humans. Animals that are less sentient, such as fish, do not have the above mentioned advantages in the rodent models and therefore can not be used as the specific scientific models in our studies. Animals at a more immature life stage can not be used in our project as organ injury or cancer occur mainly in the mature life stage in humans. Animals that have been terminally anaesthetised do not serve the purpose in our studies as we intend to explore the long-term effects of proposed treatment on the animals, which is particularly important for the prognosis and recovery of our patients.

The rodent models used in this project are firmly established in our lab and accepted by the scientific community. In addition, mice which are genetically altered in the way we need are easy to obtain and makes them the most appropriate species for our work. The mice and rats are raised in controlled, pathogen-free environments, provided by our housing facilities. and the effect of environmental factors can be highly controlled.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Based on our previous work, along with discussions with veterinary staff, the projects have been designed in a way that minimises suffering of animals and to cause the minimum severity possible. We will monitor severity during all our experiments and raise any concerns immediately with the NVS, NACWO and/or Home Office.

Animals will be housed and maintained in groups, where possible, and given environmental enrichment and free access to food according to best practice as advised by the animal technicians. Each experiment has a strict list of possible adverse effects, humane endpoints and procedures to follow when there is any doubt over the welfare of an animal. Wherever possible the mildest pre- treatments and surgical methods will be used to obtain the most relevant data. Where a more harmful procedure must be followed, each animal will be closely monitored to ensure their health and welfare, and the welfare of the animal will be placed before scientific outcomes. In some protocols, the nature of our studies investigating anaesthetics and pain relief may even reduce pain and suffering the animals might experience.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines to ensure experiments are conducted in the most refined way. We also will follow aseptic surgery guidelines,
established in our animal facilities and the guidelines for cancer studies in rodents, which is essential for the care of the rodents with tumor xenografts.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The national center for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs) will provide latest advances in the 3Rs. We will stay informed about their new policy and knowledge and implement these advances effectively in our projects. In addition, we will be advised by the local 3Rs manager for effective and timely response and implementation.

162. Immunity to ectoparasites of ruminants

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

vaccines, ectoparasite, livestock, ruminants, immunity

Animal types	Life stages
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The specific aims of the project are:

To understand the nature of the protective immune response which is induced by exposure to, or administration of vaccines against, the ectoparasitic mite, *Psoroptes ovis* in sheep.

To use this information to improve the effectiveness of vaccines such that they will provide an important tool in the control of infestation with *Psoroptes ovis* (sheep scab or psoroptic mange).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

The vaccine that is being developed in the project will directly benefit livestock by protecting them from parasitic disease. This benefits both the welfare and productivity of the vaccinated animal but also reduces reliance on synthetic chemicals, adding to global food security and reducing environmental contamination. In addition, the parasite which is being investigated here has close relatives, which have negative health impacts on humans and other animals. i.e. scabies mites (*Sarcoptes scabiei*) and the house dust mite (*Dermatophagoides farinae*).

What outputs do you think you will see at the end of this project?

New prototype vaccine for further development to commercial products

New information on the host: parasite interaction

New information on vaccine and adjuvant effects on the immune system

Multiple scientific publications and lay articles on livestock vaccines

Who or what will benefit from these outputs, and how?

Short term beneficiaries will be researchers working in the fields of vaccinology and ruminant immunology through the availability of new information on the host:parasite interaction, immunology and vaccinology which will accelerate their own research programmes. Longer term beneficiaries include stakeholders in the vaccine and livestock industries through the production of new commercialisable tools for animal health and welfare. Societal benefits can also be seen through the reduction on reliance of injectable macrocyclic lactones and organophosphate dips with the attendant environmental and safety concerns that these bring.

How will you look to maximise the outputs of this work?

The applicants have a long track record of collaboration and effective knowledge exchange and outputs will be maximised through the following approaches:

Scientific Audiences: The results of our investigations will be published in open access journals appropriate for subject matter, 3Rs and scientific impact. All manuscripts will follow the ARRIVE guidelines [Kilkenny et al., 2010. PLoS Biol 8(6): e1000412] to promote accurate reporting appropriate for 3Rs initiatives.

During the course of the project we will attend scientific conferences (e.g. the World Association for the Advancement of Veterinary Parasitology Conference) to communicate progress and to emphasise the focus on scientific excellence in this project, highlighting crossovers in disciplines. The licence holder will attend the British Society for Parasitology Annual Spring meeting each year to communicate these aspects. The licence holder is an active member of the BBSRC's International Veterinary Vaccinology Network and will attend their annual meetings to disseminate the approach and results (both successful and unsuccessful) to this community. The licence holder interacts with a large number of researchers through formal networks, which promote co-operation and multidisciplinary networking between scientists and stakeholders. In addition, as objectives are successfully completed we will directly communicate the emerging technology by email and/or Microsoft Teams meetings to the research groups most likely to benefit from it.

Educational and Public: The licence holder teaches undergraduate and postgraduate students in parasitology and will use these opportunities to promote the outputs and principles of this project. For dissemination to the wider public, the applicant will attend the Royal Highland Show in each year of the grant, to communicate our results, their impact and context to members of the general public. The impact of the project will be made available on the host institution website as a resource for the public, policymakers and Government stakeholders in the food, animal health, environment and rural sectors.

Species and numbers of animals expected to be used

- Sheep: 950

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in these protocols are the natural hosts for the parasite under study. The life stages of the ruminants used are the most susceptible to this parasite and also the stages for which the economic impact of infestation isthe highest.

Typically, what will be done to an animal used in your project?

Animals in this project will be administered vaccines by the most appropriate route (this may be injections or sprays for example) and then infested with *Psoroptes ovis* mites using our standard challenge infestation. Typically animals would receive 3 injections of the vaccine, 2 weeks apart and would then be challenged with the mites for a maximum period of 6 weeks in experimental settings.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects on the animals are expected to be moderate. Infestation of the skin with *Psoroptes ovis* is characterized by exuberant yellowish scabs, additional signs include restlessness, pruritus, scratching, yellow-stained fleece, wool-loss, head tossing, bleeding wounds and loss of condition. In particular, the disease can cause considerable irritation or pain, or both. Typically these effects would be for the duration of the infestation, so a maximum period of 6 weeks in an experimental setting. However, we have extensive experience on the course of infestation following experimental challenge and, at termination of the experiment the area of lesion is expected to be less than 20% of total body surface area. The injection of recombinant *P. ovis* proteins as part of the vaccine is considered unlikely to cause any adverse reaction, although animals will be carefully monitored during and immediately following these injections. Quil A adjuvant has been widely employed by ourselves and others in vaccines in sheep, without any adverse reaction. Infestation of sheep scab mites will be monitored closely.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals infested with Psoroptes ovis would be expected to suffer a maximum of a moderate degree of severity. This will be controlled by limiting the number of mites used for each application to ~100 mixed stage mites. Animals will be monitored, and infestations will only be allowed to proceed until a maximum of 20% of the body surface is affected or for a maximum of 6 weeks duration.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The parasites being studied in the project are "obligate" parasites. This means that they cannot survive off of the host animal. We must therefore use host animals (sheep) to maintain these parasites before and during vaccine trials.

Which non-animal alternatives did you consider for use in this project?

Currently there are none as the mite *Psoroptes ovis* cannot be maintained off of the live ovine host. However, it is our intention to continue to work towards developing an off-host feeding and maintenance system for *P. ovis*. Previous attempts to develop such a system have successfully maintained mites in vitro for a period of 3 weeks, however the mites were unable to progress through their entire life cycle in this time (egg, larvae, protonymph, tritonymph, adult (male and female)). Future research in our group will continue to seek alternatives to replace the need to use live animals for these studies with a focus on developing an efficient off-host rearing system that is able to progress the mite life cycle from eggs to adults.

Why were they not suitable?

Currently no suitable alternatives exist but we will continue to work towards developing such a system in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimates are based on the numbers of animals used in previous studies over the last ~10 years and have been optimised through collaboration with statisticians reviewing data from our previous experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to each experiment, we review data from previous similar experiments, estimate the levels of effect of any treatment that we want to be able to record and collaborate with expert statisticians to determine the minimum numbers of animals required to accurately determine treatment efficacy

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Maintaining good animal health throughout every experiment to avoid animal numbers reducing from disease which is not related to the disease under study. In addition, wherever possible we will make samples taken from live animals and any tissues from any euthanased animals available to other researchers for their use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species being used (sheep) is the natural host for *Psoroptes ovis* and also the target species for the vaccine being developed, so are the most appropriate model species to be employed here. Vaccination and challenge of sheep consists of 3 immunisations with the candidate antigen(s) in adjuvant (QuilA) two weeks apart and animals are then experimentally challenged with a carefully controlled mite infestation. During infestation and vaccine testing, sheep are routinely monitored by veterinary staff and are treated with veterinary medicines if required, based on clinical symptoms.

Why can’t you use animals that are less sentient?

The mite, *Psoroptes ovis* has adapted to surviving on lambs and ewes and has a relatively long-lasting lifecycle (several weeks) as such the use of terminally anaesthetised animals would not be practical. In addition, as previous infestations can result in a degree of protective immunity, we need to ensure that the animals used in the trials are naive for sheep scab with no history of infestation, which is easier to guarantee in younger animals with a known history.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring post procedures will identify any areas which require refinement. For example, animals are closely monitored following vaccination and, if any of the compounds administered cause pain, appropriate analgesia will be administered

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where appropriate, the World Association for the Advancement of Veterinary Parasitology guidelines for best practise will be followed https://www.waavp.org. In addition, the ARRIVE guidelines 2.0 will be followed to allow the experiments to be performed in the most refined way and the publication of the data in the most appropriate form. https://arriveguidelines.org/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The host institution holds numerous NC3R research grants and has regular contacts with this body. In addition, we have an active 3Rs committee, which provides advice to project and personal licence holders. Any relevant advances in the 3Rs will be implemented into any of the protocols where appropriate.

163. Immunity, Inflammation and Tissue Function

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Inflammation, Immunity, Homeostasis, Macrophage, Tissue Damage

Animal types	Life stages
Mice	juvenile, neonate, pregnant, adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is: to understand how immune cells behave within and interact with their environment during health and conditions of immune challenge/disease; and to understand the molecules and pathways that regulate these activities. The objectives of this project are: to better understand the processes that drive appropriate inflammatory responses and also maintain normal tissue function; the overlap between these processes; and, how one process, when dysregulated or modulated, may negatively or positively impact on the other.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system plays a fundamental role both in normal tissue function and in the progression of number of diseases: including cancers; atherosclerosis; autoimmunity, such as arthritis; and neuroinflammatory conditions such as Alzheimer's disease. Inflammatory responses can be both protective (eg. combatting infections or repairing injury) or damaging (e.g. excess collateral tissue damage and fibrosis). Understanding the regulators of inflammatory processes will provide novel insights into therapeutic

opportunities for promoting a healthy resolution to inflammation with minimal tissue damage.

What outputs do you think you will see at the end of this project?

A holistic view, should identify novel therapeutic approaches to the regulation of inflammation and restoration of tissue function. Hence as a primary benefits we anticipate the further development of potential targets that regulate inflammation and tissue repair. The primary output of this project will development of new knowledge and publications.

Who or what will benefit from these outputs, and how?

In the short-term, this project will establish new understandings about immune mechanisms in health and disease. In the medium-term, this knowledge may help redefine physiological processes and provide new insights into tissue dysfunction and disease processes. In the longer-term our objective will be to exploit this new knowledge, where possible, for better outcomes for human disease through ongoing and new collaboration with industrial and clinical colleagues.

How will you look to maximise the outputs of this work?

The applicant is already part of national networks and has active collaborations with industrial and clinical groups. All new knowledge will be published in peer-reviewed journals, with pre-prints archived in dedicated freely-accessible repositories to accelerate knowledge dissemination to all interested parties. Opportunities for exploitation of the knowledge, for example, more detailed analysis of disease mechanisms with therapeutic objectives, will be explored with our collaborators and additional interested parties.

Species and numbers of animals expected to be used

- Mice: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project use mice. A mammalian species must be used because of the complexity of the innate and acquired immune systems in mammals. Mice are the most appropriate species because they are the species with the lowest degree of neurophysiological sensitivity in which genetic manipulation can be reliably and reproducibly achieved. Animals will be studied at all stages of life. The majority of interventions (e.g. injections) will occur in mice over the age of 4 weeks. A small number of neonatal mice may be studied to observe tissue development.

Typically, what will be done to an animal used in your project?
A significant number of animals will be used in breeding colonies to maintain lines of genetically- altered, or unique mice. Many mice will be studied without further treatment, for example, as a source of normal tissues or cells, or for study of normal tissue function. The vast majority of remaining mice that will be administered substances by injection via the

appropriate routes or will be treated orally (altered drinking water, food or by gavage). A small number of cases will involve surgery, for example to use a minipump for continuous drug delivery to negate the need for multiple injections. In another small number of cases, the mice may be exposed to radiation to enable bone marrow transplantation.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the experiments will be mild in severity. They will involve one, of a few stimuli, that evoke a self-resolving transient inflammatory response, which will be studied with various interventions to understand the processes occurring. Some procedures will involve stimuli of moderate severity, such as surgery or experimental infection, where clinical signs of adverse effects will be more evident or longer lasting. In some cases we will study mouse models of spontaneous chronic disease development, to understand how they develop and how we may intervene. In all cases, the presence of adverse effects is specifically monitored for and the mice will be humanely killed if they reach specific humane endpoints.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of mice will experience only mild or sub-threshold severity. A minority of approximately 5-10% may experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are modelling the changes in immune response and in tissues that occur over time. These are not localized to individual tissues, but are regulated by systemic changes, involving, for example, the migration of immune cells to peripheral and immune tissues.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we have developed in vitro systems for the addressing our specific questions, for example, we routinely use and produce cell line models as a direct replacement. These are both pre- existing cell lines, cell lines we make ourselves from the mice and human induced pluripotent stem cells. These can in some instances be grown in co-culture to better approximate the physiological systems we aim to model.

Why were they not suitable?

Cell lines do not display all the characteristics of the cells found *in vivo* and whilst cell culture techniques have dramatically improved, the microanatomy, distribution of multiple cell types and the presence of many diverse cell:cell and cell:extracellular matrix interactions found *in vivo*, which play complex roles in the regulation of immune cell activation and regulation, cannot be replicated *in vitro*. Current modelling approaches also do not replicate this *in vivo* complexity necessitating the use of animals. We do, however, still use cell models whenever possible to model aspects of immune responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This project will require the in house breeding of several lines of genetically modified animals. These will need to be maintained for the duration of the project and will represent the bulk of the animals used during this project. Estimates for the maintenance of minimal numbers of each line and the subsequent generation of offspring are included in this estimation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Every experiment conducted is reviewed for statistical validity. Where sufficient data is available power analysis will be conducted using freely available tools (e.g. G*Power 3.1 and the NC3R's experimental design assistant) to determine the appropriate experimental sizes required to generate meaningful data. In the absence of sufficient data, recognized approximations for experimental size will be used (e.g. the Resource Equation) or smaller pilot experiments will be conducted first to determine the variability of the experimental parameters enabling calculation of the appropriate experimental size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We aim to keep breeding colonies to the smallest size necessary, cryo-preserving lines when it is clear they will not be used for a period of time. We review the literature and conduct pilot studies to establish the variation within experiments and also try to establish alternative experimental readouts with less variation that could be used as an alternative and would require fewer animals. Our team won a local 3Rs prize for our tissue sharing initiative and we are in discussions with a commercial partner to establish the process not just institution-wide, but in multiple institutions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are primarily using genetically-modified mice to study aspects of the immune system. Many mice will receive no further intervention. The majority of the remaining mice will receive one or a small number of substance administration via appropriate routes. In some cases, recurrent administrations are needed and in a small number of animals surgically implanted osmotic minipumps (or similar) may be used in place of repeated administrations. More fundamental approaches include use of refined injections (for example, using the smallest gauge needles and limiting injection volumes as much as possible); use of refined routes (for example we use pipette feeding instead of oral gavage whenever possible, which the mouse becomes accustomed to and doesn't have the potential complication of oesophageal damage caused during gavage); use of reduced doses where scientifically appropriate to limit the potential for or intensity of adverse effects and events. All these approaches help to refine the use of animals in our research ensuring the lowest possible level of pain, suffering or distress caused.

Why can’t you use animals that are less sentient?

Our primary aim is to study the immune system in adults in a multicellular and tissue-specific manner. This requires mammals whose tissues development and physiology resembles that of humans. The use of mice enables the use of genetic modification to enable intricate dissection of disease mechanisms and mice are the mammals with the lowest neurophysiological sensitivity that can be reliably genetically modified. Lastly, the need to study inflammatory and immune processes necessitates that living animals be studied over a period of time.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have introduced a number of refinements during the course of our work, including the use of pipette feeding in place of oral gavage, the use of smallest gauge needles and injection volumes permissible for reliable data. Additionally, we routine use the lowest doses of drugs and other substances to achieve the required biological effects, with minimal adverse effects. In cases of surgery, we would consider deliver of prophylactic pain relief and hydration, always under the guidance of the named veterinary surgeon.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We routinely derive best practice instruction from publications such as Wolfensohn and Lloyd with regard to recommended administration volumes, routes and methods. We also monitor resources, such as those managed by the NC3Rs. Every experiment is reviewed prior to commencement using a proforma that considers the protocol, including its statistical validity and adherence to the requirements of the license. In addition to the current statistical considerations where we consider reduction, we will add a comment on the review of the 3Rs into this documented process, whereas previously it would have been considered, but less explicitly documented at this planning step.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are able to keep up to date with the 3Rs via several mechanisms: We have a programme of sharing 3Rs knowledge run locally, where new innovations and approaches are shared with other staff members; A member of the NC3Rs sits on our ethical review panels and offers advice on 3Rs at all stages from project licence development to ad hoc protocol development; we are also able to monitor national developments via the NC3Rs online resources and newsletters (developments of which are delivered both personally and via internal institutional communications). Our research centre is part of a multicentre national research institute and we have 3Rs champions who meet to share best practice between the centres. 3Rs advances can take many forms, from minor refinements to protocols, to changes in the statistical analysis of data and primary outputs that adjust the number of animals required for meaningful data.

164. Immunity and Resistance to Disease in Cattle

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Immunity, Vaccines, Disease, Tuberculosis

Animal types	Life stages
Cattle	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand the immune responses that are important in cattle that are vaccinated against, or infected with, important diseases that affect their health and welfare.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diseases in cattle have a significant impact on animal health and welfare, and impact on the economy. Two important diseases caused by Mycobacteria are bovine tuberculosis (TB) and Johne’s disease (a gut condition). The bacteria that cause these diseases can also infect people leading in some cases to TB or possibly to Crohn’s disease which affects the human gut.

Bovine TB has been increasing in incidence in UK cattle herd for the past 30 years and current control measures lack sensitivity and specificity. Confounded by the presence of a wildlife reservoir of disease, future control of TB in cattle will likely depend on vaccination. However this requires significant improvements in our understanding of how TB vaccines, including the human TB vaccine BCG, work. This requires further studies of the immune

response. Currently, cattle are not vaccinated against TB, and the diagnostic tests are limitations.

Johne's disease is a significant cause of economic losses worldwide with significant impact on milk production and meat quality. As with bovine TB, current control measures lack sensitivity and specificity and no vaccines are currently available.

In order to control these diseases in cattle to significantly impact animal health, and the farming economy, we need to develop new vaccines or ways to identify infected animals so we can treat or remove them from farms. Developing new vaccines or diagnostic tests requires us to understand the immune response that can lead to immunity (versus disease) and also to understand why some animals respond differently to each other (the role of host genetics). This in turn will lead to improvements in human health through disease control.

Our previous work showed that some vaccines work better than others and we have started to identify parts of the immune response that help vaccines work well. We need to understand this in greater detail so that we can provide information that will, in the future, help to make better vaccines or tests for diseases and also perhaps to breed resistant animals.

Therefore, the major aim of this project is to understand how these Mycobacteria interact with components of the immune system and how this differs when cattle are vaccinated before being infected. This will help us define targets to work with in the future. We can use animals known to have different genetics to help determine whether we can breed for resistance. We will carry out a small number of experiments with other pathogens (parasites, bacteria, viruses) for comparison.

What outputs do you think you will see at the end of this project?

The major output from this project will be the generation of new information on the immune responses of cattle to vaccines and disease. This is essential to allow us to move forward with the development of new diagnostic tests, vaccines and other disease control methods. We will publish these outputs in scientific journals and we will interact with the public and our stakeholders (companies, farmers etc.) to share what we find.

Who or what will benefit from these outputs, and how?

By determining how immunity can be stimulated by vaccines, what cells and mechanisms are involved we will provide helpful information for a number of scientific studies looking at the development of new ways to control Mycobacterial diseases (of cattle but we will also influence studies of related human diseases). We expect within the next 5 years to use the information to begin to work with companies to provide information that will allow them to develop new vaccines or tests for disease; this could include the registration of at least one new product and a patent. These studies are ultimately aimed at producing effective vaccines, diagnostic tests and other control measures against diseases of livestock that have significant impacts on animal health and the economy. These will mostly occur within the next 5-10 years.

How will you look to maximise the outputs of this work?
We will collaborate widely across the veterinary research community to disseminate our findings: this will be through our existing networks, through dissemination activities at scientific conferences and by publication. We will contribute widely to outreach events

aimed at both the public and stakeholders. It is ever-important to publish unsuccessful approaches to minimise the likelihood of duplication of failed studies. Our scientific rigour includes the dissemination of 'negative' results for this purpose.

Species and numbers of animals expected to be used

- Cattle: 170

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project uses cattle as these are the natural hosts for the important diseases we wish to study. We will use both juveniles and adults. Juveniles at the age of approximately 8 weeks have been weaned and are relatively small in size and easy to handle for the studies of cells draining in the lymphatic vessels as these require surgical preparation. Calves at the age of 6-8 weeks are known to respond more effectively to some vaccines being used to control tuberculosis and understanding why they show strong protective immunity at this age is a major objective of our work. Older cattle including young adults will be used as blood donors, in vaccination and infection studies and will be also sampled at farms where they are of known natural infection status.

Typically, what will be done to an animal used in your project?

For typical investigations on cattle they will be subject to blood sampling to access the cells and proteins of the immune response. Some animals will receive vaccines, or other substances designed to induce protective immune responses which will be measured in the blood or in relevant tissues such as the skin. Some of these animals that have been vaccinated, or non-vaccinated controls, will be infected with the pathogen of interest. After vaccination and challenge samples will be collected on a regular basis to determine if the pathogen is present and if an immune response against the pathogen can be detected. At termination of the project the majority of animals will be killed using a Schedule 1 method, those which are not killed will be re-homed. Animals may be subject to post-mortem examination where the extent of disease in infected animals is assessed, and tissue responses assessed.

We will also examine the immune response of cells as they circulate from vaccination sites to the rest of the body: this involves surgical preparation and insertion of tubing to allow collection of cells. These animals recover from the surgery and we can collect these cells over a period of up to one month.
Some animals will receive vaccines and the response will be monitored over time. Animals may also have skin biopsies taken, or samples taken from the lung: this will be done under local anaesthesia or sedation. These animals will be killed at the end of the study using approved Schedule 1 methods.
Blood donor animals that are non-vaccinated or non-exposed, and naturally infected animals that are sampled at farms may be kept alive and released from the controls of the Project Licence.

What are the expected impacts and/or adverse effects for the animals during your project?

Blood sampling: temporary discomfort at the sampling site, a very small proportion (<1%) may experience haemorrhage but this is unexpected.

Lymphatic cannulation: short term seepage of fluid following lymph node removal for less than 48h. Anaesthesia may induce adverse reactions (<1%). Following surgery analgesia will be given.

Inoculation/vaccination: The administration of substances will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. There may be mild local inflammation at the injection site lasting no more than a few days.

Infection with Mycobacteria: using the doses and regimes we have refined in previous studies animals are not expected to show any clinical signs other than transient (less than 48h) alterations in temperature, respiratory effort or diarrhoea.

Tissue sampling from the skin or lung: mild discomfort may occur and where necessary analgesia will be given. Skin biopsies will be taken under local anaesthetic. Lung sampling will be done under sedation to minimise the likelihood of damage to the respiratory tract during endoscopy.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Cattle will undergo mild or moderate severity procedures. The vast majority (~80%) will be mild and approximately 20% moderate (surgically prepared calves for collection of samples from the lymph).

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?

The objectives of the project cannot be achieved without the use of cattle. There are no good alternatives that can be used: mice can be infected with Mycobacteria but they do not have the disease outcomes as cattle and cell lines are not available to use in the lab. However, where we can we will use cells derived from blood and tissues to mimic responses that occur within animals. For example, we can use new technology to generate ‘mini-guts’ (known as organoids) in the lab to look at the early interactions of the bacteria

that Johne’s disease with the gut or we can use blood derived cells to understand how TB causing bacteria ‘hide’ from the immune response and cause infection/disease.

Which non-animal alternatives did you consider for use in this project?

Wherever possible we will use alternatives but as detailed above many of these have animal origins; for example the use of organoids requires animal tissue. There are no viable non-animal alternatives for our studies.

Why were they not suitable?

Our alternatives all require a source of animal material. While cell lines and organoids can be used to address specific questions, understanding how the whole animal responds to a vaccine or to disease cannot be mimicked in the lab due to the complexity of the body systems involved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have more than 20 year's expertise in the type of experiments being carried out and have used this, and a vast collection of data, to estimate the numbers we will use. We have consulted with experts in statistics to use the data and expertise to design our experiments optimally.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Good principles of experimental design are always used to ensure that we used the minimum number of animals to achieve robust and reliable results. All of our experiments are officially reviewed by a named vet, animal care technicians and a statistician before they can be undertaken. These study protocols include aims, numbers of animals, treatments, assessment of adverse effects, end points and our data analysis methods which are carefully scrutinised. We will refer to the NC3R's experimental design assistant as required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
Where we do not have extensive experience, or where there is limited information we will perform pilot studies to determine outputs that will inform experimental design.

In addition, we will archive samples to allow additional analyses to take place without the need to repeat experiments in animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use cattle in this project. These animals will be naive (non-vaccinated, non-diseased), vaccinated or infected with pathogens that cause disease. We will use disease models that have been designed to allow us to answer important questions with the minimum of pain, suffering and lasting harm. We will use doses of infectious agents and time-scales that do not cause overt disease or suffering and we will continually assess our methodology and refine where necessary. These parameters allow us to mimic the natural disease but with the minimum harm. The majority of animals will be blood sampled, with a smaller proportion undergoing surgery or infection studies. All animals undergoing infectious challenge or surgery will be monitored at least twice daily using well-defined clinical scoring criteria. This will allow us to continually monitor the wellbeing of the animals to minimise harm.

Why can’t you use animals that are less sentient?

Cattle are the natural hosts for the pathogenic organisms being studied and no accurate models are available. Vaccination and challenge studies will enable us to pinpoint critical factors associated with the induction of immunity, or the progression to infection. We can define both immune and genetic factors enabling well defined experiments to be carried out. These factors cannot easily be replicated in less sentient animals. The nature of our studies requires longitudinal analyses of animals as they respond to vaccines or infection; this could not be done in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have already refined a number of our protocols. For example, we have refined the post-operative care that calves receive to reduce stress to the animals from injection of anti-coagulants (these animals were previously observed have become needle-shy with 2x daily injections for up to 28 days; reducing this [to 2x daily for 3 days then daily for up to ~10 days] has had a positive impact on these animals). We will administer analgesia as required to animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will refer to guidelines published by the UK National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will monitor correspondence and guidelines from the NC3Rs on a regular basis and implement relevant changes in a timely manner. The project licence holder is in frequent

contact with the named veterinary surgeon and the named animal care workers: this will enable any changes to be made where appropriate.

165. Development and function of the mammalian brain

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

neuronal progenitors and stem cells, neurogenesis, neuronal migration, formation of neuronal connections, brain developmental abnormalities

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to study the basic steps of brain development (neurogenesis, neuronal migration, development of connectivity) to understand the molecular and cellular mechanisms determining functional cortical circuits with particular attention to the early circuits in the cerebral cortex. We also study the effects of silencing or stimulating a selected neuronal population either during development or in the adult and examining the effects on development and maintenance of connections, myelination, microglia activity and behavioural changes of the animals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The causes and remedies of many cerebral cortical developmental disorders are not known, but their prevalence in the general population numbers is high [schizophrenia (1:100); autism (1:68); attention deficit hyperactivity disorder (1:30); dyslexia (1:10); childhood epilepsy (1:200); neural tube closure defects; cerebral palsy (2:1000)]. Without the understanding of the basic developmental mechanisms such as how neurons are generated, how they migrate, differentiate, develop connections, and form functional assemblies it is impossible to contemplate that we can develop interventions to prevent or treat these conditions. It is not enough just to study the adult brain, since the developing brain is not just a smaller version of the adult brain. The management of developmental conditions requires very different approaches than in the adult. The specific and selective vulnerability of the developing brain to hypoxia, ischemia, maternal infection is still not understood, but the impact on the life on the individual and their family can be devastating. These particular studies could have direct implications on establishing general policies e.g. vaccination during pregnancy, with or without particular genetic susceptibility or management of neonatal hypoxia-ischaemia or the management of genetic or acquired conditions.

What outputs do you think you will see at the end of this project?

We shall reveal basic cellular and molecular mechanisms that are involved in the normal and abnormal development of the mammalian brain, with special attention to the cerebral cortex. We shall understand the background of some basic developmental abnormalities (such as alterations in neurogenesis, neuronal migration, formation of connections) that underlie some devastating conditions and manifest as childhood epilepsy, learning difficulties, cerebral palsy. These observations will be published in the scientific literature and some of these mechanisms will be validated in human brains.

Who or what will benefit from these outputs, and how?

Some of the outputs of our PPL will continue to contribute to our long-term goals to bring greater understanding of these basic neurobiological problems. We shall identify specific cellular and molecular mechanisms that are responsible for developmental steps. This better understanding will elevate the platform from which the prevention and treatment of many neurological and psychiatric disorders (e.g. childhood epilepsy, schizophrenia, attention deficit hyperactivity disorder, autism) can be contemplated. During the licence we shall identify some mechanisms that will eventually bring novel therapies and preventions to these conditions and disorders that affect millions of people of all ages at tremendous cost to the national economy.

Understanding the possible dangers during brain development can help with prevention or treatments of several neuronal developmental disorders. We hope to contribute to the basic knowledge base that, in time, shall have a very significant impact on this field, including clinical diagnosis and possible treatment.

Our work will provide novel knowledge that will improve reproducibility of rodent studies and will help to make the mouse a better model for biomedical research.

We expect to achieve some of our outputs in the life of this PPL, such as molecular and cellular susceptibilities of hypoxia-ischaemia, neural plasticity, role of cell populations in brain state control, but these outputs that will be published in the scientific literature and presented to colleagues and clinicians will be only the first steps towards clinical translation.

How will you look to maximise the outputs of this work?

Our laboratory is performing fundamental basic research, primarily to improve our understanding of the developing brain. We shall make our research results accessible in an open format to all our collaborators, and to all researchers through our detailed publications. To disseminate knowledge, increase impact and encourage reproducible science we deposit the preprints of our publications with open access even before our papers are accepted for publication. Members of our laboratories regularly present their data on national and international meetings and workshops. Members of the laboratory are also involved in the training and teaching of the next generation of biomedical and medical experts and through this teaching disseminate new knowledge. We regularly publish both positive and negative results and share successful and unsuccessful approaches with our colleagues.

Species and numbers of animals expected to be used

- Mice: 24,000
- Rats: 2,980

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We study the development of the cerebral cortex in mouse and rat. Rats and mice are the lowest vertebrate group that the above-described experiments can be performed in. The presence of isocortex (sixed-layered neocortex) is limited to mammals; therefore, the use of fruit fly and zebra fish is limited to certain specific questions relating to gene interactions and cascades. The genetic manipulations and the transgenic and mutant mice models contribute a great deal to the understanding of the cerebral cortical development because of the similarities of the basic patterns of cortical development to primates.

Although mice will be used in most cases, the use of rats in certain experiments is apparent. Rats could be more practical for some intrauterine surgeries or central nervous system lesions or for implantation for slowly releasing polymers purely because of their larger size. Also, rats could be more suited for some immunohistochemical analysis because numerous antibodies are produced in mouse. There is also growing evidence of differences in the cell-surface receptor expression in cerebral cortical neurons between mouse and rats, which may result in different cellular or whole animal responses for state control experiments. However, the reporter gene expressing transgenic mouse lines and mouse mutants make this species the preferred choice for most of our experiments. Also, implantation of tissue from other species (e.g. 3D printed constructs from human induced pluripotent stem cells) require immunodeficient mouse hosts. These hosts accept grafted constructs where their long-term interaction with the host can be studied in detail.
For our experiments we shall use several life stages, including embryonic, postnatal, and adult stages. We use embryonic stages to study the process of neurogenesis, neuronal migration, and formation of early connections. Neonatal stages provide access to study early circuit formation and plasticity. Adult stages will be used to study normal and abnormal organisation after normal or disturbed development. The alterations in development will be also studied in adults.

Typically, what will be done to an animal used in your project?

Most animals used in our projects will be used for histological and molecular studies without surgical procedures after collecting their brains after perfusion in terminal anaesthesia at various life stages. However, in some experiments the pregnant dams will need to undergo laparotomy to allow to perform manipulations, labelling, lesioning specific cell groups or structures. Some animals will have postnatal or adult manipulations to monitor or to modulate the function of particular cell populations or structures. Some of these animals will have genetic modifications to reveal specific neuronal populations with the expression of reporter genes and some will have genetic modifications through specific breeding protocols. The animals will be bred, and several developmental stages examined after terminal anaesthesia. Only a small fraction of the animals will go through early manipulations either in utero or at perinatal stages. Most of these animals will go through a single manipulation, but occasionally there will be some animals with multiple procedures.

What are the expected impacts and/or adverse effects for the animals during your project?

Genetically altered animals bred in this project are not expected to show any adverse effects before they are weaned. Some of our models will show some mild behavioural changes normally after 6 months of age.

A large part of our study involves the manipulation of the embryonic and adult brain. Cell labelling drugs are not expected to have any effect, but substances to cause gene alterations administered in the pregnant dam can cause transient weight loss. Physical intervention to the embryonic brain such as injection of constructs or expression of constructs with electroporation will require the pregnant dam to undergo surgery with a risk of the embryos being aborted. Animals born from these procedures may exceptionally show some subtle behavioural changes such as altered sensory perception or fine movement alteration (e.g. layer 5 alterations can change grasping), but we observed none of these over the last 5 years.

In addition to the initial manipulation in utero animals may undergo further manipulations as an adult.

Animals may undergo a selected group of behavioural tests to enable us to study the effects of the brain manipulation. These tests are not expected to cause any additional harms to the animals.

Some of the animals that undergo hypoxia-ischemia are expected to show weight loss, lethargy, poor motor control, and seizures. Our research will use paradigms that are mild or moderate to determine the factors that help in the recovery. We shall study the alterations in movement and memory and shall manage the long-term effects.
Where animals need to undergo surgery for manipulations it is expected that there will be transient pain from wounds. Analgesics will be administered during and up to 2 days post procedure until the animals are sufficiently recovered from surgery.

We will harvest embryos to explore if development can be delayed or altered under laboratory conditions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse 70% mild, 30% moderate,

Rats 70% mild, 30% moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Rats and mice are the lowest vertebrate group in which our experiments can be performed. Our studies are centred around the isocortex in the brain which is only found in mammals therefore the use of the fruit fly or zebra fish is limited to answering specific questions relating to gene interactions and cascades. Genetically altered rats and mice contribute to the understanding of the cerebral cortex development because of the ability to create basic cortex development patterns seen in primates without the need to use higher species.

There is no alternative model. The questions cannot be answered in human.

Which non-animal alternatives did you consider for use in this project?

Computer model

Mathematical modelling

Human induced pluripotent stem cell - 3D tissue printing

Human organoids

Study postmortem fixed pathological material.

Why were they not suitable?

No computer model is currently available that can replace the use of animal tissue for our objectives, as there is insufficient information on the network connectivity and circuit activity involved. Nevertheless, in the future computer models may be used to assist the interpretation of the data obtained in experiments from animal tissue.

Our laboratory is increasingly using mathematical modelling to identify the key factors involved in cerebral cortical neurogenesis and to identify the most sensitive parameters to study in biological systems.

We currently working on technologies to 3D print cortical layered constructs from human induced pluripotent stem cells, but this methodology is still at its infancy. Our collaborative team is one of the first to attempt this. These models can only recapitulate the earliest stages of cerebral cortical development and they do not reach the level of sophistication as the real tissue that developed in vivo. To explore more complex in vivo interactions, we implant these 3D printed constructs into mouse brains.

Human organoids only model the very early stages of cortical development and they do not possess the complex circuits, such as the thalamocortical connections.

We study human post-mortem fixed pathological material, but these only allow descriptive studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals estimated to be used in this project comes from experience gained in managing experiments of the type proposed in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have investigated possible means of reducing the number of animals that we will use by exploring NC3R's Experimental Design Assistant (www.nc3rs.org.uk/experimental-design-assistant-eda). This online tool helps us through the design of our experiments ensuring that we use the minimum number of animals consistent with our scientific objectives, selected methods to reduce subjective bias, and appropriate statistical analysis.

We can minimise the use of animals by considering the influence of specific variables and addressing sources of possible bias. We developed experience from our previous published studies how to design our specific experiments that will produce robust and reproducible data.

We used mathematical modelling to identify the most sensitive parameters that should be studied in detail (e.g. in cortical neurogenesis). This helped us to identify factors that influence our experimental results the most. NC3R's Experimental Design Assistant also advised us the use of the most efficient statistics. This can also reduce the number of animals required and maximise the information obtained per experiment.

To further increase the reproducibility and validity of our experimental research we use PREPARE guidelines (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) – (https://norecopa.no/prepare). This resource gives valuable guidance for formulating of the study, good communication between researchers and biomedical facility and methods.

We will ensure the minimum number of animals used whilst still enough for statistical analysis. For this, experimental design will be optimised to obtain answers to the questions addressed, and statistical power analysis will be employed ahead of commencement of experiments. We shall be conducting all our experiments so that we comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines) when we publish. This will enable the scientific community of readers and reviewers to scrutinise and reproduce our research.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Good colony management will ensure that we only produce those animals required for our experiments and to maintain the colony. Where the genetical manipulation allows we will breed homozygous animals to further reduce the number of animals being produced. Details concerning strain data will be obtained from the inhouse animal tracking database. Where possible we will share our transgenic rodent colonies with other groups within our establishment to reduce the need for duplicated colonies.

We shall optimise the number of animals used by relying on our considerable pilot studies. Most of the proposed experimental methods have been used in our laboratory previously and this helps with the estimation of the number of animals to reach our objectives.

We have already used computer modelling is selected suitable areas to explore the most important parameters of cerebral cortical neurogenesis to guide our studies. We shall continue to collaborate and consult with our mathematical modelling colleagues to explore and identify the most biologically relevant mechanisms that we should explore with experiments in more details. These decisions will optimise the use of animals.

We archive our experimental material, so the raw data is available online to the entire laboratory. This can reduce the use of new experimental animals on questions that can be analysed on archived material. We also established several web-based resources to share results on gene expression patterns to reduce animal use of new animals. Our laboratory pioneered the establishment of transcriptomic atlases and posted these freely to the broad scientific community.

By harvesting and storing as many post-mortem tissues as possible from our animals we can reduce the need for new experimental animals to answer some of our questions from this archived material. We will also offer other post-mortem tissues that are not relevant to our scientific question to other groups within the establishment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of species and models:

We will use rats and mice for this project. We carefully considered the methods chosen for our objectives and made sure that they will cause least harm, whilst achieving our scientific objectives. Rats and mice are sufficiently close to humans to reveal principles of brain development and are species that are much used in this area, which enables us to build upon a large body of research already carried out, and to relate our findings to previous results. Whilst the bulk of experiments will be done in normal animals, we wish to utilise several reporter and knockout models to focus the mechanism of a particular gene in cortical development. At present our genetically modified mice do not express any severe phenotypes, but any additional GM mice imported into this licence would be carefully monitored and ensure any adverse phenotypes do not exceed the severity limit. The rat line (GAERS - Genetic Absence Epilepsy Rat from Strasbourg) is a recognized animal model of absence epilepsy, a typical childhood form of epilepsy. It is spontaneous mutant on the Wistar background. The strain will help answer questions in relation to absence epilepsy in the developing and adult brain.

Choice of methods:

We will use methods that will cause the least pain, suffering, distress, and lasting harm. Our main methods include the labelling of neurons and their projections of gene expression with histological methods that do not require living animals. We shall use methods when the genetically modified animals will be terminally anesthetised and perfused with fixative to preserve the structure of the brain tissue for further investigations with post mortem tracing methods (using lipid soluble tracers that travel in fixed tissue of developing brains), study gene expression with immunohistochemistry, in situ hybridisation. Some of the tissue will be collected in similar manner to keep the brain tissue alive in isolation for stimulation and recording ex vivo. This is the most refined model that can be used for the study of these questions. We shall only use in vivo methodologies when it is necessary for conclusive experiments. We shall use chemical (gene deleting/induction agents) or physical (electrophysiology) and at various stages of development (embryonic, postnatal and adult). We will always follow best practice and asepsis at all times.
We shall use manipulations that are performed at early developmental stages (in utero or immediately after birth) to alter the development of the pups. With the intrauterine manipulations we deliver constructs into specific cohorts of newly born neurons from the lateral ventricles to trace, up-regulate or down-regulate a specific gene function. For some experiments we shall use physical means of creating lesions such as whisker removal or whisker trimming or disruption to the infraorbital or optic nerve or the eye itself. These methods are essential to study the long-term systems effect which is not possible in in vitro culture system. Although it is not a complete replacement, it is increasing used as an alternative than creating knockout or knock in genetically modified animals.

These are considered the least severe procedures to answer the scientific questions related to the role of sensory input in brain development. We shall only remove one of the eyes (instead of both) to reduce the lasting effects on the animas. There are other genetically altered mice that could be used in these experiments (develop smaller or no eye) but they exhibit other developmental harmful phenotypes which if used would increase the level of harm to the animals.

We model developmental conditions that can have devastating effects on human infants, such as maternal inflammation and hypoxia – ischaemia. We will place animals in altered

conditions to mimic the effects seen in the human such as maternal inflammation and hypoxia-ischemia with or without ligation of some blood vessels supplying the brain. Animals will be placed into conditions where there are altered gas levels (hypoxic conditions for 1-2 hours) to produce mild or moderate hypoxia to keep suffering to a minimum. It is not expected that any deaths will result from the hypoxia as the protocol is well established, however there is the risk of maternal rejection on returning the litter to the dam.

The corresponding animal models will show some adverse effects (e.g. maternal inflammation induced by toxic molecules from outer membrane of Gram-negative bacteria, such as lipopolysaccharides; maternal stress caused by amphetamine intake), but these effects cannot be ameliorated because we specifically would like to study these maternal effects on cortical development in foetuses. However, we will not use doses that cause high abortion rates or severe phenotypes in dams, as that would render the animal samples collected not fit for the purpose of the experiments. Similarly, adverse effects are expected in pups subjected to the perinatal hypoxia-ischaemia protocol and in some adult animals showing neurodegeneration following gene manipulation in selected cell populations. In both cases, the manipulation is necessary to investigate the proposed scientific questions. Suffering will be kept to a minimum by determining the shortest survival post-onset-of-symptoms necessary to address the scientific questions.

We will use the least aversive behavioural tests that are well established to enable us to assess the effect of our manipulations on the animal’s ability to perform such tests.

Whenever possible we will harvest brain tissue under terminal anaesthesia and use post-mortem tracing with carbocyanine dyes, a non-invasive method that we pioneered.

Why can’t you use animals that are less sentient?

We study cerebral cortical development and some of our experiments are at very immature life stages when most of the neurons are generated and they still in migration to their destination. We also have to study later stages to explore the consequences of altered development.

Our work revolves around the development of the mammalian cerebral cortex which is not present in a lower species such as the fruit fly or zebrafish. Species such as birds and amphibia do not have the complex mammalian brain required for our work.

For most of our work we use animals that have been terminally anaesthetised, and tissue has been collected for future molecular or histological analysis. Some of the tissue kept alive for in vitro experiments that allow some degree of manipulations. We can perform some brain manipulation whilst the animal is terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We shall use good aseptic practice when performing surgery. All stereotaxic injections into the brain, intrauterine surgery, and peripheral or central nervous system lesions will be done under aseptic conditions to prevent any post-surgery infections under general anaesthesia

We shall use increased monitoring during and after surgery to observe the condition of the animals and the level of anaesthesia. We use postoperative assessment charts to keep record of the recovery.

The most appropriate inhalation anaesthesia will be used during surgeries.

We shall manage pain during and after surgery. Analgesics suitable for the species will be applied peri- operatively as standard to minimise suffering and monitored regularly for at least three days (at least once daily in addition to the normal checks by the technicians). A general pain-scoring chart will be used to record the well-being of the animals, as well as any adverse effects specific to the operations performed on that animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow LASA guidelines on best practice (https://www.lasa.co.uk) to improve animal welfare and quality of science.

We follow the NC3R's Experimental Design Assistant (www.nc3rs.org.uk/experimental-design- assistant-eda) to make sure that the experiments are conducted in the most refined manner.

To further increase the reproducibility and validity of our experimental research we use PREPARE guidelines (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) – (https://norecopa.no/prepare).

We shall be conducting all our experiments so that we comply with the ARRIVE guidelines (www.nc3rs.org.uk/arrive-guidelines) when we publish. This will enable the scientific community of readers and reviewers to scrutinise and reproduce our research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay informed about advances in the 3Rs by regularly attend the welfare meetings and 3Rs Research Day at our establishment.

We subscribe to the NC3R's website (https://www.nc3rs.org.uk) to get information on 3Rs resources, news, and events.

We have regular interactions with the NC3Rs Regional Programme Manager who also advise us on available grant support and 3Rs studentships. Our laboratory submitted application for both grants and studentships in the past.

Our laboratory currently collaborates with the Chair of the 3Rs subcommittee and learn about the best practices through joined laboratory meetings and discussions.

All new members of the laboratory will receive specific 3Rs training that will focus on the development and use of alternative platforms to study human cerebral cortex development. The specific 3Rs training will include experimental design (including the use of the NC3Rs EDA), implementation of the ARRIVE guidelines (especially randomisation/blinding), development of non-invasive imaging methods, development of other non-invasive assays for studying physiology and behaviour in mice and aseptic stereotaxic surgery. Furthermore, high animal welfare standards are essential in all

research. Key element of 3Rs specific training in this project will be the importance of good animal welfare for high quality scientific data.

166. Molecular mechanisms regulating sleep and circadian rhythms

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Sleep, Circadian rhythms, Neuroscience, Signalling

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the molecular mechanisms that generate and regulate sleep and circadian rhythms.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Sleep and circadian rhythms (SCR) are a core component of our physiology, and their disruption (SCRD) leads to several acute and long term health consequences including mental health conditions, metabolic syndromes, and neurodegenerative disease.

Furthermore, SCRD is a feature of most neuropsychiatric conditions and core determinant of quality of life, but is rarely treated. This is mainly as we understand very little about the molecular pathways that control sleep and circadian rhythms. This project aims to develop the substrate with which novel therapeutic interventions that target these pathways can be developed

What outputs do you think you will see at the end of this project?

An increased understanding of the mechanisms by which SCR are regulated leading to

publications

novel targets for drug development

patents on translatable findings

novel small molecule or biological drugs for the treatment of SCRD that will be developed in collaboration with pharmaceutical companies.

Who or what will benefit from these outputs, and how?

The publications and information on novel targets will be of benefit to the scientific community and other stakeholders including policy makers, advisory bodies and the pharmaceutical sectors. The outputs will be seen within 5 years.

Patents will ensure proper commercialisation of the findings from this research. Preclinical development of novel drugs will facilitate the development pipeline of novel therapeutics. For example, we will identify the best in class compounds, with the appropriate readouts of efficacy, dosing information and route of administration to enable transition to clinical trial. These benefits will be realised within 5 years.

How will you look to maximise the outputs of this work?

Dissemination of new knowledge: Outputs will be presented at conferences and as online preprints prior to publication in peer reviewed journals. All our work will be open-access and published with access to full raw data. Our work generated large datasets of interest to the entire neuroscience community, and these will be freely distributed.

Commercialisation: Patents will be filed through relevant channels and licensed, leading to spin-out companies or collaborations with the biotech/pharma sectors.

Species and numbers of animals expected to be used

- Mice: 8500
- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Mice are the species of lowest neurophysiological sensitivity that are appropriate for such studies, and have well-characterised circadian and sleep biology. Extensive genomic data coupled with the wide range of existing genetically altered models make mice the only viable model for such studies. Adult animals are required for behavioural monitoring. Aged animals (over 15 months, but less than 2 years) will be used to model the sleep and circadian disruption seen in the elderly. Mice will also bred through to the adult stage under conditions of circadian disruption to model the effect of shift-work/sleep disruption on reproduction/epigenetic inheritance.

Adult rats will be used for experiments on circadian rhythm entrainment for a limited number of studies where mice are unsuitable, as this parameter is very sensitive to slight environmental changes in mice.

Typically, what will be done to an animal used in your project?

Animals (either wild type, or genetically altered to target specific genes in sleep/circadian rhythms) will be housed in a cage equipped with a running wheel/other equipment to monitor behaviour in a chamber in which the light environment can be controlled, to be able to simulate an environment that disrupts sleep and circadian rhythms (similar to a shift work environment). The animals will receive an intervention, which is typically an injection of a compound being tested, and their sleep and circadian behaviour in response monitored. Most animals will be monitored for 4-6 weeks, with <25% of experiments lasting 3-6 months. Occasionally, samples such as blood may be taken from the animals, or an animal may undergo surgery to allow for the implantation of electrodes to enable recording of sleep EEG, or administer drugs/biological substances directly into the brain, if they cannot enter it from the bloodstream.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will have deficits in sleep and circadian rhythms resulting from modification of the environmental light/dark cycle, genetic alteration or the administration of drugs. Any adverse effects are typically mild (distress from single housing, temporarily heightened or reduced activity, some strains may show weight loss or gain) and mice will not be kept in an experiment beyond 12 months and not maintained beyond 15 months, with an exception made for experiments with aged mice (<5% of the experiments), which model the significant sleep/circadian rhythm disruption also seen in aged humans.

The animals may undergo surgery to administer substances intracranially or via implantation of an osmotic minipump, or to implant electrodes, and will experience transient discomfort associated with surgery (< 1 week), mitigated with analgesia. Most of the substances administered will be well characterised, and few side effects expected.

The models required for studies on metabolism may be diabetic and/or obese, typically induced by feeding of a high fat diet for 3-12 months or by a genetic alteration in the satiety pathway.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice 50% Subthreshold, 25% Mild 25% Moderate

Rats 100% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work involves the study of complex physiological and behavioural systems. This necessitates the use of whole animals as no suitable alternatives exist. Mice are the species of lowest neurophysiological sensitivity that are appropriate for such studies, and have well-characterised circadian and sleep biology. Extensive genomic data coupled with the wide range of existing genetically altered models make mice the only viable model for such studies.

Which non-animal alternatives did you consider for use in this project?

We have investigated the use of 1) Cultured cells 2) *ex vivo* tissue 3) human stem cell derived neuronal cultures/fibroblast cultures for our studies. All of these are currently already used in our group as models in which to investigate the molecular basis of the genes/drugs we investigate.

Why were they not suitable?

None of the models listed above can fully recapitulate in vivo sleep and circadian rhythms, which are a behavioural readout resulting from complex organ/system level interactions. Whilst the majority of mechanistic analysis will be carried out in the models above, final validation of the resulting changes in sleep/circadian behaviour will require animal experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

Numbers for is this project have been estimated from previous experience of experiments of this nature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Efficient planning to make sure maximum data output from a single experiment; for example collection of tissues for omics analysis at the end of a protocol.

Validation of which aspects of the investigations can be replicated in vitro; for example circadian period can be accurately modelled in vitro requiring far fewer animals for in vivo experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Target identification from in vitro high-throughput screens and large datasets, allowing multiple targets to be investigated in parallel.

Validation of target action in vitro, with only significant results being progressed to animal studies.

Efficient breeding with use of littermate controls and both sexes wherever possible. Sharing of tissue and efficient archiving of samples from each experiment.

Pilot studies with small cohorts will be conducted where appropriate to determine statistical power.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use primarily mice, as a large amount of genetic information and genetically altered models suitable for circadian rhythm and sleep research are available. Some assays will require rats, where the mouse's sensitivity to particular stimuli, such as handling, that control circadian rhythms makes it unsuitable as a model, but rats will be limited to less than 5% of the overall experiments.

The methods in majority have been optimised to cause only mild and transient distress. These include alteration of the light dark cycle (for example to simulate jet-lag), monitoring of activity using non- invasive methods, the occasional withdrawal of blood from a superficial vessel and the occasional administration of drugs / other substances and the alteration of diet. In some cases, these methods cumulatively cause moderate distress to be experienced, for example daily dosing of a drug by injection, but these methods will be optimised to cause the lowest experimental load to be experienced by any animal.

Why can’t you use animals that are less sentient?

Mice have the lowest neurophysiological complexity to still be useful for the research outlined, which requires a complex nervous system. Circadian rhythms and sleep are behaviours that need to be assessed in freely moving adult animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In most cases, the animal's activity will be continuously monitored using an online readout, with automated alerts to the experimenter in case of any gross alterations. Where activity is not monitored, the animals will be monitored as frequently as appropriate for the intervention; for example twice- weekly weighing when a new drug/diet is administered until a stable baseline or trajectory is reached. Animals will also be habituated to any handling of changes in the environment prior to experiments (e.g. gentle handling, exposure to novel environments). Peri-operative care and pain management will be provided as standard.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will reference the below websites, in addition to following the ARRIVE guidelines, a 20-item checklist designed to improve the reporting of research using animals widely implemented in many journals. We will also follow literature specific to the field of circadian rhythms that specify experimental design protocols to ensure reproducibility with minimal animal numbers and suffering (e.g. in the journal of biological rhythms).

www.nc3rs.org.uk https://norecopa.no https://www.lasa.co.uk

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Subscribe to the 3Rs newsletter and attend the termly Animal Welfare meetings organised within the institution, and also regularly attend the 3Rs conference. The following websites will be referenced: www.nc3rs.org.uk, https://science.rspca.org.uk.

We will try new advances including non-animal based models of circadian rhythms for their capacity to replace some of our animal experiments and already use a wide variety of such technologies.

167. Understanding the role of the host immune response and tumour microenvironment to enable the generation of novel immunotherapeutic strategies to treat cancer

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

cancer, antibody, immune-modulation, microenvironment, host factors

Animal types	Life stages
Mice	adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to understand the role of the host immune response and tumour microenvironment in cancer to enable the generation of novel immunotherapeutic strategies for clinical application. The specific objectives are:

Determine the mechanism of action of monoclonal antibodies (mAb), how they may be potentiated by pharmacological drugs and/or immune-modulatory agents/and or other modalities with the aim of developing improved clinical reagents;

Understand how the immune environment both systemically and locally changes and develops with cancer, how this is impacted by host factors (e.g. body composition) and the potential impact that this may have on anti-cancer immunotherapy;

Elucidate the mechanistic requirements for and then develop strategies to overcome cancer and/or host induced immune suppression thereby promoting immune responses to cancer using mAb, mAb derivatives and/or other immune-modulatory agents and delivery systems.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is the cause of one in four of all deaths in the UK with a greater proportion still affected by cancer during their lifetime. Despite advances in screening and diagnosis cancer incidence continues to rise, largely as a result of an aging population and the impact of our modern lifestyle. The majority of cancers are diagnosed late and treatment frequently involves surgery, accompanied by chemotherapy or radiotherapy. Despite these invasive and toxic interventions patients often relapse due to the survival of small numbers of tumour cells. In spite of decades of work on treatment regimens, the survival for many cancers remained unchanged until very recently. Immunotherapy, whereby the power of the patient's own immune system is harnessed to eradicate cancer cells, is an attractive adjunct to current treatments as it offers the possibility to be administered with maximal specificity, minimal toxicity and provide long term immune protection against recurrence. Indeed, immunotherapy has transformed the outcome of some cancer patients but these responses are variable and frequently limited to a minority of patients in a restricted number of malignancies. Clearly there is a need to develop new therapies for use either as an alternative to, or in combination with, conventional treatments.

What outputs do you think you will see at the end of this project?

Immunotherapy offers the potential to be applied to a wide range of cancers with highly specific reagents allowing us to treat patients by harnessing or effectively 'educating' the patient's own immune system to destroy unwanted cells while leaving normal tissue mostly untouched. Consequently, if applied appropriately, unlike conventional treatment, immunotherapies should not be associated with long-lasting toxicity. In addition, immunotherapy has the potential to provide vaccination leading to the establishment of immunological memory such that the patient's immune system will continue to recognise and kill their tumour cells on an ongoing basis, reducing the potential for relapse of their disease. Monoclonal antibodies (mAb) are the most successful immunotherapies translated to the clinic to date. Despite their undoubted impact, patient responses are variable and frequently limited to a minority of patients in a restricted number of cancers. Understanding what prevents more patients responding is a critical focus for much of the immuno-oncology research community and the focus of this programme. Through this programme we aim to understand how and why mAb immunotherapies work or fail in vivo (in live animals) and the role of microenvironmental and host factors in these variable responses. Through this better understanding we aim to deliver benefits through the development of new immunotherapy drugs and strategies that can then be tested clinically to enhance and widen patient responses. Other benefits are expected to emerge from the informed design of combination treatments in which mAb are given alongside conventional drugs and other emerging immunomodulatory (immune system altering) approaches. The ultimate aim is to develop and /or improve treatment options for patients with a range of cancers This will be achieved through the development of new treatment and/or reagents based upon a better understanding of the mechanisms involved. This may involve the patenting of new reagents/approaches as appropriate in collaboration with our funders and/or pharmaceutical companies. Several reagents developed under current and previous licences have been, or are already in, clinical trials. We have ongoing collaborations with at least six pharmaceutical companies and institutes for the development of new reagents and planned clinical trials.

We will also publish in peer-reviewed journals, present at scientific conferences and participate in public outreach activities. Primarily, our data will be of interest to scientists, pharmaceutical companies and clinicians. Principles established during these studies should also be applicable to immunotherapy against infectious diseases for both clinical and veterinary applications.

Who or what will benefit from these outputs, and how?

There will be multiple beneficiaries from our studies. In the long-term we aim for our primary beneficiaries to be cancer patients who we hope will benefit from our discoveries in the form of new and more effective treatments for their disease. In the short-term, we will publish our results in peer- reviewed journals, present at scientific conferences and participate in public outreach. Our data will be of interest to scientists, pharmaceutical companies and clinicians - and will serve to help them make further progress towards a deeper understanding of the complexity of immunotherapy in the context of cancer, its microenvironment and host. This greater understanding is anticipated to lead to new and better cancer drugs in the future. The benefits from our findings will not be entirely restricted to cancer as our aim in this context has strong parallels to the requirements for the immune system to fight infection. Therefore, the principles established during these studies should also be applicable to immunotherapy against infectious diseases for both clinical and veterinary applications. Furthermore, cancer and autoimmunity can be considered to be somewhat like opposite sides of the same immunological coin; in that the opposite effect to that required in cancer (where we seek to turn on an immune response where one is lacking) is required in the treatment of autoimmune disorders (where we seek to turn off an overactive immune response). This means that the drugs that we develop, should they prove to be inhibitors rather than activators, or the understanding that we obtain through our studies that may not be of use in the treatment of cancer may well be of use for the treatment of autoimmune diseases.

How will you look to maximise the outputs of this work?

We will aim to maximise our outputs by publishing and presenting our findings widely and freely, including in our University online open-access repository. Where possible we publish in open access journals, with full disclosure of the associated raw data, enabling our studies and results to be accessible to all. We have an excellent track record in publishing our findings (>60 to date with myself as an author), including those where approaches were not ultimately successful. In addition, almost all of our work is performed in collaboration with other academic groups and/or Biotech/Industry partners and so shared knowledge and expertise further maximises our outputs.

Species and numbers of animals expected to be used

- Mice: 14030

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Whilst all attempts are made to reduce the use of animals by using in vitro methodology (in vitro experiments on human and mouse immune cells, explant studies (tissue grown in culture medium out of the body) and organotypic models), it is inevitable in work of this nature that in vivo investigation must be undertaken. The animal models detailed are critical to facilitate in vivo proof of concept and efficacy in an amenable and manipulable system, not possible in humans. We are investigating the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro and so systemic in vivo studies remain fundamental to the study of complex tumour microenvironments, host factors and therapeutics. Further, advances, such as the availability of genetically altered mice and the development of more specific and sensitive techniques and reagents, continually permit a refinement and reduction in the types of experiments and the numbers of animals that are required (e.g. as highlighted by the organisation 'Fund for the Replacement of Animals in Medical Experiments', http://www.frame.org.uk) and this is something to which we remain committed. The increasing availability of genetically altered mice has allowed genetic dissection and more meaningful modelling of human disease.

Adult mice will be used for this study since they have a mature immune system and are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically 'identical', thereby reducing variability and allowing valid conclusions to be drawn from experimental data;

Numerous tumour models have been established in mice that are strain specific;

Numerous strains of genetically altered mice have been developed (often replacing the mouse receptor with the human receptor) several of which will be central to this programme of work and have been developed by us to answer our specific aims and objectives. These mice will allow us to understand the mechanistic requirements for effective therapy in 'human' relevant in vivo contexts. These experiments are simply not possible in humans and will enable us to validate and extend our findings in a 'human' setting and to help inform the generation of novel agents for use in patients.

Typically, what will be done to an animal used in your project?

This programme of work has 13 protocols that enable experiments to be conducted that meet our aims and objectives. The experiences of animals under these protocols will differ and below are detailed typical experiences for each:

Terminal bleeding for serum or cells. Mice (which may have been given special diet to alter their body composition) will be administered a suitable non-recovery anaesthetic and bled by cardiac puncture to obtain blood for serum or cells.

Tissue sampling and harvesting in the absence or presence of tumours. In experiments designed principally to measure effects on the immune system, mice (which may have been given special diet to alter their body composition) will be injected with material (such as an antibody or a combination of immunotherapy/immune-modulatory substances) and then the immune response measured by taking peripheral blood (much as we do for

patients) and measuring changes in the immune cells (typically over a period of days to weeks). These experiments are often done in the presence of a growing tumour, typically introduced earlier through injection (although mice that generate spontaneous tumour models may also be used), allowing us to assess infiltration of immune cells into the tumour after different treatments. Mice will then be euthanised and their tissues examined to understand how the immune response is developing in the different organs.

Immunotherapy of tumour models. In experiments designed principally to measure anti-tumour efficacy, mice (which may have been given special diet to alter their body composition) will be injected with an appropriate tumour model or mice that generate spontaneous tumours may be used and subsequently these would be administered treatments (such as a direct targeting and/or immune modulatory antibodies and/or other immune-modulatory substances) and tumour growth monitored over time through established means in experiments that may last several months, allowing us to determine if the treatments have cured the mice or delayed the tumour growth. Cured mice may be rechallenged with tumour or other sources of antigen to assess the induction of long-term immunological memory. A proportion of these mice may be monitored as above for their immune response during these experiments (peripheral blood or tissues).

Maintaining tumour cell lines and establishing humane endpoints. A minority of passaged (maintained) tumour models cannot be passaged in vitro whilst maintaining suitable characteristics for in vivo experimentation and therefore these models need to be passaged in vivo. Typically, mice will be administered a defined number of tumour cells and the tumours monitored and permitted to grow to the minimum point required to permit subsequent use of this tumour material for appropriately powered experiments. We constantly strive to use the most appropriate model to address our scientific objectives and therefore periodically need to acquire or develop new models which need to have their humane tumour endpoints established to ensure we can reproducibly use the models for our objectives whilst minimising welfare impact. Typically, a small number of mice (which may have been given special diet to alter their body composition) would be administered tumour cells by an appropriate route and tumour growth and animal welfare monitored to determine a suitable endpoint and ensure no unexpected or excessive harms are evident. These would be followed by pilot tissue sampling and harvesting or immunotherapy experiments to ensure the utility of the model.

What are the expected impacts and/or adverse effects for the animals during your project?

We typically identify mice by ear notching - this is expected to result in only mild and transient pain with no healing problems. Some mice in our studies are provided ad libitum altered diet (e.g. high-fat diet) to alter their body composition, or agents in their water to induce gene expression. Although these have the potential to impact welfare we have not observed these in our studies to date.

Mice will be injected with various immune-modulatory substances using a combination of volumes, routes and frequencies. Injections will cause momentary needle stick pain, minimised by using the needle of the smallest suitable gauge. The minimum number of administrations and routes will always be used to achieve the scientific objectives. Typically, the animals will not receive more than 3-4 intraperitoneal injections a week or 2-3 intravenous injections a week. On some occasions they may receive 2 injections on a given day through a combination of different routes.

For some more invasive procedures, general anaesthesia will be used to ensure the animals feel no pain.

For some experiments, mice will receive tumour cells through various routes; e.g. injected subcutaneously (under the skin) using a suitable vehicle or those spontaneously arising or induced. The tumours grow at their respective sites and can be measured over time using digital calipers, palpation or imaging. Mice are euthanised at a size that is deemed to not impact their normal behaviour. Throughout, the health status of the animal is the primary consideration used to define humane endpoints. Experiments will be terminated, or individual mice euthanised at the earliest signs of tumour-associated symptoms such as piloerection (goose bumps making the fur stand up), restricted movement, abnormal posture, abnormal gait, hunching, and/or weight loss up to, but not reaching, 20% body weight.

In many of our experiments, designed to measure immune changes, peripheral blood is taken from a superficial vessel. Pain from bleeding is controlled by suitable anaesthesia/analgesic with rapid healing and no long-lasting harm.

When the immune system is stimulated, for example with immunomodulatory agents, this can result in symptoms similar to those experienced during an infection (lethargy, fever etc). This can result in mice becoming less mobile, exhibiting pilo-erection etc. Typically, these symptoms are transient (first few hours) but can recur as the immune response develops (e.g. after several days) potentially resulting in further effects such as weight loss. These effects are therefore carefully monitored with mice euthanised if their symptoms become more severe or pass defined humane endpoints.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Experience from our current project licence has helped to determine the expected proportions of mice experiencing various severities for this project to be:

Sub-threshold - 0.6%

Mild - 64.5%

Moderate - 34.9%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst all attempts are made to reduce the use of animals by using in vitro methodology (in vitro experiments on human and mouse immune cells, explant studies and organotypic models), it is inevitable in work of this nature that in vivo investigation must be undertaken. The animal models detailed are critical to facilitate in vivo proof of concept and efficacy in an amenable and manipulable system, not possible in humans. We are investigating the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro and so systemic in vivo studies remain fundamental to the study of complex tumour microenvironments, host factors and therapeutics. Further, advances, such as the availability of genetically altered mice and the development of more specific and sensitive techniques and reagents, continually permit a refinement and reduction in the types of experiments and the numbers of animals that are required (e.g. as highlighted by the organisation 'Fund for the Replacement of Animals in Medical Experiments', http://www.frame.org.uk) and this is something to which we remain committed. The increasing availability of genetically altered mice has allowed genetic dissection and more meaningful modelling of human disease.

Adult mice will be used for this study since they have a mature immune system and are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically 'identical', thereby reducing variability and allowing valid conclusions to be drawn from experimental data;

Numerous tumour models have been established in mice that are strain specific;

Numerous strains of genetically altered mice have been developed (often replacing the mouse receptor (part of the cell which binds to a substance) with the human receptor) several of which will be central to this programme of work and have been developed by us to answer our specific aims and objectives. These mice will allow us to understand the mechanistic requirements for effective therapy in 'human' relevant in vivo contexts. These experiments are simply not possible in humans and will enable us to validate and extend our findings in a 'human' setting and to help inform the generation of novel agents for use in patients.

Which non-animal alternatives did you consider for use in this project?
We have made large strides to make more use of human material during the course of our current project licence. We now make extensive use of lymphocyte cones (blood cells collected from donors provided from NHS Blood Service) as a source of human immune cell populations for a range of immune assays and have built a range of clinical collaborations to allow us access to human tumour and healthy control material to study human cancer directly. Although powerful, these models are limited in both longevity and importantly complexity compared to in vivo systems and so we therefore still need to use appropriate mouse models to allow us to study our objectives in a whole-body system over a protracted time period and with facets such as biodistribution, pharmacokinetics and toxicity to be understood.

Further to this, and to try and better link between simple ex vivo culture assays and complex whole- body systems we have also embarked on a programme to develop appropriate human multi-cellular organotypic models for studying malignancy and the

impact of body composition on inflammation and cancer. To date we have published a model of lymphoma and demonstrated that we could model aspects of the tumour microenvironment and run limited antibody effector studies. We have also been developing a model of Osteosarcoma (a form of bone cancer) and have published a review of available models including; human organotypic, chorioallantoic membrane (a model using chicken eggs) and in vivo mouse models to widen awareness and interest in this area in the field. Finally, we have begun a project to develop a three-dimensional breast cancer organotypic model of obesity associated adipose inflammation. Here, we will again use a fully human system to investigate breast cancer development, progression and treatment response.

It is difficult to quantify the reductions in mouse numbers that these changes have facilitated given that the experimental systems are complementary and not interchangeable as they address distinct scientific questions. However, without question, access to and greater use of human material to address basic scientific questions enables us to replace animals in some circumstances and this should continue to grow in the future.

Why were they not suitable?

We need to investigate the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro. Each of the systems we have developed above, model different aspects of the immune response but none fully recapitulate the complexity and inter-relationships of a whole organism and so systemic in vivo models remain fundamental to our studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?
I have a current project licence and have been monitoring annual usage. This existing PPL has been interrupted by moving to a new animal facility and the coronavirus pandemic and therefore the numbers used do not represent those originally envisaged or planned. The number above represents predicted numbers based on current activity and taking into account reductions due to our shift to using primary human tissues, where possible, as well as likely refinements over the coming years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design is always considered in light of how animal numbers can be reduced whilst ensuring meaningful and reproducible results. We are committed to reducing animal waste, implementing the three Rs, and maximising the reproducibility of research and so follow the PREPARE guidelines (https://norecopa.no/prepare) when considering our experiments.

As a first means to reduce the numbers of mice in our project, inbred mouse strains will be used to minimise variability of response and so allow reduced numbers to be used whilst delivering reproducible data. Related to this, we routinely use age- and sex-matched mice that have been bred in the same facility (ideally litter matched where control and GA mice are being compared) to minimise variability.

We have been using a range of tumour models for some time and so are well aware of the reproducibility of controls and appropriate mouse numbers required in tumour growth and therapy experiments. Where new models or treatments are introduced, we will first confirm expected humane endpoints and then perform pilot studies to inform the design of larger studies, including dosing regimens, as well as to monitor for any signs of adverse events. For example, 2 mice per group would be inoculated with a new tumour at different cell numbers to establish tumour growth kinetics etc., even where data exists in the literature, as we are cognisant of the impacts of the local environment, microbiome etc. Similarly, a single mouse would first be treated with a new experimental treatment to judge safety, immune response etc, before proceeding to larger studies.

We are also cognisant of ensuring we minimise experimental bias. Accordingly, in experiments where we implement more subjective humane endpoints as part of a tumour therapy experiment (e.g. abdominal palpation as opposed to caliper measurements), an experienced and treatment-group blinded animal technician is consulted regarding outcome.

Where we have useful data (from historical or pilot experiments), power analyses will be used to help guide the optimal numbers of mice needed for each experiment, taking into account expected magnitudes of impact. Power analysis is performed using the PS: Power and Sample Size Calculation programme: www.biostat.mc.vanderbilt.edu/twiki/bin/view/Main/PowerSampleSize):

For immunotherapy experiments, where we use inbred strains of mice, intra-group variability is reduced. From experience, we have found that we can use considerably fewer animals per group, usually 5, to detect such a difference at the 5% significance level in many of our models (e.g. EG7, MC38, B16-OVA and TC-1).

For monitoring immunological responses we typically use 5 mice per group for each experiment. From our experience, this number of mice/group allows us to identify with a statistical power of 95% a 3-fold difference in the number of CD8 T cells between 2 groups at the 5% significance level.

Therefore, the proposed mechanistic studies will be performed with experiments utilising groups of 5 mice, in a standard vehicle versus drug manner. We aim to test the candidate antibodies and immune modulators (identified by prior human and murine in vitro experiments) for efficacy in a selection of tumours. Throughout, replicate experiments will be performed to ensure reproducibility and when appropriate studies may be combined to increase sample size. To assess animal survival, endpoints will be plotted against time for each group in an experiment and the differences between groups will be analysed by appropriate statistical tests.

Should substances or tumour models be used for the first time, pilot studies will be performed on individual mice and humane endpoints established as indicated above. Substances will be administered and monitored after 1, 4 and then 24h for adverse effects before proceeding; a dose escalation schedule conforming to accepted practice will be

used should adverse effects be predicted. When agents are used for the first time in the laboratory, their dose will be based on previous published data whenever possible.

When new tumour lines are introduced they have to go through quarantine to ensure safe introduction into the animal facility. As an additional measure of reduction, we use this period to also monitor growth and humane endpoints reducing the need for additional animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mice used across experiments are inbred thereby minimising intra-group variability and allowing reduced mouse numbers for experiments (we also, wherever possible, when breeding GA strains will use GA-ve littermate controls when available). Experiments are always designed with the fewest animals consistent with obtaining statistically valid results. We have performed Power analysis and our own extensive experience with these models to determine the numbers of mice required to deliver statistically significant results. Where appropriate, small pilot experiments are carried out to determine factors such as dose or route of administration.

Where multiple inter-relating parameters are to be evaluated, to prevent use of excess mice, we will employ higher dimensional analysis tools. Significant technological advances have enabled more information to be obtained from one individual mouse than was previously possible (e.g. using multi- parameter flow cytometry and RNA-seq technology), enabling multiple parameters to be assessed simultaneously from small samples. These technologies thereby facilitate longitudinal studies and reduce the need to cull multiple mice at different time points to sample from the spleen for instance. For example, we have largely moved from 3 to 8 and 16 colour flow cytometry, reducing the sample input requirements accordingly.

During the course of our current PPL, we have instigated a policy that new in vivo experiments must be detailed on a ‘study-plan’ detailing: the aims, number and strain of mice, substances/cells administered, treatment dates, confirmation of required competencies and/or delegation of procedures, any known or anticipated adverse effects, and appropriate risk assessments. This has to be submitted to myself and the NACWO before an experiment is allowed to begin. An example of this document (Figure 1) is shown below:

Home Office

Figure 1. Study Plan Template

This has facilitated a more detailed dialogue between PPLh and PILh prior to work and if necessary a discussion about the number of mice being used. More recently this process has included approval by representatives of the AWERB committee. This serves to ensure animal numbers are optimised.

Other optimisations to reduce animal use include:

Tumour cells being stored frozen when possible to prevent mice being used to passage tumour in vivo.

Consideration of freezing additional animal tissues (whole and as single cell suspensions) when an animal is sacrificed to provide controls for staining in different immune situations, relieving the need to cull specific mice for this comparative purpose.

Similarly, harvesting tissues; blood (for serum production), spleens (for lymphocytes) and bone marrow (to generate macrophages) when appropriate mice are culled for other purposes.

The in vitro use of immune cells isolated from mouse tissues offers several benefits and aids in optimising number of animals used for in vivo experiments. Importantly, this strategy is in line with the 3Rs. Due to the relatively low numbers of cells required to perform in vitro assays, such experimental approaches allow the screening of a high number of drugs or combination thereof, with potential for in vivo activity, while minimising the number of animals required. Furthermore, they allow refining doses, and identifying potential mechanisms of action and adverse reactions, prior to in vivo testing. In addition, in vitro assays using mouse immune cells represent a powerful reductionist approach to study their activation. They allow the isolation and analysis of distinct cell subsets, and the direct assessment of drugs on each individual cell population, otherwise difficult to accomplish.

For monitoring immunological responses in vitro, we generally use 1 mouse per experimental setting with 3 technical replicates and repeat the experiment two to three times. From our experience, this number of mice allows us to identify with a statistical power of 95% a 1.5 fold difference in immunological responses (eg. cell proliferation, upregulation of activation markers, cytokine expression, phagocytic uptake) between the control and treatment arms at the 5% significance level.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice for these studies as they are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically ‘identical’, thereby reducing variability and allowing valid conclusions to be drawn from experimental data with as few animals as possible.

Numerous tumour models have been established in mice that are strain specific;

Several strains of genetically altered mice have been developed such as those expressing tumour antigens of interest (hCD20, HER2 etc.) and mice with genes of interest removed or added in order to elucidate immune mechanisms e.g. mice in which the mouse Fc gamma receptors have been replaced with their human counterparts. If required, we will generate new human knock-in (KI) mice to enable us to validate our findings in a ‘human’ setting and to help generate novel agents for use in patients as we have done with our unique human stimulator of interferon gene (STING) knock-in mouse model.

When evaluating immune-modulatory and immunotherapy approaches, we begin with in vitro evaluation and progress to pre-clinical animal models when sufficient promise is obtained. Our in vitro studies may include assays to determine the ability of reagents to kill or affect the growth or survival of target cells, and to recruit immune effector mechanisms. Where appropriate, we will first establish effects on in vitro cell lines and ex vivo primary material. However, in vitro lines and primary cells become adapted to cell culture conditions and are not present in a complex multicellular tissue/organ and therefore do not best recapitulate in vivo responses, hence the need for animal experiments.

In order to understand the mechanistic requirements for effective immunotherapy, cells may be obtained from WT or genetically altered mice with deficient/altered immune effector systems e.g. Fc gamma receptors or complement knock-out mice deficient in key effector molecules. For those reagents that show promise in vitro, we will determine if this translates into an in vivo effect using the most appropriate models. Typically, we would first examine reagents in the absence of tumour or other 'altered' host factors (e.g. increased fat mass), to assess immune-modulation, without unnecessarily increasing the welfare impact to animals by adding to the cumulative harm from further interventions and/or activities of the tumour. We ensure humane end-points are established that minimise the harm to the animal without compromising the accuracy of the experimental data.

Why can't you use animals that are less sentient?

Our work largely involves study of the immune system, which is a complex, multi-faceted, interacting system that is spread throughout the body and organ systems. The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapy strategies and their mechanisms in these animals - less sentient species have very different immune systems. More immature animals also do not display mature immune systems (the immune system becomes educated with age and development) that we seek to investigate and understand for clinical benefit. Anaesthesia reagents frequently interfere with multiple bodily functions which would alter the immune response and cannot be used for the extended periods required (days to weeks) to follow immune responses induced and so are not routinely used unless required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continually review our procedures and if unnecessary harms are identified or can be reduced, modified protocols are implemented through discussion with the NACWOs, PPL holder, academic lead for the BRF and named vet as required. We also seek to ensure the best housing and conditions for the animals are provided.

Over the course of my current PPL we have instigated the changes below that demonstrate our commitment to refinement:

We have moved to a new purpose-built animal facility that is more conducive to high quality in vivo research utilising a 'barrier' system meaning that all materials coming into the unit are clean and enter via a dedicated positive-pressure pass-through hatch. All personnel entering must now change into scrubs, and pass through an air-shower on entering (and leaving). The new facility also houses a separate quarantine facility that is no longer inside the main unit, but attached and accessible separately, with dedicated technicians only permitted.

All new strains of mice entering quarantine undergo rederivation before offspring are allowed in the main unit. All new cell lines must be screened in mice in quarantine, and serum from hosts/sentinels assessed for the presence of pathogens before cells are allowed to enter the main unit. All mice in our new facility are housed in individually ventilated cages. These changes minimise the risk of infection with obvious potential implications for the welfare of the animals and the quality of the research. In addition, the IVCs permit less disturbance to the animals as an additional refinement.

We have also implemented a number of new policies to improve welfare and reduce adverse experiences. All mice undergoing an injection now undergo a 'second check' by the person performing that procedure, within 30 mins - 4 hours. This was instigated to prevent animal welfare impact should an unanticipated adverse event occur. If a procedure is delegated to a technician, this second check also incorporates a 'positive handover' between the technician and the PILh to transfer the responsibility for the mice back to the PILh to ensure it is always clear where responsibility for welfare ultimately lies.

In response to changing guidelines a number of further and specific refinements have been put in place, including:

CO2 entering a chamber during schedule 1 culling, now enters from the top rather than from the bottom in line with current best practice. Flow rate is 20% of chamber volume/min. 3 min dwell time, where the CO2 is stopped but the chamber remains untouched so they remain in maximum CO2. Nb: the machine is serviced annually to check that it is still within parameters and we check that there is adequate CO2 pressure before starting and stay in the room during the CO2 delivery.

Mice are handled by ‘cupping’ or by gently moving them using a dedicated tunnel, prior to any restraint to ensure mice are calm and habituated to the person performing injections, serving to reduce anxiety when handling mice.

Instigated a policy that needles are only to be used once. This is to prevent mice receiving an injection with a blunted needle. Initially during the early part of this PPL the refinement was for needles to be used less than 5 times, but latterly we implemented the new single use policy unless specific justification is provided that is approved by BRF management committee.

We have transitioned towards venesection as our primary means to take blood samples instead of tail tipping. While this is not always possible (for instance when mice are receiving concurrent intravenous injections) new PILh are now trained in venesection and established PILh who regularly bleed mice have undergone re-training. Although retraining was delayed during COVID-19 restrictions and due to staff shortages and altered work-patterns/shifts, this has recently been re-initiated.

During the course of this PPL, we instigated a policy that new in vivo experiments must be detailed on a ‘study-plan’ (see Figure 1) and encompass the aims and how they address the PPL objectives, number and strain of mice, substances/cells administered, treatment dates, confirmation of required competencies and/or delegation of procedures, any known or anticipated adverse effects, welfare measures and monitoring employed and appropriate risk assessments. This study-plan has to be submitted to the PPL and then responsible NACWO for approvals prior to experiment commencement. This has ensured that there is evidence of an appropriately detailed dialogue between PPLh and PILh prior to work and as necessary enabled a discussion about the number of mice used and procedures administered.

We also have a new system that records training competencies for individual PILh to ensure that training on all procedures is renewed every 3 years. Training is conducted by dedicated trainers using Detailed Operating Procedure (DOP) forms written specifically for this purpose. As PPLh I have access to these records, and reference is made to them on the ‘study plan’ (see Figure 1) ensuring that PILh also review their records regularly.

We have regular BRF Users meetings (approx 3 times per year) to discuss issues that arise within the animal facility and these are well attended by the personal licence and project licence holders, named animal care and welfare officers, animal technicians, home office liaison and compliance officer, named veterinary surgeon and establishment licence holder. Any issues and incidents that PILh need to be aware of are discussed at this meeting. We have also embarked upon a strategy of ensuring that PPLh and PILh undergo regular refresher training at least every 3 years to ensure that they remain abreast of changes to best practices and aware of their responsibilities under ASPA.

When possible, genotyping protocols for new Tg mice have been refined to allow PCR only protocols for screening, reducing the need to bleed mice prior to experimentation. Moreover, some existing transgenic strains (e.g. human CD20 transgenic) that were

previously screened via blood are now done so by PCR from ear notches reducing the number of procedures the mice undergo.

We have also adopted the practice of transferring male mouse nesting material, not substrate, to minimise male mouse aggression (the nest has calming pheromones in it, but the sawdust aggravates aggression as it holds the testosterone).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are a number of detailed publications and guidelines for the welfare and use of animals in cancer research that provide excellent guidance on the methodologies, study design and best practice that we will follow and adapt as appropriate to our research (Guidelines for the welfare and use of animals in cancer research: Workman, P., Aboagye, E., Balkwill, F. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010). https://doi.org/10.1038/sj.bjc.6605642).

We will continue to follow the ARRIVE guidelines https://arriveguidelines.org/ which provide a checklist of the minimum information required to be reported by groups using animals in research. ARRIVE guidelines are essential to help overcome issues in science such as reproducibility, reducing bias and the correct use of statistical methods of analysis.

In addition, we will follow and consult NORECOPA https://norecopa.no/3r-guide : Norway's National Consensus Platform for the advancement of the 3Rs (Replacement, Reduction and Refinement associated with animal experiments) database platform and PREPARE https://norecopa.no/prepare (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for better science experiments using animals to ensure that we are using the best models for our research.

Finally, regular communication within our research group and communication with our peers at seminars and conferences ensures we're aware of any new or updated best practice. Best practice information is also disseminated by our Named Information Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have regular BRF Users meetings (approx 3 times per year) to discuss issues that arise within the animal facility and these are well attended by the personal licence (PILh) and project licence (PPLh) holders, named animal care and welfare officers, animal technicians, home office liaison and compliance officer, named veterinary surgeon and establishment licence holder. Any issues and incidents that PILh need to be aware of are discussed at this meeting. Further to this, this platform is used to disseminate information from ASRU, NC3Rs and other organisations and to provide details of training opportunities to enhance welfare and research practice. We have also embarked upon a strategy of ensuring that PPLh and PILh undergo regular refresher training at least every 3 years to ensure that they remain abreast of changes to best practices and aware of their responsibilities under ASPA. These advances are further communicated through our active team of NACWOs and regular email updates. We will also stay up to date with specific cancer groups, databases and alternatives (NC3Rs) for cancer models such as: https://resources.researchanimaltraining.com/faqs/breast-cancer- research-alternatives-database; https://data.jrc.ec.europa.eu/dataset/352f7dfd-05cf-434b-a96a- 7e270dc76573.

168. Breeding and maintenance of genetically altered mice

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Mouse, Breeding, Transgenic

Animal types	Life stages
Mice	juvenile, adult, pregnant, aged, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this work is to, breed and maintain mice with genetic alterations and supply them for research into the control of disease, ill-health or abnormality and/or the study of normal and abnormal physiology, biology or behaviour. They will be used for the discovery and development of new cancer treatments and prevention of this disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One in two of us will personally experience a positive diagnosis of cancer in our lifetime and cancer research is crucial to improve the prevention, treatment and detection of these cancers. Genetically altered mice are valuable animal models that contribute to the elucidation of a wide range of biological processes and diseases such as cancer. Although

in vitro approaches provide critical data, the use of animal models is essential to understand the very complex scenario of this disease.

What outputs do you think you will see at the end of this project?

A supply of genetically altered and non-genetically altered mice for use in research into cancer mechanisms and treatment.

Who or what will benefit from these outputs, and how?

A single centralised breeding project licence, managed by an individual with specialised technical expertise in the required breeding methodologies and with stringent colony management is administratively efficient and has anticipated welfare benefits.

These are:

Reduction in animal numbers by effective liaison with end-user projects, to ensure the appropriate strains of the desired specification are bred (best model for the disease areas), with minimal wastage and sharing of animal lines and/or tissues by several research programmes.

Reduced transport time for the animals, as fewer animals have to be brought in.

High health status, with direct benefit on welfare and science. The standard of facilities available for the work is high, and reflects a good level of investment. Secondary benefits will also be delivered through assisting other project licensees in meeting their objectives.

Under the previous licences there been a proven record of efficient generation and breeding of genetically altered animal strains and this project will continue and improve the provision of high quality animals to the researchers.

The output of the programme will be used by the scientists at the Establishment in both in vitro and in vivo studies aimed at understanding the processes involved in cancer initiation and metastases, as well as in the evaluation of newly discovered cancer targets in vivo before taken further in clinical trials.

How will you look to maximise the outputs of this work?

Myself and technicians in my team will hold regular meetings with and communicate as required with the institute group leaders (principal investigators) and scientists to ensure transgenic breeding is managed effectively and excess stocks are kept to a minimum. We will use proprietary software to manage the colonies efficiently. Where mouse strains are not required for a long time embryos / sperm of those mice will be preserved by freezing.

Species and numbers of animals expected to be used

- Mice: 90,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Researchers have studied laboratory mice as models of human cancer for many years and there are many standard protocols, methods and reagents that have been optimised for use with mice. Their use as cancer models has already provided exceptional insight into the biology and genetics of human cancers. Although it is possible to identify genes and targets that may cause susceptibility to a certain disease in vitro this can often only be fully investigated in an animal model that has been manipulated to study the gene effect. Without animal models it is impossible to determine what effect these changes will have on a whole living system. In vitro assays cannot adequately model the complete array of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes.

The majority of the research projects that we support require the mice to be adult at the time of tissue collection or enrolment into experimental protocols, in order to reflect typical ages of cancer development in humans. Some particular projects may necessitate the use of fetal, embryonic or immature mice, either because the processes being studied are developmental ones that have a relevance in cancer, or because the combination of transgenes is lethal at later stages of development.

Typically, what will be done to an animal used in your project?

Genetically altered animals will be bred under this licence in order to understand further different processes associate with cancer. The various steps involved will be:

Mice will be bred for research purposes. Some of the mice will be genetically altered to help address questions in cancer research and so may have phenotypic characteristics that require more regular monitoring. Animals will be monitored for unpredicted adverse effects. All procedures will be undertaken by trained, competent people.

Mice that are no longer going to be used will be humanely killed following the accepted protocol. No mice with genetic disabilities exceeding moderate severity will be bred on this licence.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the mice bred with alterations of genes for the purposes of investigating cancer mechanisms may display clinical symptoms that require regular and frequent monitoring. These potential clinical symptoms include: sub-cutaneous / abdominal masses; rectal prolapse; swollen eyes; skin spots; hairlessness; hind-limb issues. During the course of the previous five years these symptoms have only been seen rarely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The proportion of mice that are anticipated to display clinical signs resulting from gene alterations that lead to a moderate severity rating is, based on previous experience less than 1%. The proportion of animals that are expected to display clinical signs resulting

from gene alterations that lead to a severe severity rating is, based on previous experience less than 1%.

All mice will be managed so that they do not suffer if developing early signs of the clinical symptoms.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The different animal models maintained and bred under this license will integrate the complete range of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes, focusing on cancer. This cannot be achieved without the use of animals.

The mouse is one of the model organisms that most closely resemble humans. The human and mouse genomes are approximately the same size, and display an equivalent number of genes, which are functionally conserved. Definitively, mouse models are important for placing the findings of in vitro studies or correlative analysis of human samples into an appropriate and meaningful in vivo context

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives have been excluded by the Project Licences for which we are providing mice. The reason why is that cancer is a multi-faceted disease dependent upon the interaction of many different cell types interacting in a dynamic three-dimensional environment.

Why were they not suitable?

The reasons for not being suitable was provided by the individual Project Licences for which we are providing mice.

In general the study of cells in culture (in vitro) and less sensitive organisms provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above to allow us to investigate the impact of the relationship between the immune systems in the promotion of cancer cell growth and spread.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design

studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimations of numbers of animals required are based on actual numbers used in previous project licences for breeding and predicted future requirements of Project Licences being supplied with mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design will be covered under separate experimental PPLs, the mice will be transferred to these as required. Breeding programmes will be agreed in advance and regularly reviewed to optimally meet anticipated demand. Breeding programmes will be optimised wherever possible to produce only the required genotype.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Freezing of eggs / embryos and sperm will be carried as routine by a separate team responsible for cryopreservation of mouse strains, working under a different project licence.

Archiving of mouse strains will avoid unnecessary need to maintain colonies by continuous breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Researchers have used laboratory mice as models of human cancer for many years. There are several reasons that make this rodent the best model to use: the mouse has a short reproductive cycle, large litter sizes, is easy to maintain and can be readily shipped from breeding facilities to research locations. Only natural mating methods will be used and these are not anticipated to cause pain, suffering, distress or lasting harm.

Why can’t you use animals that are less sentient?

The mouse is the least sentient mammal for which there are many well established laboratory protocols and a significant amount of background data. A mammalian model is required in order to more closely model the processes relevant to cancer that are seen in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All mice in the facility are regularly monitored in order to detect any potential welfare issues.

In addition to usual daily checks all breeding females are checked for pregnancy and this is flagged when detected, so that conditions such as dystocia can be monitored for. Litters are noted as soon as they are detected, but to minimise stress new litters are not usually disturbed to count pups for the first couple of days after birth.

Breeding performance (including factors such as litter sizes, lost litters, aggressive behaviour and age) and stock levels are monitored by the technicians who are responsible for each line, who then communicate with users as needed regarding potential replacements or other changes required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Breeding and Colony Management Best Practices. https://nc3rs.org.uk/breeding-and-colony- management. Wells DJ, Playle LC, Enser WEJ, Flecknell PA, Gardiner MA, Holland J, Howard BR, Hubrecht R, Humphreys KR, Jackson IJ, Lane N, Maconochie M, Mason G, Morton DB, Raymond R, Robinson V, Smith JA and Watt N. Assessing the welfare of genetically altered mice. Laboratory Animals (2006) 40, 111–114.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Project Licence holder and other team members will attend meetings such as the annual meetings of Laboratory Animal Science Association (LASA) and Institute of Animal Technology (IAT), as well as smaller national meetings such as the National Centre for 3Rs (NC3R) Understanding Animals in Research (UAR) meetings. The Project Licence holder will stay abreast of relevant literature. Relevant advances will usually be initially implemented in the form of pilot projects and, where technically feasible, will then be implemented more widely.

169. Novel immunotherapeutic strategies to treat Cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, antibody, immunotherapy, immune-modulation, immune system

Animal types	Life stages
Rats	adult
Mice	adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to explore the utility of new anti-cancer reagents for use in the clinic. The specific objectives are:

To produce and characterize new anti-cancer reagents.

To determine how these reagents work and how they can be improved.

To develop strategies to promote/modulate the immune response to cancer and to understand how this happens

To understand how tumours form with the aim of developing reagents that can stop them.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In 2020 there were more than 19 million new cases of cancer diagnosed alongside 10 million cancer- related deaths worldwide. With such a high worldwide healthcare burden, the need for effective anti- cancer treatments is paramount. Although the conventional treatments of surgery, chemotherapy and radiotherapy have been effective in the treatment of certain cancers and in improving outcomes for many patients, frequently these treatments fail and tumours come back. Understanding why tumours form and how they overcome treatment is critical for developing more effective treatments. In the last 2 decades it has become increasingly clear that tumour cells interact with the host immune system. This knowledge has led to a huge surge in the field of immunotherapy – which studies how the immune system can be leveraged to treat diseases including cancer. The idea is to redirect or reinvigorate the immune response against cancer, in therapies that are highly specific and effective with the potential to prevent tumour recurrence, in the same way we become immunised against measles or mumps.

What outputs do you think you will see at the end of this project?

Immunotherapy offers the potential for treating a wide range of cancers in a highly focussed and specific way. The immune system has the amazing ability to distinguish pathogens from the host and can do the same in recognising, detecting and removing cancer cells.

The most successful immunotherapy drugs explored to date are monoclonal antibodies (abbreviated as mAb). Using these cancer-specific reagents, we can direct the patient’s own immune system to destroy unwanted cells while leaving normal tissue mostly untouched. Consequently, unlike conventional treatment, mAb treatment will not be associated with long-lasting toxicity. In addition, it has the potential through what is termed "immunological memory", which forms the basis of vaccines, to mean that the patient will continue to recognise and kill their tumour cells on an ongoing basis, reducing the potential for relapse. In this project we will deliver these benefits through the development and characterization of new immunotherapeutic reagents and treatment strategies.

Potential benefits from our work also arise from our ability to develop new combinations of treatments in which mAb are given alongside conventional and other emerging methods, including other mAb. The ultimate aim is to develop and /or improve treatment options for patients with a range of cancers.
However, this can only be achieved through a far better understanding of the interaction between the cancer cells and the immune system.

Therefore, during our programme of work we anticipate discovering and patenting new reagents and approaches for cancer treatment alongside our partners such as Cancer Research UK and Biotech/pharmaceutical companies. Several reagents developed under our current and previous licences have been or are already in clinical trials.

Who or what will benefit from these outputs, and how?
There will be multiple beneficiaries from our studies. In addition to those cancer patients who may benefit from our discoveries in the longer-term, we will publish our results in peer-

reviewed journals and present at scientific conferences in the short-term. This manuscripts will be available on eprints 3 months after publication. Our data will be of interest to scientists, pharmaceutical companies and clinicians - helping them to make further progress towards deeper understanding and ultimately hopefully new and better cancer drugs in the future. Moreover, often our aim in cancer is to stimulate the immune system to attack the cancer cells and the same is often true in infection. Therefore, the principles established during these studies should also be applicable to immunotherapy against infectious diseases for both clinical and veterinary applications. Furthermore, the opposite effect is required in the treatment of autoimmune disorders (a condition in which the body's immune system mistakenly attacks healthy tissues) and so drugs that we develop, should they prove to be inhibitors rather than stimulators (reduces the effect rather than boosts it), or understanding that we gain that is not of use in the treatment of cancer, may well be of use for the treatment of these diseases and for the benefit of human health.

How will you look to maximise the outputs of this work?

We will maximise our outputs by publishing our findings widely and freely. Where possible we publish in open access journals, with full disclosure of the associated raw data, enabling our studies and results to be accessible to all. We have an excellent track record in publishing our findings (>180 to date with myself as an author), including those where approaches were not ultimately successful. In addition, almost all of our work is performed in collaboration with other academic groups and/or Biotech/Industry partners and so shared knowledge and expertise further maximises our outputs.

Species and numbers of animals expected to be used

- Mice: 14304
- Rats: 16

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Whilst all attempts are made to reduce the use of animals by using in vitro methods (e.g. isolating and performing experiments on various types of blood cells that are an essential part of the immune system outside of the body) and explant studies (using tissue grown in a culture medium out of the body), it is inevitable in work of this nature, assessing the immune system, that in vivo investigation must be undertaken. Animal models are critical to facilitate in vivo (in a living animal) proof of concept and efficacy in an amenable and manipulable system, not possible in humans. We are investigating the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro (in an artificial environment) and so systemic in vivo studies remain fundamental to the study of new complex tumour microenvironments and therapeutics.
Rodents (principally mice) will be used for this study since they are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically 'identical', thereby reducing variability and allowing valid conclusions to be drawn from experimental data.

Numerous tumour models have been established in mice that are strain specific; although none fully capture every aspect of the human disease, models can be selected that allow specific questions to be addressed to facilitate translation.

Numerous strains of genetically altered mice have been developed. These genetically altered mice allow more meaningful modelling of human disease. These experiments are simply not possible in humans and will enable us to validate and extend our findings in a 'human' setting and to help inform the generation of novel agents for use in patients.

Mice will be used as they possess a mammalian immune system, reflecting that of humans.

For the raising of certain monoclonal antibodies we will use rats, as they allow the generation of antibodies to mouse targets (not possible to raise in mice) to serve as tool reagents and for dissection of mechanism of action prior to development of human antibodies.

Typically, what will be done to an animal used in your project?

A series of different types of experiments are proposed which enable us to introduce and measure immune-modulatory agents (including antibodies) and assess their effects on the immune system as well as tumour cells.

In experiments designed to develop new antibody drugs, mice will be injected with material to enable them to mount an immune response over a period of weeks, before the mice are euthanised and their B cells isolated to make hybridomas.

In experiments designed to measure effects on the immune system, mice will be injected with material (such as an antibody) and then the immune response measured by taking peripheral blood (much as we do for patients) and measuring changes in the immune cells (typically over a period of days to weeks). A proportion of mice will be euthanised and their tissues examined to understand how the immune response is developing in the different organs. These experiments are often done in the presence of a growing tumour, introduced earlier through injection, allowing us to assess infiltration of immune cells into the tumour after different treatments. A proportion of mice are then followed to measure tumour growth over time in experiments that may last 1-2 months, allowing us to determine if the treatments have cured the mice or delayed the tumour growth.

What are the expected impacts and/or adverse effects for the animals during your project?

We typically identify mice by ear notching - this is expected to result in only mild and transient pain with no healing problems.

Mice will be injected with various immunomodulatory substances using a combination of volumes, routes and frequencies. Injections will cause momentary needle stick pain minimised by using the needle of the smallest suitable gauge. The minimum number of

administrations and routes will always be used to achieve the scientific objectives. Typically, the animals will not receive more than 3-4 intraperitoneal (i.p.) injections a week or 2-3 intravenous (i.v.) injections a week. On some occasions they may receive 2 injections on a given day through a combination of different routes.

For some more invasive procedures, general anaesthesia will be used, to ensure the animals feel no pain.

For some experiments, mice will receive tumour cells through various routes; e.g. injected subcutaneously (under the skin) using a suitable vehicle. The tumours grow at this site and can be measured over time using digital calipers. Mice are euthanised at a size that is deemed to impact their normal behaviour, which may vary for different tumour models, based upon previous research.
Throughout, the health status of the animal is the primary consideration used to define humane endpoints. Experiments will be terminated, or individual mice euthanised at the earliest signs of tumour- associated symptoms such as piloerection (goose bumps making the fur stand up), restricted movement, abnormal posture, abnormal gait (movement when walking), hunching, and/or weight loss up to, but not reaching, 20% body weight.

In many of our experiments, designed to measure immune changes, peripheral blood is taken from a superficial vessel. Pain from bleeding is controlled by suitable anaesthesia/analgesic with rapid healing and no long-lasting harm. When the immune system is stimulated, for example with immunomodulatory antibodies, this can result in symptoms similar to those experienced during an infection (lethargy, fever etc.). This can result in mice becoming less mobile, exhibiting pilo-erection etc. Typically these symptoms are transient (first few hours) but can recur as the immune response develops (e.g. after several days) potentially resulting in further effects such as weight loss. These effects are therefore carefully monitored with mice euthanised if their symptoms become more severe or pass defined humane endpoints.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

During our current project licence the proportion of mice experiencing sub-threshold, mild, moderate or severe severities was as follows and we expect similar proportions in our new project licence:

sub-threshold 0.2%

mild 80.2%

moderate 19.6%
severe <0.1%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst all attempts are made to reduce the use of animals by using in vitro methods (in vitro experiments on various immune cells and explant studies using tissues grown outside of the body - see below), it is inevitable in work of this nature, involving the immune system that investigation in vivo (in an entire living organism) must be undertaken. The animal models proposed are critical to facilitate in vivo proof of concept and efficacy in an amenable and manipulable system, not possible in humans.

We are investigating the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro and so systemic in vivo studies remain fundamental to the study of new complex tumour microenvironments and therapeutics. Further, advances, such as the availability of genetically altered animals and the development of more specific and sensitive techniques and reagents, continually permit a refinement and reduction in the types of experiments and the numbers of animals that are required (e.g. as highlighted by the organization 'Fund for the Replacement of Animals in Medical Experiments', http://www.frame.org.uk) and this is something to which we remain committed. The increasing availability of genetically altered mice has allowed genetic dissection and more meaningful modelling of human disease.

Specifically, mice will be used for this study since they are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically 'identical', thereby reducing variability and allowing valid conclusions to be drawn from experimental data.

Numerous tumour models have been established in mice that are strain specific; although none fully capture every aspect of the human disease, models can be selected that allow specific questions to be addressed to facilitate translation.

Numerous strains of genetically altered mice have been developed, often replacing a mouse gene with its human counterpart, allowing us to study these interactions in vivo for the first time. For example, the human target of an antibody may replace the mouse counterpart, allowing antibodies directed against the human target to be tested. These experiments are simply not possible in humans and will enable us to validate and extend our findings in a 'human' setting and to help inform the generation of novel agents for use in patients.

Which non-animal alternatives did you consider for use in this project?

As a group, we have sought to increase our access to primary human material to reduce the requirement for animals wherever possible. We are now able to purchase lymphocyte "cones" from the local blood transfusion service and this enables us to perform

experiments using human peripheral blood lymphocytes. These cones are a natural by-product produced when people donate platelets, and contain many other immune cells of interest. We also have links with clinicians resulting in access to primary human tumours enabling us to investigate the effects of mAbs on human T cells infiltrating a tumour site in vitro. While we ultimately still need to use mice to study the influence of mAbs on a growing tumour and in a whole body system, better access to human material has enabled us to answer some clinically-relevant questions without the use of mice. It is difficult to accurately quantify the reductions in mouse numbers that this change has facilitated since the two experimental systems are not interchangeable but address distinct scientific questions. However, undoubtedly access to human material and the ethical clearance to address basic scientific questions enables us to replace animals in some circumstances.

In an attempt to help predict efficacy and toxicity of certain mAb we made use of the lymphocyte cones and have developed and adopted an in vitro assay using human cells as a replacement to mouse in vivo studies.

We are also evaluating in vitro protocols (phage display) to produce mAbs to our selected targets. This will reduce the number of animals used in the coming project licence, although these make up a very small proportion of the total animal usage.
Finally, we have also explored the use of organoid/ three-dimensional (3D) in vitro systems to study more tissue-relevant impacts of our immune interventions. Organoids and other 3D systems are typically small, self-organized 3D tissue cultures attempting to replicate the complexity of an organ/tissue, or to express selected aspects of it. Over a period of 6 years we were able to develop a 3D system to mimic certain aspects of a particular type of lymphoma microenvironment. Importantly, this model did not incorporate T cells, nor tumour-derived immune cells and so was unable to fully mimic the situation in lymphoma patients. It also represents a model of just a single type of lymphoma, with a similar amount of development required to produce equivalent models for other lymphoma sub-types and tumours. Therefore, as above we see these models as complementary to, rather than fully replacing the mouse models - with each addressing distinct scientific questions.

Why were they not suitable?

We are investigating the in vivo effects and interactions between various arms of the immune system, with a view to therapeutic application in humans. These interactions occur between different tissues and organs, and as such they cannot be fully reproduced in vitro. Each of the systems we have developed above, model different aspects of the immune response but none fully recapitulate the complexity and inter-relationships of a whole organism and so systemic in vivo models remain fundamental to our studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have a current project licence and have been monitoring annual usage. This new project licence (PPL) represents a reduction of almost 50% in comparison to our estimate from

our current PPL and takes into account our shift to use primary human tissues where possible as well as likely refinements over the coming years, alongside principal investigators within our research group holding their own project licences.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design is always considered in light of how the animal numbers can be reduced whilst ensuring meaningful and reproducible results. We are committed to reducing animal waste, implementing the three Rs, and maximising the reproducibility of research and so follow the PREPARE guidelines (https://norecopa.no/prepare) when considering our experiments.

As a first means to reduce the numbers of mice in our project, inbred mouse strains will be used to reduce variability of response and so allow reduced numbers sufficient to deliver reproducible data. Related to this, we routinely use age- and sex-matched mice that have been bred in the same facility (ideally litter matched where control and genetically altered mice are being compared) to minimise variability.

We have been using a range of tumour models for some time and so are well aware of the reproducibility of controls and appropriate mouse numbers required in tumour growth and therapy experiments. Where new models or treatments are introduced, we will first perform pilot studies to inform the design of larger studies, including dosing regimen, expected humane endpoint etc, as well as to monitor for any signs of adverse events. For example, 2 mice per group would be inoculated with a new tumour at different cell numbers to establish tumour growth kinetics etc. even where data exists in the literature as we are cognisant of the impacts of the local environment, microbiome etc. Similarly, a single mouse would first be treated with a new experimental treatment to judge safety, immune response etc, before proceeding to larger studies.

We are also cognisant of ensuring we minimise experimental bias. Accordingly, in experiments where we implement more subjective humane end points as part of a tumour therapy experiment (e.g. abdominal palpation as opposed to caliper measurements), an experienced and treatment-group blinded animal technician is consulted regarding outcome.

Where we have useful data (from historical or pilot experiments), power analyses will be used to help guide the optimal numbers of mice needed for each experiment, taking into account expected magnitudes of impact. Power analysis is performed using the PS: Power and Sample Size Calculation programme: www.biostat.mc.vanderbilt.edu/twiki/bin/view/Main/PowerSampleSize):

For immunotherapy experiments, where we are using inbred strains of mice, intra-group variability is reduced. From experience, we have found that we can use considerably fewer animals per group, usually 5, to detect such a difference at the 5% significance level in many of our models (e.g. EG7, MC38, B16-OVA and TC-1).

For monitoring immunological responses we typically use 5 mice per group for each experiment. From our experience, this number of mice/group allows us to identify with a statistical power of 95% a 3-fold difference in the number of CD8 T cells between 2 groups at the 5% significance level.

Therefore, the proposed mechanistic studies will be performed with experiments utilising groups of 5 mice, in a standard vehicle versus drug manner. We aim to test the candidate immune stimulators (identified by prior human and murine in vitro experiments) for efficacy in a selection of tumours.
Throughout, replicate experiments will be performed to ensure reproducibility and when appropriate studies may be combined to increase sample size. To assess differences in animal survival between groups appropriate statistical tests will be used (e.g. Kaplan Meier curves will be analysed by Log rank test).

Should substances or tumour models be used for the first time, pilot studies will be performed on individual mice and humane endpoints established as indicated above. Substances will be administered and monitored after 1, 4 and then 24h for adverse effects before proceeding; a dose escalation schedule conforming to accepted practice will be used should adverse effects be predicted. When agents are used for the first time in the laboratory, their dose will be based on previous published data whenever possible.

When new tumour lines are introduced they have to go through quarantine to ensure safe introduction into the animal facility. As an additional measure of reduction, we use this period to also monitor growth and humane endpoints reducing the need for additional animal use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mice used across experiments are inbred thereby minimising intra-group variability and allowing reduced mouse numbers for experiments. We also wherever possible when breeding Genetically altered strains will use their non Genetically altered (e,g, transgene negative) littermate controls when available. Experiments are always designed with the fewest animals consistent with obtaining statistically valid results. We have performed Power analysis to determine the numbers of mice required to deliver statistically significant results, although through experience we find we can often use smaller numbers of animals without sacrificing statistical significance as they are inbred strains. Where appropriate, small pilot experiments are carried out to determine factors such as dose or route of administration.

Where multiple inter-relating parameters are to be evaluated, to prevent use of excess mice, we will employ higher dimensional analysis tools. Significant technological advances have enabled more information to be obtained from one individual mouse than was previously possible (e.g. using multi- parameter flow cytometry and RNA-seq technology), enabling multiple parameters to be assessed simultaneously from small samples. These technologies thereby facilitate longitudinal studies (repeated observations of the same variables over time) and reduce the need to cull multiple mice at different time points to sample from the spleen for instance. For example, we are moving from 3 colour flow cytometry to 8 and more colour flow cytometry, reducing the sample input requirements accordingly.

Since the start of our current PPL, we have instigated a policy that new in vivo experiments must be detailed on a ‘study-plan’ detailing: the aims, number and strain of mice, substances/cells administered, treatment dates, confirmation of required competencies and/or delegation of procedures, any known or anticipated adverse effects, and appropriate risk assessments. This has to be submitted to myself and the Named Animal Care & Welfare Officer (NACWO; person who is responsible for checking the

welfare of the animals) before an experiment is allowed to begin. An example of this document is shown below:

This form must be filled in and sent to the PPL holder and NACWO before the start of the experiment. Once reviewed by PPLh and NACWO this form will be considered by BRF Management Group.

This has facilitated a more detailed dialogue between PPL holder (PPLh) and personal licence holder (PILh) prior to work and if necessary a discussion about the number of mice being used. More recently this process has included approval by representatives of the Animal Welfare Ethical Review Body (AWERB) committee. This serves to ensure animal numbers are optimised.

Other optimisations to reduce animal use include:

Tumour cells being stored frozen when possible to prevent mice being used to passage tumour in vivo.

Consideration of freezing additional animal tissues (whole and as single cell suspensions) when an animal is sacrificed to provide controls for staining in different immune situations, relieving the need to cull specific mice for this comparative purpose.

Similarly, harvesting blood (for serum production), spleens for lymphocytes and bone marrow (to generate macrophages) when appropriate mice are culled for other purposes.

The in vitro use of immune cells isolated from mouse tissues offers several benefits and aids in optimising number of animals used for in vivo experiments. Importantly, this strategy is in line with the 3Rs. Due to the relatively low numbers of cells required to perform in vitro assays, such experimental approaches allow the screening of a high number of drugs or combination thereof, with potential for in vivo activity, while minimising the number of animals required. Furthermore, they allow refining doses, and identifying potential mechanisms of action and adverse reactions, prior to in vivo testing. In addition, in vitro assays using mouse immune cells represent a powerful reductionist approach to study their activation. They allow the isolation and analysis of distinct cell subsets, and the direct assessment of drugs on each individual cell population, otherwise difficult to accomplish.

Furthermore, having identified that the hIgG2 isotype is especially powerful for driving immune- stimulation in vivo, we are now following up on the molecular basis behind these findings with colleagues in Biology and Chemistry, using molecular simulations and other in silico approaches (reducing the need for animal experiments). We plan to develop prediction tools to guide our studies, further reducing the numbers of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rodents for these studies as they are the most appropriate species of mammal that have the following characteristics:

The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals;

Individual mice within a given inbred strain are considered genetically ‘identical’, thereby reducing variability and allowing valid conclusions to be drawn from experimental data with as few animals as possible.

Numerous tumour models have been established in mice that are strain specific;

Numerous strains of genetically altered mice have been developed such as those expressing tumour antigens or human receptors (part of the cell which binds to a substance) of interest (human CD20, human OX40 etc.) and mice with genes of interest removed or added in order to elucidate immune mechanisms e.g. mice in which a mouse Fc gamma Receptor (FcgR) has been replaced with its human counterpart. If required we will source new human knock-in (KI) mice to enable us to validate our findings in a ‘human’ setting and to help generate novel agents for use in patients as we have done.

When evaluating immunomodulatory and immunotherapeutic approaches, we begin with in vitro evaluation and progress to pre-clinical animal models when sufficient promise is obtained. Our in vitro studies may include assays to determine the ability of reagents to kill or affect the growth or survival of target cells, and to recruit immune effector mechanisms. Where appropriate, we will first establish effects on in vitro cell lines and ex vivo primary material. However, in vitro lines and primary cells become adapted to cell culture conditions and are not present in a complex multicellular tissue/organ and therefore do not best recapitulate in vivo responses, hence the need for animal experiments.

In order to understand the mechanisms operating, cells may be obtained from unmodified, wild type (WT) or genetically altered animals with deficient/altered immune effector systems e.g. FcgR or complement knock-out, mice deficient in key effector molecules. For

those reagents that show promise in vitro, we will determine if this translates into an in vivo effect using the most appropriate models. Typically, we would first examine reagents in the absence of tumour, to assess immunomodulation, without unnecessarily increasing the harm to animals by adding to the cumulative harm from further interventions and/or activities of the tumour. We ensure humane end-points are established that minimise the harm to the animal without compromising the veracity of the experimental data.

Why can't you use animals that are less sentient?

Our work largely involves study of the immune system, which is a multi-faceted, interacting system that is spread throughout the body and organs, linked by the vasculature. The cellular and molecular interactions of the rodent immune system are broadly similar to those of humans, allowing us to investigate clinically relevant immunotherapeutic strategies and mechanisms in these animals - less sentient species have very different immune systems (e.g. zebrafish lack adaptive immunity). More immature animals also do not display mature immune systems (the immune system becomes educated with age and development) that we seek to investigate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continually review our procedures and if unnecessary harms are identified or can be reduced, modified protocols are implemented through discussion with the NACWOs, PPL holder, academic lead for the BRF and named vet surgeon (NVS) as required. We also seek to ensure the best housing and conditions for the animals are provided.

As examples, of our commitment to these aspirations over the last 4 years we have:

Moved to a new purpose-built animal facility. This unit is more conducive to high quality in vivo research utilising a 'barrier' system meaning that all materials coming into the unit are clean and enter via a dedicated positive-pressure pass-through hatch. All personnel entering must now change into scrubs, and pass through an air-shower on entering (and leaving). The new facility also houses a separate quarantine facility that is no longer inside the main unit, but attached and accessible separately, with dedicated technicians only permitted.

All new strains of mice entering quarantine undergo rederivation before offspring are allowed in the main unit. All new cell lines have to be screened in mice in the quarantine room, and serum from sentinels assessed for the presence of pathogens before cells are allowed to enter the main unit. All mice are now housed in individually ventilated cages (IVCs). These changes minimise the risk of infection with obvious potential implications for the welfare of the animals and the quality of the research. In addition, the IVCs permit less disturbance to the animals as an additional refinement.

We have also implemented a number of new policies to improve welfare and reduce adverse experiences. All mice undergoing an injection now undergo a 'second check' by the person performing that procedure, within 30 mins-4 hours. This was instigated to prevent animal welfare impact should an unanticipated adverse event occur. If a procedure is delegated to a technician, this second check also incorporates a 'positive handover' between the technician and the PILh to transfer the responsibility for the mice back to the PILh to ensure it is always clear where responsibility for welfare ultimately lies.

In response to changing guidelines a number of further and specific refinements have been put in place. These include:

that CO2 entering a chamber during schedule 1 culling, enters from the top rather than from the bottom in line with current best practice. Flow rate is 20% of chamber volume/min. 3 min dwell time, where the CO2 is stopped but the chamber remains untouched so they remain in maximum CO2. Nb: the machine is serviced annually to check that it is still within parameters and we check that there is adequate CO2 pressure before starting and stay in the room during the CO2 delivery.

that mice are handled by 'cupping' or by gently moving them using a dedicated tunnel, prior to any restraint to ensure mice are calm and habituated to the person performing injections, serving to reduce anxiety when handling mice.

a policy that needles are only to be used once. This is to prevent mice receiving an injection with a blunted needle. Initially during the early part of my current project licence (PPL), the refinement was to be used less than 5 times but last year we implemented a new single use policy unless specific justification is provided that is approved by the BRF management committee.

we have now transitioned towards venesection (tail pricking) to take blood samples instead of tail tipping. While this is not always possible (for instance when mice are receiving concurrent i.v. injections) new PILh are now trained in venesection and established PILh who regularly bleed mice have undergone re-training.

During the course of this PPL, we instigated a policy that new in vivo experiments must be detailed on a 'study-plan' that encompass the experimental aims and how they address the PPL objectives, number and strain of mice, substances/cells administered, treatment dates, confirmation of required competencies and/or delegation of procedures, any known or anticipated adverse effects, welfare measures and monitoring employed and appropriate risk assessments (see study-plan template in Reductions above). This study-plan has to be submitted to the PPL and then responsible NACWO for approvals prior to experiment commencement. This has ensured that there is evidence of an appropriately detailed dialogue between PPLh and PILh prior to work and as necessary enabled a discussion about the number of mice used and procedures administered.

We also have a new system that records training competencies for individual PILh to ensure that training on all procedures is renewed every 3 years. Training is conducted by dedicated trainers using Directly Observed Practical (DOP) skills forms written specifically for this purpose. As PPLh I have access to these records, and reference is made to them on the 'study plan' (see above) ensuring that PILh also review their records regularly.

An additional refinement implemented has been to modify the humane endpoint for our CT26 tumour experiments; reducing the tumour size from 400mm2 to 300mm2 for most experiments; this allows us to obtain sufficient scientific information whilst reducing the risk of tumours impairing the welfare of the animal such as through impaired movement. When possible, genotyping protocols for new transgenic (Tg) mice have been refined to allow PCR only protocols for screening, reducing the need to bleed mice prior to experimentation. Moreover, some existing transgenic strains (e.g. human CD20 transgenic) that were previously screened via blood are now done so by polymerase chain reaction (PCR; a technique for amplifying genetic material useful in transgenes) from ear notches reducing the number of procedures the mice undergo.

We have also adopted the practice of transferring male mouse nesting material, not substrate, to minimise male mouse aggression (the nest has calming pheromones in it, but the sawdust aggravates aggression as it holds the testosterone).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are a number of detailed publications and guidelines for the welfare and use of animals in cancer research on cancer models that provide excellent guidance in the methodologies, study design and best practice that we will follow and adapt as appropriate to our research (Guidelines for the welfare and use of animals in cancer research Workman, P., Aboagye, E., Balkwill, F. et al. Guidelines for the welfare and use of animals in cancer research. Br J Cancer 102, 1555–1577 (2010). https://doi.org/10.1038/sj.bjc.6605642).

We will follow the ARRIVE guidelines https://arriveguidelines.org/ which provide a checklist of the minimum information required to be reported by groups using animals in research. ARRIVE guidelines are essential to help overcome issues in science such as reproducibility, reducing bias and the correct use of statistical methods of analysis.

In addition, we will follow and consult NORECOPA https://norecopa.no/3r-guide: Norway's National Consensus Platform for the advancement of the 3Rs (Replacement, Reduction and Refinement associated with animal experiments) database platform and PREPARE https://norecopa.no/prepare (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for better science experiments using animals to ensure that we are using the best models for our research.

Finally, regular communication within our research group and communication with our peers at seminars and conferences ensures we're aware of any new or updated best practice. Best practice information is also disseminated by our Named Information Officer.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have a very active Biomedical research facility (BRF) users group, meeting approx 3 times per year to discuss issues that arise within the animal facility. These are attended by the PILh, PPLh, NACWO, Home Office Liaison Contact (HOLC) and establishment licence holder. Any issues and incidents that PILh need to be aware of are discussed at this meeting. Further to this, this platform is used to disseminate information from Animals in Science Regulation Unit (ASRU), National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and other organisations and to provide details of training opportunities to enhance welfare and research practice. We have also embarked upon a strategy of ensuring that PPLh and PILh undergo regular refresher training at least every 3 years to ensure that they remain abreast of changes to best practices and aware of their responsibilities under the Animals (Scientific Procedures) Act 1986 (ASPA). These advances are further communicated through our active team of NACWOs and regular email updates. We will also stay up to date with specific cancer groups, databases and alternatives (NC3Rs) for cancer models such as https://resources.researchanimaltraining.com/faqs/breast-cancer-research-alternatives-database; https://data.jrc.ec.europa.eu/dataset/352f7dfd-05cf-434b-a96a-7e270dc76573.

170. Development, breeding, maintenance, and validation of genetically altered rodents

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Genetically Altered Animal, Knockout Transgenic, Knockin Transgenic, Genome Manipulation, Embryo Transfer

Animal types	Life stages
Mice	adult, pregnant, juvenile, embryo, neonate, aged
Rats	juvenile, adult, pregnant, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is two-fold:

- to create, breed, validate and maintain colonies of rodents with genetic modifications (changes to their genes)
- use cryopreservation (controlled freezing) techniques to archive and preserve the integrity of the genetically modified rodents for future use.

The intention is to supply research teams within the company or external collaborative research establishments, with genetically altered animal (GAA) models that are relevant to the human disease condition to support research into developing understanding of disease and treatments for patients.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

GAA models are vital to further the understanding of how genes work in human health and disease (Chenouard V *et al* 2021). The ability to alter genes within a living organism is a powerful tool to directly investigate the importance of a gene and / or it's protein products in specific biological/biochemical pathways and further the understanding of its function in disease states. Characterisation (in depth study) of such genetically altered (GA) rodents may lead to the development of new animal disease models displaying some or similar characteristics to those seen in human disease conditions. These new animal models may then be used to improve the understanding of the origins of human disease and in the development and evaluation of potential new medicines which may ultimately result in a cure or treatment to the disease condition in humans.

It is important for the company to leverage GAA technology to:

- generate rodent models to discover the function of genes (and/or their protein products) in the underlying biology associated with various human disease states
- establish translational (human disease-relevant) models for pre-clinical research that better reflect the human disease condition
- provide an essential resource for understanding disease mechanisms & biomarkers, improving diagnostic strategies and for testing therapeutic interventions
- support the company's emerging focus on using genetic & genomic technologies to identify and prosecute novel targets to develop next generation medicines

What outputs do you think you will see at the end of this project?

- Creation, re-derivation, validation, breeding and supply of novel, and existing GA rodent strains for scientific advancement
- A well validated, robust and reliable platform for generating high quality genetically altered rodents, through continual refinement of both genetic manipulation techniques and in vivo procedures
- Preservation of genetically altered lines of animals for future use, through established cryopreservation (controlled freezing) techniques reducing animal usage and avoiding extended breeding programs
- Publications or the sharing of new information subject to intellectual property restrictions

Who or what will benefit from these outputs, and how?

Genetically altered rodents have made significant contributions to human biological and medical research through supporting the development and testing of novel therapies, treatments and cures for diseases and disorders. GA models produced under the previous

project licence had an impact across a number of disease areas (including:- Neuroscience, cardiovascular, immunological, respiratory and oncology). For some examples see:

- Lomas DA et al; Development of a small molecule that corrects misfolding and increases secretion of Z α1-antitrypsin. EMBO Mol Med (2021)

- Vantourout J C et al; In Vivo Half-Life Extension of BMP1/TLL Metalloproteinase Inhibitors Using Small-Molecule Human Serum Albumin Binders. Bioconjugate Chem. 2021, 32, 2, 279–289.

Benefits from the output of this project licence are expected to be:

In the short to medium term, scientific projects will benefit from the use of specifically requested GA rodents (through this project licence) to enable scientific studies, generate meaningful data and push projects forward towards the generation of novel therapeutics.

An additional medium term key benefit will be delivered through assisting other project licensees in meeting their objectives (discovery and development of new medicines) with supply of scientifically validated GA models, delivering the most appropriate animals for the task.

Ultimately, in the long term, the aim is that patients suffering from disease and disabilities will benefit from any new therapies, cures and treatments that may be attained through supporting data generated from GA rodents provided under this project licence.

How will you look to maximise the outputs of this work?

Data generated by research teams using GA rodents provided under this project licence are expected to be included in scientific publications as part of the process of investigating and validating new disease targets and new treatments for disease. Additionally, where work is considered to be 'pre- competitive' (e.g. method development), whereby it does not contain information that is subject to intellectual property constraints, it will be published as appropriate. The company also supports the view that publication of unsuccessful approaches ('negative data') is a valuable scientific output from properly conducted research, and these types of data would not be excluded from a publication strategy. Where possible, GAA models will be shared with academic institutes to directly support scientific research and potentially reduce overall animal usage.

Information generated using this licence is stored in a searchable, secure company database, so that it is always accessible to other internal company researchers. Therefore, data will be accessible in the future, even after likely project and personnel changes, and the information will be a valuable future resource when looking to reproduce or regenerate certain GA rodent lines.

As part of the GA rodent platform strategy outlined in this project licence, we will look to collaborate with both internal and external partners that are experts in the fields of bioinformatics, designing genome editing tools and GA model characterisation. This will allow generation of reagents, genetic characterisation and genotyping to be done externally in most cases, freeing up resource internally that can be used elsewhere on this platform.

Species and numbers of animals expected to be used

- Mice: 40000
- Rats: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents, especially mice are an ideal species for use when creating genetically altered models for research purposes due to their ability to be robustly genetically manipulated and their similarities with humans in term of physiology and genome (the complete set of genes present in an organism).The technology employed to generate genetically altered mice is well-developed, and such animals are widely used across the medical, academic and scientific research communities. The multitude of successful genetically altered models available proves they are a suitable and robust species for gene manipulation. Additionally, there is the advantage of having a fast reproductive cycle lending itself to the high throughput nature of research and to generating and managing breeding colonies to support this. All life stages will be used throughout protocol 3 on this project licence as the nature of breeding and maintaining colonies of genetically altered mice affects the full life cycle. Juvenile, young adult and, on occasion, adult animals (up to 1 year of age) will be used throughout protocols 1 and 2 of this project licence as creation of GA rodents requires the harvest of oocytes from, or implantation of embryos into,
females with sexually mature reproductive systems in order to bring pups to term and raise them until weaning. Aged animals (up to 24 months of age) will be used on protocol 4 of this project licence as using older animals is essential for the development of certain types of model looking into diseases related to natural aging, for example age-related neurodegeneration.

Typically, what will be done to an animal used in your project?

Typically animals on this project licence will remain on the same protocol for the duration of their use unless being transferred to protocol 1 (for superovulation), protocol 2 (wild type females only for embryo transfer), protocol 4 (if aged animals are required) or authority of another project licence for scientific use. See below for what will typically be done to an animal on each protocol.

Protocol 1 - Superovulation

(a) Administration of agents (such as hormones) by intra-peritoneal or subcutaneous injection (typically 2) to increase the yield, and stimulate the release of, premature egg cells (superovulation). If early stage embryos are needed these animals may also be mated following superovulation.

(b) Humanely killed following successful mating, and egg cells / embryos harvested post mortem for cryopreservation, in vitro fertilisation or subsequent implantation into recipient females (performed under protocol 2). The animals themselves will not progress on to any other protocols.

(c) Superovulated female mice that have not successfully mated, may be used for natural mating if required

Protocol 2 - Embryo Transfer

- Wild type (non-genetically altered) female mice will be rendered pseudopregnant (false pregnancy) by mating with a sterile male, these females are referred to as recipients.

- Surgery will be performed to transfer early stage embryos (generated by either superovulation (protocol 1), in vitro fertilisation, revival of cryopreserved embryos or natural mating) into the reproductive tract of recipient pseudo-pregnant females.

- Surgery will be done under general anaesthesia, sections of the reproductive tract will be exposed for embryo delivery. Incisions will be stapled / sutured and the animals allowed to recover.

- Pre and post-surgery, recipient females will receive analgesics (pain relief) and may receive antibiotics as agreed in advance with the named veterinary surgeon (NVS), usually when the animal is under general anaesthesia to minimise discomfort.

- Where appropriate (i.e. where later stage embryos (blastocysts) can be used), the embryo transfer will be carried out using non-surgical methods, and in such cases the pseudopregnant female mouse may be immobilised using brief anaesthesia. The expectant mothers will be bought to term (typically 21 days post-surgery) with the offspring produced being authorised by protocol 3 from two thirds of the way through gestation. After weaning of offspring (typically at 21 days of age), dams will be humanely killed and will not progress on to any other protocols.

Protocol 3 - Breeding, maintenance and validation of genetically altered animals (mild)

- Animals born through protocol 2 procedures will be ear notched at typically 2-4 weeks of age for identification purposes. The tissue removed during the identification process may also be used to genotype (genetically identify) the animals.

- If further information is needed to characterise the genetic modification (e.g. to determine gene expression levels, impact on biomarkers, changes in clinical pathology or histopathology) then animals may have a blood sample taken from a superficial vessel (typically once) for this purpose. If larger blood volumes are required or alternative tissues / methods for collection are needed for genetic modification characterisation purposes and where Schedule 1 methods have the potential to compromise the samples (e.g. blood clotting, contaminated cerebrospinal fluid, damaged or compromised tissue); these will be obtained as part of a terminal procedure under non-recovery anaesthesia.

- Typically, once genotyped, animals will be:

    - used for breeding to maintain the colony
    - or kept alive and used as sentinels (only wild type animals that have undergone no regulated procedures) within our animal facility (to reduce the need to order in extra animals for this purpose)
    - or transferred to protocol 1 (female mice only), protocol 2 (female WT mice only) or protocol 4 of this project licence
    - or transferred to another project licence within the company or externally to a collaborator for further scientific study

- At the end of use on this protocol animals will be humanely killed

Protocol 4 - Maintenance and validation of genetically altered animals up to 24 months of age (moderate)

- Any GA rodents (and their wild type counterparts), that are required to be aged up to 24 months of age will be transferred to protocol 4; and may be transferred to protocol 4 from weaning. In most cases animals moved on to protocol 4 would have already been genotyped and genetically characterised, if not this will be done on protocol 4. Typically animals will have the same experience as those on protocol 3 above. Aged animals will not be used for mating and will not be kept alive and used as sentinels.

What are the expected impacts and/or adverse effects for the animals during your project?

Protocol 1 - Superovulation

- The superovulation procedures are expected to result in no more than transient discomfort, as a result of the physical insertion of a needle either intra-peritoneally or subcutaneously.

Protocol 2 - Embryo Transfer Surgery

- Animals may experience discomfort moving around for up to 24 hours post-surgery, but a comprehensive peri-operative pain management regimen will be in place to keep pain and suffering to a minimum.

- Animals are expected to display abnormal behaviour immediately following surgery as a result of the anaesthetic (e.g. subdued, "wobbly" gait, lack of appetite). These effects will be transient, lasting no more than 60 mins following surgery as the anaesthetic wears off. Animals are expected to make a rapid and unremarkable recovery from the anaesthetic within 2 hours.

- Less than 5% of animals may show local effects such as skin inflammation, infection or wound breakdown.

Protocol 3 - Breeding, maintenance and validation of genetically altered animals (mild)

- Ear notching (removal of a small amount of tissue (1-2mm) from the ear) may cause very mild transient localised discomfort

- Removal of blood from a superficial vessel may cause mild transient localised pain.
- Incidence of adverse effects are expected to be low, occurrences of pregnancy complications are monitored and if above background frequency for a particular strain, will be investigated with the NVS, project licence holder and named animal and welfare officer (NACWO).

Protocol 4 - Maintenance and validation of genetically altered animals up to 2 years of age (moderate)

- Ear notching (removal of a small amount of tissue (1-2mm) from the ear) may cause

very mild transient localised pain but unlikely in most cases.

- Removal of blood from a superficial vessel may cause mild transient localised pain.

- Age-related adverse effects may be seen in line with genetic background, including but not limited to, skin conditions, abnormal activity, weight fluctuations, eye complications and tumours.

- Some GA strains may have the potential to develop a harmful phenotype after a certain age in addition to the normal age-related adverse effects expected in line with their genetic background. In such cases if a harmful phenotype is expected for a particular GA strain, prior to these animals being granted authority on this licence, protocol 4 will be amended to include a list of the additional likely adverse effects, refinement controls and humane endpoints keeping impact on animal welfare to a minimum. In all cases animals will be killed before reaching that age and before the onset of clinical signs, unless such clinical signs are inseparable from the process of maintaining animals to a required age (up to 24 months) for scientific study, or unless animals are moved on to another project licence for a specific purpose (continued use).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1 - The expected severity is mild and 100% of animals are expected to experience this

Protocol 2 - The expected severity for animals undergoing surgery (majority of animals on this protocol) is moderate and 100% of these animals are expected to experience up to this severity. The expected severity of animals undergoing non-surgical embryo transfer (this technique will not typically be used, unless embryo stage required is compatible with technique, so will only be a minority of animals on this protocol) is mild and 100% of these animals are expected to experience up to this severity.

Protocol 3 - The severity classification of this protocol is mild, however the majority of animals (~80%) on this protocol are expected to to experience a severity of no more than sub threshold

Protocol 4 - The severity classification of the protocol is moderate, however the majority (>90%) of animals on this protocol are expected to experience no more than mild severity

What will happen to animals at the end of this project?

- Killed
- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A wide range of information from in silico (computer modelling) or isolated cell systems is available to increase our understanding of how potential targets for medicine may function or how they can be affected by treatment. However, due to the need to understand how different cell types and physiological processes work together and affect each other to influence biological mechanisms, relevant data cannot always be generated using such isolated cells in artificial plastic (in vitro) setups. As such, investigating diseases of complex systems such as the cardiovascular, respiratory, immune, gastrointestinal and central nervous systems, require the use of whole functioning tissue that can be found within living animals.
Understanding the response of a potential treatment in a whole animal with a physiology that is common with humans (enabling scientists to take into account complexities such as how the potential medicine is distributed and metabolised throughout the body) is vital to guide progression of such potential medicines to human clinical trials.

For these reasons it is necessary that genetically altered animals are produced, validated & maintained under this licence and made available to researchers so that specific traits (characteristics) of certain genes implicated in disease can be studied in complex living systems. Many of the effects of genetic changes and biological processes under investigation involve complex pathways that cannot be replicated outside living animals (ex-vivo).

The GA rodents created, validated & maintained under this project licence will support research efforts across a multitude of disease areas some of which require intact behavioural responses that only a conscious living animal can provide. Non-animal methods are not always able to model or replicate the complete array of behavioural responses or indeed the cellular, molecular and physiological interactions required to fully understand how genetic alterations result in normal (healthy) or abnormal (diseased) processes.

Which non-animal alternatives did you consider for use in this project?

Project teams requesting new GA models under this licence will work with an independent scientific review committee to understand the feasibility of using animal alternatives prior to reaching any conclusion to progress with in vivo work. This will be discussed with the project licence holder and often such discussions will involve, alternatives such as the use of organoid preparations & organ-on- chip technologies, ex-vivo and in vitro tissue and cell culture platforms and human cell-based assays. If any of these can address the same decision making scientific end points that the requesting project team requires from a genetically altered rodent model, then these will be pursued as alternatives. Any viable non-animal alternative options discovered may be used as examples to challenge requests coming in to this project licence from other research teams.

Why were they not suitable?

Often the inability to robustly generate data in a non-animal environment will be the main factor in a research team pursuing the development of a GAA rodent model. Specific issues often arise in that cellular or tissue based platform technologies have a limited number of cellular interactions and do not provide the full level of complexity and integration available within a living animal i.e. the inter- connected body-wide systems where cells and organs continuously communicate. Additionally these platforms are not

yet adequately able to model potential drug distribution and elimination from the body which results from a compound passing through organs such as liver and kidneys. As such, these technologies (while continuing to play a vitally important and complimentary role to animal experiments) are not yet fully developed and characterised to a stage where we can have confidence in all applications of the clinical relevance of data generated from using them. They do not adequately model the complete array of molecular, cellular, physiological and behavioural interactions necessary to fully understand how genetic modifications result in normal or abnormal processes. Under circumstances such as these, the animal model is critical and decision making in progressing therapeutics towards the clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animals to be used is based upon the numbers of animals used across previous GAA-focused licence authorities previously held within the company. These numbers take into account historical requests for GA rodent models over the last five years as well as current and future internal demands for such models. There is an anticipated steady rate of projects likely to require information provided through GA rodent models that cannot be gained from non-animal alternatives. Also considered in these estimates is the creation of novel GA rodent models, and the likely demand thereof, something not performed under the previous GAA project licence, and likely something that is to be used throughout the lifespan of this project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure the unnecessary production of GA rodents is avoided, available databases will be searched to identify existing models that could be obtained. Examples of resources available include:

- NC3Rs mouse database: http://www.nc3rs.org.uk/
- Mouse Genome Informatics: http://www.informatics.jax.org/ PubMed: http://www.ncbi.nlm.nih.gov/
- Jackson laboratory: http://jaxmice.jax.org/index.html

Animal numbers for experiments are assessed by sex, age, genotype, phenotypic traits (physical characteristics) and statistical relevance to the experimental needs and these are all considered prior to onset of the breeding programme to produce animals for study. Animals will only be bred to deliver an investigators requirement that has been established using robust statistical methods.

This licence will adopt the most efficient methods for genetically manipulating harvested embryos (such as electroporation) and in combination with more refined superovulation techniques (being investigated to increase the number of eggs produced per female) will

translate through to a decrease in the number of donor females used as greater yields of higher quality, viable embryos will be generated from each female.

When creating GA mice in house, data will be captured from each transfection session, taking into account starting numbers of embryos and tracking this to numbers of viable embryos for implantation, through to live pups born following embryo transfer. This will allow us to optimise the number of embryos to transfer to each recipient female and ultimately optimise the number of pseudopregnant females we need to reach the required number of GA founder offspring.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Good colony management and regular communication with requestors are key to minimising wastage within the breeding facility. To ensure these colonies are breeding efficiently we monitor breeding performance related to the expected background strain information and Mendelian ratio (the likely occurrence of differing genotypes (genetic variants)) anticipated from the genetic modification under study. Careful breeding programmes will be put in place to maintain the minimum numbers of animals in order to deliver the animals of relevant genotype. These breeding plans are subject to regular review by the project licence holder, responsible technician and technology manager to optimally meet anticipated demand. Wild type animals bred unavoidably as a consequence of a GA breeding programme, that have had no regulated procedure performed on them, will be made available for use on other scientific projects within the company (e.g. tissue donation, sentinels for health monitoring).

This licence provides a cryopreservation service (preserving biological cells/tissues/organs by cooling to very low temperatures) of genetically altered lines of animals for research partners, allowing the long-term storage of important lines that are not required at that moment but may be in the future. Additionally lines are monitored for usage and routinely cryopreserved to ensure they are only active when studies have been assigned to them. This enables there to be a reduction of animals that are maintained in breeding colonies within animal facilities. Where possible sperm cryopreservation will be used as this significantly reduces the number of animals required to freeze down sufficient stocks (compared to cryopreserving from females). Embryos will be cryopreserved if there is a need to preserve the genomes of both parents (for example an inbred line or strain on a complex background).

The background genetic strain used for generating a new model will be carefully considered to avoid producing unwanted mice or impacting the scientific output of the study they are being supplied for. Scientific techniques (e.g. single-nucleotide polymorphism analysis) will be employed where needed to confirm genetic background makeup and reduce the number of breeds required to to transfer an introduced genetic modification from one background strain to another (e.g. Balb/c to C57BL/6J genetic backgrounds). Additionally animal numbers will be optimised by effective liaison and rigorous review with project teams to ensure strains of the most appropriate desired specification are always used (the best model for the disease area).

Numbers are also optimised where several research programmes may use the same animal model (or indeed tissues from the same animal) and where required external collaborators also.

Newer superovulation methods (developed by the Division of Reproductive Engineering in the Centre for Animal Resources and Development at Kumamoto University) employ the use of goat inhibin antiserum in the so call "hyperovulation" process to increase the yield of eggs from a single female compared to standard superovulation. The advantages of this will be a potential reduction in the number of donor females used, as more eggs / embryos can be obtained from fewer animals. When implementing new techniques in this area, the quality of the eggs produced and the success rate of pregnancy and live pup birth rate will be carefully monitored before completely adopting new methods of superovulation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The methods that will be employed in this project licence are as follows:

Superovulation techniques - Hormones are administered to WT or GA females typically by two intra-peritoneal or sub-cutaneous injections, given at a time & dose driven by the characteristics of the background rodent strain of choice. This is the least invasive and most effective way of encouraging females to ovulate and copulate while increasing yields of oocytes or embryos compared to what would normally be obtained through natural oestrus or mating. Mice that have undergone this procedure will be killed by a schedule 1 method prior to harvest of oocytes or embryos. There is a wealth of data from past internal project licences using this technique that indicates no adverse effects, in addition to the mild discomfort caused by the injections, result from this superovulation regimen.

Induction of pseudopregnancy - Recipient females of the donated embryos, will be induced into a pseudopregnant state through mating with a sterile male prior to embryo transfer. There is a very low risk of injury to the females caused by rough treatment from males. Fighting/injuries will be reduced by ensuring, where possible, that females are in oestrus, and by replacing over vigorous males. Other methods for inducing pseudopregnancy such as repeated stimulation of the cervico-vaginal region with probes or swabs, or administration of substances intra-peritoneally, sub-cutaneously and /or into the vagina do exist. However these methods involve levels of restraint or mild pain from injections, and compared to natural mating with sterile males (held under protocol 3 of this licence), are less efficient, more invasive and more stressful to the female.

Surgical embryo transfer - The most well established and robust method for transferring embryos to recipient females is through direct surgical implantation to the reproductive tract under recovery anaesthesia. The surgical methods employed in this licence will be minimally impactful as there is a large amount of expertise available in performing these surgeries making them as short in duration as possible. Additionally the methods employed will keep pain, suffering, distress and lasting harm to a minimum through use of carefully considered analgesic and anaesthetic regimens as well as optimised recovery and post op monitoring processes.

Non Surgical embryo transfer - Where later stage embryos for implantation can be used (e.g. blastocyst stage), non-surgical embryo transfer techniques will be employed. This technique involves the use of a trans cervical pipette (a device that is inserted through the cervix to expel embryos into the uterus) and has advantages over surgical embryo transfer methods in that no invasive surgical procedures are needed and thus has a lower severity. This technique may use brief general anaesthesia for restraint.

The use of genetically sterile males- Genetically sterile male mice (e.g. Protamine 1 (PRM-1) KO mice) held on protocol 3 of this project licence, will be used to render recipient mothers pseudopregnant prior to undergoing embryo transfer. This method surpasses the previous method of using vasectomised males, as the animals are born sterile and therefore will not have to undergo general anaesthesia and invasive surgical procedures to render them sterile.

Non-aversive handling techniques - the use of cupping and / or tunnel handling techniques to retrieve animals will be encouraged and employed where possible as these methods have been shown to be less aversive to the animals compared to e.g. handling by the base of the tail. The use of non-restrictive restrainers will also be used where possible to minimise stress and discomfort for the animals.

The methods used for this programme of work have been chosen and where necessary, will be developed further to represent the least severe and most effective and robust ways of producing GA rodent models.

Why can’t you use animals that are less sentient?

The end users of this licence (those researchers and project teams that are requesting GA rodent models) require gene modifications to be made in species that have fully-functioning, biological mammalian systems that are comparable to humans (e.g. cardiovascular, respiratory, immune, gastrointestinal and central nervous systems). Rodents, such as mice, are the least sentient and most feasible to use species that offer such comparisons to humans. This allows researchers to determine the effects of specific genetic manipulations, in the presence and absence of potential medicines, and the complex interactions these have with relevant physiological, fully-functioning mammalian systems.

It is not feasible to use more immature life stages as creation of GA rodents requires the implantation of embryos into females with mature reproductive systems in order to bring pups to term and raise them until weaning.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Embryo Transfer Surgery - Working closely with experts including the NACWO and NVS, the embryo transfer surgery technique will be refined through optimising various aspects of the procedure. For example, this may be through, but not limited to, adopting increased post op monitoring, core body temperature monitoring throughout procedure, alternative wound closure techniques, enhanced anaesthesia setup (to improve ergonomics and incorporate the use of face masks when clipping fur) and administration of additional perioperative analgesia.

Non-surgical Embryo Transfer Surgery (NSET) - The embryo transfer technique (performed solely under protocol 2) is via a surgical laparotomy method, and only applicable to a small number of animals used on this licence (pseudopregnant embryo recipient females). This is due to the need to use early (1 to 2-cell stage) embryos for in vitro fertilisation (IVF) or genetic manipulation using electroporation. In order to maintain viability, these early stage embryos need to be transplanted into recipient female oviducts with minimal in vitro culture, this is only possible via a surgical procedure for this stage of embryo. NSET involves implanting embryos further down the reproductive tract into the uterine horn, entering through the vagina using a trans cervical pipette. Therefore, only later stage embryos are suitable for this technique (e.g. blastocyst stage). Currently culturing on from earlier stage embryos to blastocyst stage in vitro, leads to significantly reduced viability and in many cases loss of the embryos. Microfluidic embryo culture devices have made steps in the right direction to improving embryo development in vitro (Mancini V et al 2021), however these still remain to be fully validated in the field and are not readily available commercially. If and when NSET techniques become reliable and viable to use in the lifetime of this project they will be investigated with the intention of reducing the number of animals having to go through surgical procedures for embryo transfer.

Genetic identification - Where possible non-invasive methods (compared to biopsy) will be sought to genotype (genetically identify) GAAs, for example by coat colour or observable reporter gene such as green fluorescence protein.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Diehl KH et al (2001) - A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes: JOURNAL OF APPLIED TOXICOLOGY 21, 15–23

Guidance on the operation of the Animals (Scientific Procedures) Act 1986. (Home Office 2014).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The role of the sponsoring company named information officer (NIO) includes the sharing of animal welfare, best practice and 3Rs related information. The NIO also liaises directly with the company project licence holder network through their own regular meetings, and also raises this type of information and discussion points at the institutional Animal Welfare and Ethical Review Body (AWERB) of which I am a member. I am also separately aware of the 3Rs related work of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). Experience to date has shown that 3Rs issues and advances are highlighted, discussed and actions are implemented within the company centrally and effectively via these forums. Additionally I also plan to attend external conferences, meetings and training courses as well as collaborate with other establishments to learn and share best practices in the field of genetically altered animal research.

171. Provision of an outsourced drug discovery platform for metabolic and cardiovascular diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Metabolism, Cardiovascular

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new and improved treatments for metabolic and cardiovascular disease. As part of this work we will optimise experimental models of disease to ensure they are fit for purpose.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will generate crucial data in the preclinical (before human dosing) development of potential new drugs, generating important information that cannot be found without the use of animals. The clients that we work with are developing test agents (potential new drugs) which will hopefully contribute to helping people with various metabolic and cardiovascular diseases where current treatments are not available or need

improving upon. For example, Pulmonary Arterial Hypertension (PAH) is a rare but severe cardiovascular disease where 40% of patients die within 3 years of diagnosis. To be able to test new drugs for diseases like this, it is necessary to use rodent 'models' which mimic areas of the disease to provide proof-of-concept data and to determine which drugs are likely to work well in humans as a treatment for the disease.

What outputs do you think you will see at the end of this project?

This project will generate important data in the preclinical development of potential new drugs for metabolic and cardiovascular disease. We aim to use this licence to test potential therapeutics in each of the disease areas listed, and to progress the most promising treatments which reduce disease severity through various stages of drug development and into the clinic. We are currently working on a series of drugs for PAH which have shown promising results in our rats that have a form of PAH. We aim to support the progression of these drugs through to the stage that they are able to enter clinical trials within the duration of this licence. We also aim to work with several other clients in each of these disease areas to offer a similar service.

These studies will determine which test agents are suitable for further preclinical development and for progression to clinical trials. They will also identify test agents which are not suitable for further development. This is an important benefit, as it will streamline research and ensure that animals are not used unnecessarily in developing compounds that will ultimately fail further down the development pathway. We prioritise ensuring that our models are designed such that unsuitable test agents are identified as early as possible in the testing process. One particular example of this is in our PAH work, where a class of new drugs are known to have the potential to cause an unwanted side effect of heterotopic ossification (bone formation in inappropriate locations). This project includes a protocol to allow us to rule out test agents with this side effect early in the development process.

Data from studies performed in this project may also be used in applications by our clients for further funding or as part of applications to allow test agents to be progressed into clinical trials.

Who or what will benefit from these outputs, and how?

This project will generate important data in the development of potential new drugs. Work under this licence is expected to result in the progression of new treatments for cardiovascular and metabolic disease through the stages of drug development and ultimately into human clinical trials.

Our focus on using a science-led approach will enable key decisions to be made at each development stage on whether a test agent is likely to become a successful drug. This allows test agents which are not suitable as drugs to be abandoned at an early stage using the fewest number of animals possible for each test agent. The identification of test agents as unsuitable for use in humans at an early stage of development will also ensure a better success rate in the drug discovery process than has been seen previously in the pharmaceutical industry.
Ultimately, this project will contribute to the successful development of new drugs for cardiovascular and metabolic diseases, which will benefit patients who currently have limited treatment options available.

PAH is a disease with an estimate global prevalence of 1%. This disease can affect both

sexes and all age groups, with a higher risk in females. PAH has a high mortality rate, with patients surviving on average only 3-5 years from diagnosis. Effective treatments would therefore have a significant impact on the lives of patients diagnosed with PAH.

Non-alcoholic fatty liver disease (NAFLD) has a global prevalence of 25%, and it is estimated that up to 5% of the UK population may be affected by the more serious form of the disease, non-alcoholic steatohepatitis (NASH). These diseases are closely associated with obesity, and therefore the number of patients suffering from them and who would benefit from new treatments is likely to increase. The average age of people with NASH is 40-50, with this age decreasing due to the increasing problems with obesity in society. The mortality rate is higher for patients with NASH than the general population, with liver damage from NASH increasing risk of liver failure and cancer.

How will you look to maximise the outputs of this work?

All studies are designed such that the outputs from each animal are maximised. Expert knowledge is utilised not only from within the preclinical (animal work) team performing the animal studies, but also from other teams at our company and our clients' companies. This ensures that all relevant work that has been performed in the laboratory is taken into consideration when designing the animal studies. The *in vitro* (in the dish/test tube) and bioanalysis teams at our company are experts at analysing tissue and blood samples collected from animals, and they help with details of sample collection and storage to ensure that the samples are collected and stored in the best way possible. They are also experts at working with small samples, particularly very low volume blood samples, meaning that they can analyse lots of different biomarkers and test agent levels from each animal.

In addition, we will seek expertise from our established networks both within our establishment and further afield, to ensure that we make use of any new knowledge or better methods of performing animal studies. We will also use these networks to give information to others about any ways in which we can help via our research. This will include sharing information about unsuccessful approaches in addition to sharing information on any refinements and improvements. We will maintain good communication with managers of the animal facilities to ensure that any tissues from animals being killed that are not required for our work can be made available to other researchers.

Due to the nature of the work undertaken in this project we are unlikely to be able to publish data, as this would put ourselves or our clients at a competitive disadvantage. However, where advances are made in study design, we will publish or share these wherever possible.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Both mice and rats are well established ‘models’ for use in both preclinical drug research and more generally in research into metabolic and cardiovascular diseases. This is due to their similarities to humans, with these 'models' mimicking aspects of human physiology and disease. They are very well characterised, meaning that there is a lot known about how the body works in mice and rats, both when healthy and with diseases. Adult rodents will be used for the work outlined in this project as we wish the biology of the animals to be fully developed to better represent the patients of the diseases the test agents are designed to treat.

Typically, what will be done to an animal used in your project?

The majority of animals used in this project will be part of studies that aim to test whether new drugs can improve or prevent development of symptoms associated with metabolic or cardiovascular disease. This will include investigation of any potential unwanted side effects that could be caused by the new drugs. Drugs will most commonly be administered intraperitoneally (into the abdominal body cavity), subcutaneously (under the skin), orally (either using a dosing tube or via adding the test agent to the food or drinking water) and less frequently intravenously (into a vein) or intramuscularly (into the muscle). On occasions a slow-release device will be implanted for the subcutaneous or intraperitoneal administration of drugs. At the end of all studies blood and/or tissues will be collected. These may be frozen or preserved using a fixative. Tissue may be placed into fixative after death or the fixative may be injected into the bloodstream or directly into the heart of an anaesthetised animal who will not regain consciousness between the injection of fixative and death.

In metabolic studies investigating NASH (non-alcoholic steatohepatitis) and NAFLD (non-alcoholic fatty liver disease), mice will be fed a high fat (or normal) diet to cause them to develop the liver problems associated with the disease. In these diseases, fat builds up in the liver, accompanied by liver inflammation in the case of NASH. Long-term, this causes damage to the liver and can reduce liver function. Animals will usually be fed the altered diet for 4 or more weeks and be administered with test agent throughout the study. Blood samples may be taken during the study to monitor the disease progression and effectiveness of the drug administration. At the end of the study terminal blood samples will usually be collected from anaesthetised animals immediately before death (meaning the animals are unconscious prior to blood collection and will not re-awaken) and mice humanely killed prior to collection of tissues.

Our PAH studies will use one of two methods to induce the disease in the animals. In the first, the sugen-hypoxia (SUHx) model, the majority of animals will be subjected to a hypoxic environment of 10% oxygen for 3-4 weeks (the equivalent of being at the top of a high mountain). A small subset of control animals will remain in a normoxic (normal air) environment throughout the studies. Animals may either be humanely killed immediately upon removal from the hypoxic environment or returned to a normoxic environment for several weeks prior to killing. Animals will be administered with a PAH enhancer by subcutaneous injection immediately prior to entering the hypoxic environment, and this administration may be repeated during the hypoxic period. They will also be administered with test agent at regular intervals. This will usually be during the hypoxic period in mice and after the hypoxic period during a period in normoxia in rats. Blood samples may be taken during the study to monitor progression. At the end of the study, the heart and blood vessels may be cannulated to measure pressure, prior to collection of a terminal blood sample. Cannulation is performed in terminally anesthetised animals, and involves the insertion of a thin, flexible probe into the heart via a connecting blood vessel. Animals will

be humanely killed prior to collection of tissues. The second method is the monocrotaline (MCT) method. This method will only be performed on rats, who will be injected with MCT via subcutaneous or intraperitoneal injection to induce a form of PAH disease which is similar to human PAH. The MCT only needs to be administered on one occasion to induce disease which is similar to human PAH. A small subset of control animals will be administered with vehicle (the liquid the drug is administered in but without drug). The animals will then be administered with test agent at regular intervals, with sample collection and heart cannulation as for the SUHx method.

In heterotopic ossification (HO) studies investigating the potential unwanted side effect of some test agents designed to treat PAH, animals will be subjected to muscle injury either via chemical or physical means. The reason for the muscle injury is that HO normally only occurs at the site of an injury, not in healthy tissue. Therefore, an injury must be caused to check if this side effect would be a problem if the test agent was used in humans. Muscle injury will be performed under anaesthesia and this will involve either injection of a toxin into the muscle or physical muscle damage by the dropping of a ball bearing onto the muscle. The injury is made to one of the rear limbs. Animals will be administered with pain relief if needed. However, this is not usually required, with animals able to move normally after the injury. Animals will be administered with test agent on one or more occasions, often directly into the site of muscle injury. Blood samples may be taken during the study to monitor progression. At the end of a study a terminal blood sample may be collected immediately before death and all animals will be humanely killed prior to collection of tissues.

Where possible, we will make any tissues not required for our work available to other researchers after the death of the animal.

What are the expected impacts and/or adverse effects for the animals during your project?

In studies investigating NASH/NAFLD mice will be fed a diet high in fat and/or given sugars in their drinking water. This may cause obesity due to the high fat content of the diets used. However, where the diet is less palatable (meaning that the animals do not like the taste as much as normal), animals may lose (or not gain) weight meaning that their weight will be lower than that of control animals at the end of the study. Diets will be made as appealing as possible to the animals, but sometimes the use of a less palatable diet can give better results in the studies and shorten the studies which reduces the overall impact on the animal. The fat in the diet may cause their coat to become greasy, which ultimately may lead to hair loss through over grooming.

During HO studies, animals may experience some pain associated with the induction of muscle injury. This will resolve within a few days of muscle injury occurring. In our experience, pain relief is not normally required; animals are able to move normally immediately after injury.

During PAH studies using the SUHx method, animals lose up to 10% of their body weight within the first 1-2 days of exposure to the hypoxic environment and demonstrate reduced activity. After this acclimatisation period, activity levels increase and eating behaviour and weight gain proceed normally. Animals who receive a PAH enhancer and exposure to the hypoxic environment and are then returned to the normoxic environment will develop a more severe disease. It is expected that some animals will be found dead in the rat model of this design. These animals suffer sudden death due to heart failure, and do not experience severe suffering. During PAH studies using the MCT method, rats similarly

develop features of PAH as in the SUHx model and may also experience sudden death due to heart failure.

The test agents administered in all studies in the project are not expected to cause any lasting harm. Animals may lose some body weight initially whilst adjusting to them. Where a slow-release device is used, these animals will undergo surgery under general anaesthesia, with quick recovery expected. The location of the slow-release device is not expected to have any effect on the animal's ability to move freely. Blood sampling is not expected to cause any lasting discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse - Mild: 38% Mouse - Moderate: 62% Rat - Mild: 14%
Rat - Moderate: 86%

What will happen to animals at the end of this project?

- Killed

Replacement

**State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.
Why do you need to use animals to achieve the aim of your project?**

The work undertaken under this project licence cannot be fully replaced with *in vitro* (conducted in a laboratory without use of animals) or *ex vivo* (conducted on animal tissue but not in live animal) models. Wherever possible, work is performed in *in vitro* or *ex vivo* models prior to *in vivo* (animal) studies, to ensure that the *in vivo* studies are well designed and that the maximum amount of data is obtained from each study. This can be validating the target of a test agent and/or testing the action of the test agent itself in a suitable cell line to ensure the test agent is acting as expected before moving into animal studies. This may also be performed in *ex vivo* samples, providing data not available from established cell lines, but without requiring full *in vivo* experimentation. Our *in vitro* and *ex vivo* work ensure that wherever possible we generate proof of concept data before moving into animal studies, thereby reducing the number of animal studies performed in total and preventing test agents which are unlikely to be viable therapeutic agents being moved forward to *in vivo* studies.

However, isolated cells cannot reproduce the complex nature of the entire system of a living animal. This is particularly true for the areas of research covered by this licence. Metabolism involves complex interactions between different organs in the body, which cannot be recapitulated in the lab. Similarly, the cardiovascular system and flow of blood around the body cannot be recreated in a cell-based system.

Which non-animal alternatives did you consider for use in this project?

Work can be performed in the laboratory to ensure that test agents are acting as expected

before moving into animal studies. These may be using cell lines grown in the lab, or using tissues collected from animals. We have previously performed these types of experiments for example by looking at the effect of a test agent on liver cells collected from a mouse. We use these studies before moving into animals to make sure that test agents that are unlikely to be useful to humans do not get tested in animals.

Why were they not suitable?

Whilst cell-based work in the laboratory can be used to test how test agents act on cells, they cannot model the effect on whole organs, or the interaction between different organs which is a crucial element of metabolic and cardiovascular diseases. In addition, cell-based work does not test the effects the body might have on a test agent, for example how it gets into the blood, travels around the body and how it is removed from the body. No alternative is available that can replace the need to test potential therapeutics in a live animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used has been estimated by analysing the number of animals used on previous projects and looking at the number of animals required for each type of study. This was then combined with a prediction of likely demand of future projects to give the numbers in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have extensive experience in designing experiments of the types in this project, which has given us confidence in the number of animals required to ensure that no animals are used unnecessarily, but also that the data generated is reliable. Through experience we tend to use a standard group size for some of the studies under this project, using 6 per group for heterotopic ossification studies and 14 per group for PAH studies. We regularly refer to the PREPARE and ARRIVE guidelines and make use of the NC3Rs Experimental Design Assistant to ensure that we are using the correct number of animals for every study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Data from pilot studies and previous experience are used to ensure that the numbers used are both as low as possible, but also large enough to generate reliable data. Within our company, a member of the wider team has generated a tool for performing power calculations and can be consulted to assist with study design. This expert regularly tests the tool against peer-reviewed power calculators and can adjust as necessary.

Where genetically altered animals are required, these will usually be provided by our breeding project, which will ensure that animals are bred efficiently using as few animals as possible by communicating need with colony managers. Where animals are obtained from external sources, only the number of animals required for the study will be purchased or imported.

Wherever possible, our *in vivo* scientists will be blinded to the treatment status of an animal, meaning that they do not know which treatment the animal is receiving. This reduces bias, enabling more reliable information to be gathered from a smaller number of animals. Where possible, those who carry out analysis on blood and tissues collected during the study are also blind to any treatment with test agent.

Baseline data (e.g. bodyweight, biomarker levels) are recorded and animals assigned to treatment groups to ensure there are no differences in baseline measurements between the groups at the start of the study. Once assigned to a treatment group number, the treatment status for each group will be assigned randomly.

Good planning ensures that within any series of studies we can control for variability that might be introduced. To limit this variability we look at using animals of a similar age/weight range, testing different batches of test agent in the lab first, using the same source of reagents (chemicals used during the experiments), keeping records of observations made and standardising as many components of an *in vivo* model as is practicable.

Whilst all studies in this project will require live animals, we will coordinate with other groups to offer post-mortem tissues for their work, where this is suitable for their work and does not affect the outputs from our own studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals will be housed in a purpose-built, state of the art facility, that is free of disease-causing organisms such as bacteria, viruses and parasites. They will have access to food, water and items that enhance their environment, such as tunnels, chew sticks and mezzanine levels to climb on. Our company staff and the animal care staff are competent in rodent welfare and will ensure that animal suffering is minimised. We aim to house rodents in groups to promote normal behaviour. However, aggressive behaviour can occasionally result in animals being singly housed to prevent injury.

We will use both mice and rats during this project. Some of these will have a genetic alteration that will not cause them harm, but which provides a more appropriate model in which to perform experiments using test agents for particular diseases.

Our NASH/NAFLD, HO and PAH studies are all performed using well-established

protocols, which reliably reproduce the important characteristics of the human diseases required for the testing of new drugs whilst minimising the harms to animals. We work to ensure that we introduce further refinements to our disease models wherever possible.

Test agents will often be tested first under our test agent profiling licence prior to testing in animals mimicking human disease. Where it is hard to predict the potential side effects of a test agent in the disease model, studies will be performed in a small number of animals first who will be monitored for at least 2 hours or overnight in the case of test agents where side effects are likely to take longer to be seen. Where side effects are observed, the dose may be altered to ensure no long-lasting side effects are seen before any longer-term studies are performed.

Dosing will always be performed using the least invasive route (e.g. oral gavage via food or water if possible), and where a needle is required using the smallest needle possible.

Amendment April 2022: For mouse PAH studies, the mice need to be under brief anaesthesia for an injection that requires them to stay still so that the drug doesn't touch the skin, potentially causing irritation. In most studies these injections need to be repeated several times. Therefore, under the guidance of the NVS we have seen some success in giving supportive subcutaneous saline to these mice to prevent dehydration and will continue to trial the use of it to gather more firm data on its effectiveness.

Why can't you use animals that are less sentient?

Adult rodents such as mice and rats are essential for studying complex diseases, where all systems must be similar enough to humans to find the most effective drugs. The complexity of metabolic and cardiovascular diseases requires the use of living animals, where the bodily systems are functioning and interacting with each other. Due to the length of the studies, which span weeks to months, terminal anaesthesia is not a possibility.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have a demonstratable history of refining our procedures and practices to minimise harm to our experimental animals. For example, we always use the smallest needle possible for dosing to minimise any pain and distress to the animal. We also investigate the suitability of test agents administered orally to be dosed via the drinking water rather than via oral dosing, where the dose is administered via insertion of a tube down the throat. We recently implemented this for a test agent, allowing us to switch from twice daily oral dosing to dosing via the drinking water. We will also sometimes use a slow-release device for dosing. Whilst this requires an initial surgical procedure, it reduces the need for the stress of regular injections.

During all studies, general animal condition and body weight will be monitored regularly. We are developing a detailed scoring system to monitor any side effects observed due to dosing. Animals will be housed in social groups in the vast majority of cases, with animals housed alone only where this is absolutely necessary (for example when an animal within a cage demonstrates aggressive behaviour). Where anaesthesia is used, care will be given to support animals during anaesthesia and recovery, using heat mats to maintain body temperature and providing soft diet and hydrogel to aid recovery as appropriate.

Where an altered diet is used, we will ensure that animals are introduced to the diet over a period of weaning, allowing them to acclimatise to the diet before a full switch is

performed. This will minimise the risk of weight loss due to a sudden switch to an altered and potentially less palatable diet. For new diets which have not previously been used we will review these using a small pilot study to ensure that they are palatable before using them for large numbers of animals. Where animals are hyperglycaemic (have increased blood sugar levels), we will replace the bedding more frequently when an increase in urination is observed.

For PAH studies, we have refined the method of injection of PAH enhancers that can cause sores at the site of injection by ensuring that we pinch the site of injection as the needle is withdrawn. This has reduced the incidence of sores. For mice, the PAH enhancers are administered under anaesthesia to further reduce the incidence of sores, with subcutaneous saline also administered to assist with recover from the anaesthesia given the potential reduce activity levels whilst in hypoxia.

For HO studies, the level of muscle injury has been refined to cause an injury that does not significantly affect the behaviour of the animals or reduce movement, but is still sufficient to assess the potential for test agents to cause HO.

We use microvettes (small capillary blood collection tubes coated with anticoagulant to prevent blood from clotting) to collect small blood samples from animals. This allows us to take small samples in the most efficient way possible.

Where possible, when animals are purchased from an external supplier these will be handled regularly during the acclimatisation period to reduce the stress for the animals when procedures commence.
Where diet consumption is not crucial to the outcome of a study, we also provide treats such as sunflower seeds after handling and procedures to assist in habituation for the animals to the procedures and any restraint required.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be using PREPARE guidelines for the planning of studies and follow the latest version (2020) of the ARRIVE guidelines for ultimate reporting of data. The LASA document ‘Guidance on dose level selection for regulatory general toxicology studies for pharmaceuticals’ will be used when planning studies, to help guide study design. This document, particularly the section detailing the report of the Federation of European Laboratory Animal Science Association (FELASA) working group on pain and distress has also been used when setting the humane endpoints within this project. We use the resources on the NC3Rs website for guidance on the best practice for procedures such as blood sampling and for refinements to handling and husbandry. We will also regularly check the current list of LASA publications, to ensure that any relevant to work under this project are taken into consideration.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

When designing animal studies we consider the appropriate guidelines, including the guidance from the Laboratory Animal Science Association (LASA), the National Centre for the 3Rs (NC3Rs) and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). This will include the PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellent) and ARRIVE (Animal Research: Reporting of *In Vivo* Experiments) guidelines which provide guidance on the design and reporting of

animal studies. This guidance will influence our study design. One example of this is the use of the NC3Rs guidance on the number and volume of bleeds to be taken from rodents in the design of pharmacokinetic studies. We regularly check the NC3Rs website, along with other external resources such as Norecopa (a resource of databases and guidelines from Norway) and Jax (a genetic animal strain resource providing a hub of research information), to ensure that we are using the most refined methods and are aware of any improvements to procedures that have been developed.

172. Provision of an outsourced drug discovery platform for the development of therapeutic drugs for cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, tumour models, therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is ultimately to develop new and improved treatments for cancer. We plan to develop new, or refine existing cancer models to improve the translatability of our work from animals to human medicine, resulting in the selection of the best drug candidates to take forward for further development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a leading cause of death worldwide, accounting for nearly 10 million deaths in 2020, with the number of new cases rising year on year (Ferlay J, et al. Global Cancer Observatory: Cancer Today.
Lyon: International Agency for Research on Cancer; 2020). In the UK, over a quarter of all

deaths involve cancer with the most common types being breast, lung, colorectal, prostate, skin and stomach cancer. In most cases, if cancer is left untreated it is highly likely that it will lead to death.

One cancer we hope to target is the particularly difficult to treat triple negative breast cancer (TNBC), which accounts for 15% of all breast cancers. There are currently fewer treatments available to treat this rare type of breast cancer, meaning that mortality rates are higher. Specific data on average age at death from triple negative breast cancer is not available, but with non-triple negative breast cancer mortality increases with age. In the UK in 2016-2018, almost half of deaths from breast cancer (48%) were in people aged 75 and over (Cancer Research UK website). However, younger women (<40 years old) are 1.53 times more likely to develop TNBC than older women (>60 years old), so age at death is likely to be lower in people with TNBC.

Whilst there have been significant advances in treatments for many cancers, deaths as a result of cancer still remain high. This is partly due to the type and number of cancers that exist and the fact that some have ineffective or no treatments available. Added to this, individual patients may respond differently to the same treatment, and patients who previously responded well may go on to develop resistance to the treatment, rendering it ineffective.

Our work aims to use animals, in combination with experiments that take place in the lab, to support the development of new treatments for cancer and address the unmet clinical needs of some cancers. The use of animals is an essential part in the process of developing new treatments for cancer. Animal studies enable us to replicate complex aspects of the disease in the entire biological system, including the interaction of cancer cells with other cells and organs in the body. They enable us to test the effect of new treatments on the disease (for example tumour growth) in a relevant and intact biological system. This work will enable key decisions to be made regarding which treatments should continue to be developed, and ultimately, which will make it into clinical trials, where they are tested in humans.
Our approach to the work ensures that this is done in the most efficient way possible, and that the benefit gained from every animal is maximised.

What outputs do you think you will see at the end of this project?

Work carried out under this licence may involve the development of new animal tumour models (creating incidences of cancer in animals, similar to the human condition) and potentially the improvement of existing animal tumour models. Collectively these will allow us to test the ability of new drugs to treat specific cancers in a manner that more closely replicates the human condition. As part of this project we hope to develop or improve 3-6 animal tumour models (for example using different types of cancer cell) and to test the effects of at least 5-10 new anti-cancer drugs using these models, or currently available models.

This project may provide important information to progress new cancer treatments through the phases of drug development. New test agents will be evaluated for their ability to treat cancer in animal models that replicate the conditions in human cancer. The information gathered will enable us to identify the most appropriate treatments to take forward to human clinical trials and, importantly, quickly determine which drugs should not be progressed any further.

In addition, this work will increase our knowledge of how new drugs work and will help us

to identify changes in the body that occur in response to the drug. We can use this further down the line to monitor responses in humans during clinical trials.

Data from studies under this project may be used to support patent applications and applications by clients for additional funding. Data produced may also support the design of regulatory studies for clients.

Who or what will benefit from these outputs, and how?

This project will generate important data in the development of new drugs. To assist with this, we will utilise our test agent dosing project licence to allow us to understand how drugs distribute in the body after dosing, how quickly they are eliminated, and the dosages that are well tolerated in rodents. This will aid in the design of dosing strategies for studies under this licence. Ultimately, work carried out under this licence is expected to result in the progression of new cancer treatments through various stages of drug development and ultimately into the clinic to treat patients with various forms of cancer.

Our focus on a science-led approach will enable key decisions to be made at each development stage on whether a test agent is likely to become a successful drug. This allows unsuitable drugs to be abandoned at an early stage and enables us to use the fewest number of animals possible per drug development programme. The identification of test agents as unsuitable for use in humans at an early stage of development will ensure a better success rate in the drug discovery process than has been seen previously in the pharmaceutical industry. Ultimately, this project will contribute to the successful development of new anti-cancer drugs, which may benefit patients with various forms of cancer who may otherwise have died from their condition.

The development of new or improved cancer models will enable us to test new drugs in as close an environment to the human condition as possible. This will increase the likelihood of patients benefiting from these new drugs.

How will you look to maximise the outputs of this work?

All studies are designed such that the outputs from each animal are maximised. Expert knowledge is gathered not only from within the preclinical (animal) team performing the animal studies, but from other teams within our company, or our clients' companies. This ensures that all relevant work that has been performed in the laboratory is taken into consideration when designing animal studies. The in vitro (in the test tube) team at our company are experts at analysing tissue and blood samples collected from animals, and they help with details of sample collection and storage to ensure that the samples are collected and stored in the best way possible. They are also experts at working with small quantities of samples, particularly small volumes of blood samples, meaning that they can often analyse lots of different biomarkers (a measurable indicator of a disease state or other physiological state) and test agent levels from each animal.

In addition, we will seek expertise from our established networks, to ensure that we make use of any new knowledge or incorporate better methods of performing animal studies. We will also use these networks to provide information and training to others on the models and techniques we use in our research. We will maintain good communication with managers of the animal facilities to ensure that any tissues from animals being killed that are not required for our work can be made available to other researchers if suitable.

Although there are times where we will not be able to share animal model information (for

example, where it would put us at a competitive disadvantage), we aim to publish or share our findings (especially control data) wherever possible.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the most common type of animal used for developing new cancer treatments. Mice are well characterised, meaning that a lot is already known about how the body works in mice, and a large selection of different tumour cell types are already available for use in mice. This means that for the most common types of tumours, such as, lung, skin, breast and bowel cancer, cells are already available allowing us to easily evaluate new drugs designed to treat these kinds of tumours.

Adult mice will be used for the work outlined in this project licence as we want the biology of the animals to be fully developed as this will better represent the patients we aim to treat.

Typically, what will be done to an animal used in your project?

The majority of animals will be part of studies that aim to test whether new drugs can alter the growth rate of tumours. Typically, tumour cells will be implanted by injection under the skin on the flank of the animal, or, less commonly, cells will be injected into the mammary fat pad (breast) tissue, or directly into a vein. Except when injected into a vein, tumour cells will grow into tumours at the site of injection.

When injected into a vein, tumours cells will travel via the blood and form tumours around the body, most commonly in the lungs. The size of the tumours will be monitored as part of the experiment.

Tumours that grow just under the skin (flank and breast tumours) can be measured using callipers or simple hand-held imaging devices. Tumours will be measured a minimum of twice weekly, and the frequency of measurements will be increased during the faster growth phase. Tumours growing internally require monitoring by non-invasive imaging and by following the overall condition of the animal closely. For non-invasive imaging, animals will be anaesthetised as it is important that they remain still to produce the image. Animals will be imaged at least weekly when tumours are present, with frequency increasing during the faster growth phase. Tumours will typically be allowed to develop over a 4-12 week period, however, actual study duration will be dependent upon the type of cancer cell injected and how quickly they grow. Tumours are not expected to cause pain, however, any animal showing signs of pain will either be treated with a suitable dose of pain killer if appropriate for the scientific outcome of the study, or humanely killed.

As part of a study, animals will typically be dosed with anti-cancer agents (e.g. chemotherapies) over a period of several weeks or months and dosing will be initiated

typically when tumours reach a volume of 100 mm^3. Dosing will often take place on a daily basis, but this may vary depending upon the test agent. Drugs will be administered more commonly by the intraperitoneal (inside the body cavity), subcutaneous (under the skin) and oral (by mouth) routes and less frequently by the intravenous or intranasal routes. For intraperitoneal, subcutaneous and oral administration, mice will be held securely by a trained researcher for the dose to be administered. For intravenous dosing, mice will be placed briefly in a specially designed rodent restrainer, the tail will be warmed using warm water or a heat lamp to dilate the blood vessels and make them easier to see before administering the dose. For intranasal dosing, mice will be briefly anaesthetised and placed on their backs to allow the dose to be administered directly into the nostrils.

Less commonly, as part of some studies, animals bearing tumours may be given radiation treatment directed at the tumour either alone or alongside other anti-cancer treatments. Animals will be anaesthetised throughout the treatment and are expected to make an unremarkable recovery.

Blood samples, or small samples of tumour tissue, may be collected during some studies to measure levels of the test agent or to assess how well the drug is working. Blood samples are usually small in volume and are taken from a superficial vein such as the tail vein. Larger volumes of blood may be collected at the end of a study when an animal is under deep terminal anaesthesia. Small samples of tumour may be collected from live animals under anaesthesia using a very fine needle. Other non- regulated procedures such as passive urine collection (allowing the animal to pass urine naturally on to a clean surface so that it may be collected) may be performed.

At the experimental end point, animals will be humanely killed and tumours will be dissected and typically examined to look for evidence that the test treatments have worked.

What are the expected impacts and/or adverse effects for the animals during your project?

The most common adverse effects in the studies described in this project licence will arise from the tumours themselves or from the test agents. We are developing a scoring system that will enable us to monitor and ultimately minimise the level of suffering an animal experiences on our experimental protocols. Our scoring system will take into account the animals body weight, activity level, general body condition, posture and the condition of any visible tumours and will be used to classify the degree of suffering an animal experiences. We also take into account the duration of adverse effects and the cumulative experience of the animal. Therefore, an animal that experiences, for example, several short periods of reduced activity following dosing may experience mild suffering, but an animal that experiences several longer periods of significantly reduced activity that are accompanied by another clinical sign such as weight loss, may be experiencing more moderate suffering.

Metastases (cancer cells that have spread to other parts of the body) resulting from mammary fat pad tumours, and as a result of systemically (intravenously) administered cancer cells, can be difficult to detect and may cause the animals adverse effects as their size and number increases. Signs that an animal may have a number of internal tumours that are starting to affect normal functioning include reduced activity, weight loss (greater than 15% from starting body weight), poor body condition or poor posture. Again, we will use our in-house developed scoring condition to minimise the level of suffering an animal

may experience. Animals will be killed before they exceed moderate suffering.

Any animals with tumours large enough to impede normal mobility or their ability to eat and drink will be humanely killed.

The treatment of animals with known anti-cancer treatments or test agents designed to treat cancer may cause adverse effects, similar to humans. Following some treatments, mice may display reduced activity, hunched posture and fur bristling. For most treatments these effects should be short lived and mild, however some animals may experience moderate effects, which may include sustained weight loss of up to 15% of starting body weight and/or longer lasting reduced activity.

A small incision in mammary fat pad tissue may be required in order to visualise the tissue fully to enable us to give an accurate injection of tumour cells into the tissue. Incisions will be performed as a surgical procedure under recovery anaesthesia, and animals are therefore likely to experience some pain as a result of the incision. Pain relief will be provided as appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Mild 30%

Moderate 70%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Wherever possible we use cell-based experiments, however, even where cells are used it is still necessary to use animals to understand the complex nature of cancer. Animals enable us to study the whole body, allowing us to study both how cancer cells interact with other cells and organs within the body and how cancer cells spread throughout the body. It is not possible to fully study this in isolated cells and/or organs.

Which non-animal alternatives did you consider for use in this project?

Our company regularly uses a range of in vitro (taking place in a test tube in the laboratory) methods utilising cells (typically cancer cells) to understand how a novel test agent might affect the cellular functioning of those cells. From these experiments we can prioritise test agents and only take forward those that have the desired effect, and therefore

those that look the most promising for the treatment of particular types of cancer.

Why were they not suitable?

Cell-based methods are useful to test the impact that novel test agents have on a cellular level, for one particular type of cell, but they do not model how cancer cells interact with other types of cells and organs, or how they spread throughout the body. In addition, cell-based methods do not test the effects that the body might have on a test agent, for example, how it is absorbed, distributed and excreted from the body, all of which can alter how effective the test agent might be. Testing a new drug in an intact biological system, such as a well understood rodent system, enables us to study the complex interactions of cancer with other cells/organs in the body, as well as monitoring how the test agent performs in an intact biological system. None of the alternatives mentioned can replicate this, although cell-based testing enables us to triage drugs and only take the best candidates forward for further development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we will use throughout the five year lifespan of this licence has been estimated based on the number of cancer projects we have coming up in the next 12 months, combined with a prediction of likely demand of future projects for new clients over the remaining years of the licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have extensive experience in the design of experiments of the types in this project, which has given us confidence in the number of animals required to ensure that no animals are used unnecessarily, but also that the data generated is robust and reliable. Through experience, whilst we do tend to use a standard group size for the majority of our tumour studies (6 mice per group), we regularly refer to the PREPARE guidelines (https://norecopa.no/PREPARE) and make use of the NC3Rs Experimental Design Assistant (https://nc3rs.org.uk/3rs-advice-project-licence-applicants-reduction) to ensure that we are using the correct number of animals for every study. When designing experiments to look at the effect of novel test agents on tumour growth, where the test agent has not previously been dosed before, we look at published literature or client data to determine the variability observed with similar test agents and/or similar tumour models. We can then use the NC3Rs Experimental Design Assistant, or our own in-house developed tool to help determine the most appropriate group size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

An initial experiment using reduced numbers of animals is often conducted first of all,

which enables adjustments to be made before conducting the full experiment. Such experiments are referred to as pilot studies.

Data from pilot studies and previous experience are used to ensure that the numbers used are as low as possible, without compromising the robustness and reliability of the data. Within our company, a member of the wider team has generated a tool for performing power calculations and can be consulted as necessary to assist with study design.

Wherever possible, our in vivo scientists will be blinded to the treatment status of an animal, thus reducing bias. This enables more reliable information to be gathered from a smaller number of animals. Those who carry out analysis on samples (e.g. blood or tissues) collected during the study are also blind to the treatment status of the animal.

Baseline data (e.g. tumour size (where relevant), bodyweight) are recorded and animals are randomly assigned to treatment groups so there is no difference between the groups at the start of the study.

Good planning ensures that within any series of studies we can control for variability that might be introduced by external factors. To limit this variability we use animals of a similar age/weight range, test batches of test agent in the lab first, use the same source of animals and reagents, keep records of observations made and standardise as many components of an in vivo study as is practicable.

We will coordinate with other groups to share tissue including post-mortem tissues to reduce overall mouse numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.
Animals will be housed in a purpose-built, state of the art facility, that is free of disease-causing organisms such as bacteria, viruses and parasites. They will have access to food, water and items that enhance their environment, such as tunnels, chew sticks and mezzanine levels to climb on. Our company staff and the animal care staff are competent in rodent welfare and will ensure that animal suffering is minimised. We aim to house mice in groups to promote normal behaviour. However, aggressive behaviour can occasionally result in animals being singly housed to prevent injury.

The most common type of tumour model we expect to use is the subcutaneous tumour model, which involves injecting cancer cells just under the skin (in the subcutaneous layer) in the flank of the mouse. This results in tumour growth at the site of injection. This is the simplest method available for inducing tumours in mice and results in the least harm to the animal as the tumour is self-contained within the subcutaneous layer and therefore cannot interact with organs or spread to other regions within the body. This technique can be used for different types of cancer; allowing the search for effective treatments for different

cancer types without needing to induce the cancer in the usually affected organ or tissue.

Other methods, such as mammary fat pad tumours and metastatic tumours will be employed when we need to answer more complex questions such as how cancer cells interact with different organs, how cancer spreads throughout the body, or how tumours respond to novel test agents in these different settings.

Why can't you use animals that are less sentient?

Adult mice are the lowest species of mammal that allow us to adequately study the complexities of human cancer. Due to the length of most studies, which span weeks to months to allow for tumours to grow, terminal anaesthesia is not a possibility. It is also important that we are able to monitor the behaviour of the animals in a conscious state as this allows us to monitor for adverse reactions to any test agents administered.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have a demonstrable history of refining our procedures to minimise harm to our experimental animals. This includes our basic practice of always using the smallest needle possible for dosing to minimise any pain and distress to the animal. We also investigate the suitability of test agents to be delivered via a route that causes the least harm. For example, we recently implemented this for a test agent, allowing us to switch from twice daily oral dosing (where the dose is administered via insertion of a tube down the throat) to dosing via the drinking water. The palatability of drug in drinking water will be carefully considered, and if appropriate, we may consider flavouring the water to increase its palatability.

General welfare monitoring is particularly important when conducting mice tumour studies. Animals undergoing tumour studies will be carefully monitored using our in-house body condition scoring system. Using this system, mice will be assigned scores based on body weight changes, changes in general condition (e.g. coat, posture and body condition), activity levels, condition of any visible tumours (colour and whether tissue necrosis or ulceration is present), as well as the number and size of any tumours (by non-invasive imaging such as the Peira TM900 handheld imaging device for measuring subcutaneous tumours or calliper measurements). Significant ulceration is not expected in the majority of animals as pilot work will be conducted to establish the rate of tumour growth that is least likely to result in ulceration at the tumour site. However, if ulceration develops, animals will be closely monitored and scored using our in-house developed scoring sheet, which will score ulcers as either dry or wet (exuding pus or clear fluids). Animals with wet ulcerated tumours persisting beyond 48 hours with no signs of improvement will be humanely killed. For dry ulcers, advice may be sought from the vet and minor interventions will be implemented if appropriate to allow the animals to continue the study.
Mice with increasing scores will be monitored more frequently to ensure that no animal suffers more than is necessary during each study. In our experience, assessing the whole body condition of the animal gives us much more information on the degree of suffering an animal experiences compared to measuring tumour diameter alone. Animals can often tolerate large tumours (particularly subcutaneous tumours) without a negative impact on overall wellbeing, making measurement of tumour diameter alone unsuitable for understanding the true impact on the animal, or when to kill an animal. Therefore, while our scoring system does take into account the size of tumour(s), this is considered collectively with the above factors to assess the impact of the tumour on the animal as a whole, meaning that we gain a more accurate picture of the animal's health and can

intervene early if welfare is significantly impacted. This in turn prevents the loss of valuable data and promotes maximum benefit from each animal that might otherwise have been lost when using a one-factor humane end-point.

Mice will be group housed where possible and provided with an enriched environment in order to minimise stress. Should pain relief be required, we will consider adding the pain relief to a palatable substance such as Nutella to allow the animals to take it voluntarily. During pilot work to establish mammary fat pad tumours in mice, we propose to inject cancer cells into two mammary fat pads of the same animal. This will allow us to compare variables such as the delivery vehicle (Matrigel) used to deliver cancer cells and the number of cancer cells injected to determine how they affect tumour growth in the same animal. This will allow us to reduce the number of animals used, particularly in the early stages of studies where we aim to determine the best conditions for each new cancer cell line.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We use the Workman et al guidelines (Workman, P et al. Guidelines for the welfare and use of animals in cancer research. 2010. British Journal of Cancer. 102 p1555) to inform our experiments. In addition, we follow the PREPARE guidelines for the planning of studies (Smith et al., PREPARE: guidelines for planning animal research and testing. 2020. Laboratory Animals). LASA (Laboratory Animal Science Association) also has a range of published guidance documents with principles that can be applied to our animal studies which are found at https://www.lasa.co.uk/current_publications/.

In addition we will also refer to the following when conducting our work:

Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217

LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. (E Lilley and M. Berdoy eds.). http://www.lasa.co.uk/publications/

Smith D, Anderson D, Degryse A, Bol C, Criado A, Ferrara A, Franco NH, Gyertyan I, Orellana JM, Ostergaard G, Varga O, Voipio H (2018) Classification and reporting of severity experienced by animals used in scientific procedures: FELASA/ECLAM/ESLAV Working Group report. Lab Animal 51(1S): 5-57. doi: 10.1177/0023677217744587

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

When designing animal studies we consider the appropriate guidelines, including the guidance from LASA, the NC3Rs, and the PREPARE guidelines. This guidance will influence our study design.

173. Evaluating new targets for treating cardiovascular disease and cardiotoxicity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cardiovascular disease, cardiotoxicity, calcium handling, oxidative stress, therapeutic targets

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify molecules or proteins within the heart that are directly associated with cardiac contractile dysfunction either as a result of underlying chronic hypertension or resulting from the toxic effects of drugs or biomaterials. To target the identified molecules or proteins with a view to reducing or reversing the cardiovascular damage.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease (CVD) remains the leading cause of morbidity and mortality globally and there is a strong need for improved and more targeted treatments. The left ventricle of the heart is responsible for pumping blood around the body and CVD can result in left ventricular dysfunction (impaired contractile function) from a number of underlying causes including high blood pressure and blood vessel damage. What is now also recognised is the contribution that certain drugs or devices can make to the overall CVD burden that leads to left ventricular dysfunction. Certain FDA-approved drugs and devices can have off-target effects that can lead to a condition termed cardiotoxicity (CTX). This is an umbrella term that covers a variety of toxic or damaging effects on the heart, many of the effects presenting in a similar way to those seen in CVD. Anti-cancer drugs in particular can have both short- and long-term toxic off target effects on the heart and this can ultimately result in heart failure. The underlying reasons for this off-target CTX are not well understood. As well as drug-induced CTX, patients with implants or devices have also been reported to present with varying degrees of off-target CTX as a result of the implant. In particular, patients with metal-on-metal (MoM) hip implants can suffer toxic off-target cardiovascular effects and this is due to cobalt ions being released over time from the MoM bearings and accumulating in the heart. Again, the mechanisms underlying cobalt-induced cardiotoxicity are not well understood. The progression of CVD or CTX is complex and variable but we know that three key pathways are likely to contribute (i) alterations in cardiac calcium handling (will affect heart contractility) (ii) increased inflammation (can contribute to heart tissue remodelling and dysfunction) and (iii) increased oxidative stress (can alter the energy available to the heart and lead to dysfunction). These may all contribute to the left ventricle of the heart becoming dysfunctional, with impaired cell-cell communication and an inability to pump blood effectively around the body. Access to human tissue to study these conditions is very limited. Therefore, this project will use a pharmacological rodent model of chronic high blood pressure to study novel potential therapeutic targets for the treatment of CVD and will use anti-cancer drug or cobalt treatments in rodents to study potential novel therapeutic interventions in drug- and device-induced CTX.

What outputs do you think you will see at the end of this project?

New potential targets for treatment of hypertension-induced left ventricular dysfunction will be identified.

Novel cellular mechanisms responsible for (i) anti-cancer drug-induced and (ii) metal-on-metal hip implant induced cardiotoxicity will be identified.

Research will be presented at national and international scientific conferences.

Research will be published in peer-reviewed scientific journals (at least one article per year) and, where appropriate, in newspapers for dissemination to the general public.

Who or what will benefit from these outputs, and how?

In the short-term, research information generated from our pharmacological models will benefit a number of research groups across the University of Strathclyde, Glasgow Caledonian University, University of Glasgow and Queen Elizabeth University Hospital. These are groups with whom we are currently collaborating and this will increase the capacity for research outputs, ensuring best use of the animal model. The cardiovascular, cancer and orthopaedic research community (Masters students, PhD students, research scientists, academics and clinicians) will benefit from our research outputs presented at national and international scientific meetings as well as networking events.

In the medium term, the cardiology, oncology and orthopaedic clinical community will benefit from research publications and ongoing collaborative projects. This work will inform upon potential treatments in clinical practice going forward.

In the longer term, people with CVD, cancer or MoM hip implants will benefit from the research findings should the novel targets identified from this project be taken forward to clinical trials.

How will you look to maximise the outputs of this work?

We will present our research at national and international scientific conferences and, follow up with publication in peer reviewed journals. Where appropriate, we will disseminate our research in news articles to the general public.

We currently have ongoing collaborations with cardiovascular and orthopaedic consultants and from the work in this project, will aim to develop and extend these collaborations to also include consultants in the field of oncology.

There are few network groups in the field of cardiotoxicity and we will plan to develop networking research groups (including basic scientists and clinicians) across Europe and further afield to share our knowledge from this work and build strong collaborations in this area

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rats or adult mice will be used for these studies. These are both well recognised models for assessing CVD characteristics as well as assessing the effects of drugs on the heart. The use of adults is essential to mimic the effects we would anticipate in adult humans.

Typically, what will be done to an animal used in your project?

To induce chronic high blood pressure, animals will be implanted with a minipump (a small oblong device) filled with a drug called angiotensin II. Age/weight matched controls will be implanted with minipumps filled with vehicle (we envisage using a very limited number of controls since the manufacturer has already established that vehicle-filled pumps have no adverse systemic effects). The pump will normally be inserted under the skin on the animal's back, parallel to the spine. This enables a constant rate of drug delivery and avoids multiple injections of drug. The pump will typically be left in place for four weeks to induce increased blood pressure. Typically, after four weeks the animals will have their blood pressure monitored using a tail cuff measurement and will then be put under

anaesthesia to have their heart function monitored by echocardiography (this is a non-recovery procedure).

To investigate the cardiotoxic effects of anti-cancer drugs, the same process will be followed, except minipumps will be filled with the appropriate anti-cancer drug of choice.

To investigate the effects of cobalt, animals will receive daily doses of cobalt chloride over a period of up to four weeks. Age/weight matched controls will receive daily doses of vehicle (e.g., sterile water). At the four week time point (if not before), blood pressure and heart function will be monitored as described above.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals receiving angiotensin II will gain less weight than an age-matched control and possibly lose some weight compared to their pre-treatment weight. They will develop high blood pressure and the contractility of the heart will be impaired. There can be some variation in the extent of these signs, similar to what would be observed in humans. If significant signs of ill health (due to chronic elevation of blood pressure) are seen, the animal will be used immediately with a terminal procedure (echocardiography) if possible or humanely killed.

Animals receiving anti-cancer drugs may gain less weight than age-matched controls and possibly lose some weight compared to their pre-treatment weight. There may be an increase in blood pressure and an impairment of heart contractility, however this is only likely to happen towards the end of treatment duration. Animals receiving cobalt chloride may experience some discomfort through repeated daily injections but this will be minimised through good handling practise and injection technique. The cobalt treatment at the dose and duration given is not likely to cause any obvious impact on animal weight gain. There may be a small impact on heart contractility but this is not likely to be significant and if it does occur, is only likely to be towards the end of the treatment duration.

Both blood pressure measurements and echocardiography are non-invasive procedures. Animals will need to be anaesthetised for echocardiography in order to keep them still to gain accurate monitoring of the heart. There may be temporary minimal discomfort during the induction of and recovery from anaesthesia but it is very short-lived.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the severity will be moderate for the animals injected with angiotensin II, anti-cancer drugs or cobalt. Severity should be mild for control animals injected with vehicle saline solution.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to obtain cardiac tissue or cells from patients with cardiovascular dysfunction or heart failure since these patients are already very ill. Even if biopsies were possible, the amount of tissue available would be far too small to enable sufficient data to be generated. The use of an animal model ensures that the physiological features of cardiovascular disease in humans can be mimicked and also ensures sufficient heart tissue can be analysed. We can therefore study both the progression of heart disease and importantly, the effects of targeted intervention strategies.

Which non-animal alternatives did you consider for use in this project?

Where possible we will use commercially available cardiac cells (e.g. cardiac fibroblasts) to gain information however, the data we can retrieve from these is limited. We cannot source adult cardiac myocytes since these are not commercially available and we would be restricted to using neonatal or progenitor cells. We will use these alternatives wherever possible. At present, after checking databases such as Altweb and AltBIB we have not found non-sentient alternatives to our experimental needs.

Why were they not suitable?

For this project, it is essential to gain in vivo information on cardiac dysfunction for correlation to the human patient and we cannot gain that from isolated cells. Also any data examining progression of CVD or CTX in terms of mechanism of action must be performed on adult cells and tissue. Using the cardiac myocyte cell types that are commercially available restricts us to non-adult models and therefore poses major limitations in data interpretation. By using cells in general, we are also restricted in examining disease progression in any detail. We can only monitor relatively short-term effects. Cells kept in culture will change appearance and function over time and therefore any interpretation of data is more limited. Using cells in culture also means we cannot gain information on whole heart function which is far more complex.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated our animal numbers based on our previous work using a surgical model of heart disease, as well as our previous work using infusion of cardiotoxic anti-cancer drugs or cobalt. We have used the minimum number of animals we need to show meaningful statistical differences between experimental and control groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

NC3Rs EDA as well as advice from our University statistician, basing the numbers on our previous experimental work. We have ensured that as much cardiac material as possible is used from each animal to enable several experimental outputs and a reduction in the overall numbers needed. The heart tissue from each animal will be sectioned into different parts, each of which can be used for different types of assessment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For some experiments, tissue will be divided into a number of samples and prepared in specific solutions for long term storage. This will allow experimental analysis of a number of different parameters over a period of time from one animal. It will also enable several investigators to work with the same animal. If we are isolating cardiac myocytes from an animal, there will be a sufficient number of cells to ensure these are given to several investigators on the day of isolation and this will ensure multiple outputs from one animal. We will also ensure that, where appropriate, we share material from each animal. For example, researchers working on pulmonary tissue and vessels can dissect these from our rats and researchers working on brain can dissect this from either mice or rats once we have the heart removed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a rat or mouse model of chronic Angiotensin II infusion. Angiotensin II is a hormone produced in the body that is important in regulating blood pressure. The infusion model in rats or mice is a well recognised model and will mimic the progression of increased blood pressure and resulting effects on the heart that are seen in people with cardiovascular disease. Our previous work has used different surgical animal models of heart disease however, these have been invasive and there is always a risk of animal mortality due to the surgical procedure. The Angiotensin II model involves a straightforward placement of a mini-pump under the skin of the animal and this circumvents the need for invasive procedures with less likelihood of adverse effects due to surgery.

For studying anti-cancer drug-induced cardiotoxicity, we will also use a mini-pump implant and, based on previously published work by ourselves and others, will use the lowest concentration of anti-cancer drugs known to induce an effect on the heart. For cobalt-induced effects we will typically use daily injections of cobalt chloride, again at the lowest concentration known to induce an effect on the heart. This will ensure there is the lowest level of harm and distress to the animals.

Why can’t you use animals that are less sentient?

For this work we need to mimic the effects that are seen in human beings with heart disease or human beings who have had chronic treatment with anti-cancer agents or exposure to cobalt. These are invariably adults, usually older adults. A model that is less sentient would not be relevant to this study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use refined procedures that have been developed by us and by colleagues at other institutions and we will monitor the animals daily. Animals are given pain relief for mini-pump implant and are monitored daily post-operatively until fully recovered. Animals will normally be housed with a 'buddy' or "buddies" (conspecifics) for the duration of the experiment to improve overall welfare. If any of the experimental animals show signs of ill-health and deterioration that cannot be reversed, they will be used in early terminal procedures (echocardiography and tissue harvesting) or will be killed humanely.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Any relevant NC3R publications within the cardiovascular field will be adhered to. We will also take regular advice from colleagues who are working with the same models at other institutions in the UK.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will check the NC3Rs website regularly and will gain information from our Named Information Officer (NIO). We will attend any relevant NC3R research days or conferences.

174. Prenatal Therapy for Fetal and Obstetric Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

therapy, fetal, genetic disease, stem cells, gene therapy

Animal types	Life stages
Sheep	pregnant, neonate, juvenile, adult
Guinea pigs	pregnant, embryo, neonate, juvenile
Mice	embryo, pregnant, neonate, juvenile, adult
Rats	embryo, pregnant, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We are developing safe and effective methods of delivering treatments using stem cells, genes and drugs/proteins to the fetus and placenta, to reduce disability and death from congenital diseases such as thalassaemia, haemophilia, metabolic liver conditions and obstetric conditions such as fetal growth restriction, pre-eclampsia, gestational diabetes, preterm premature rupture of the membranes and preterm birth.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these

could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many fetal and placental problems are related to genes. Genetic abnormalities may be parentally inherited e.g. mutations causing thalassaemia, a disease of the blood causing anaemia and fatigue in affected people. Alterations in placental genes and/or blood supply can produce abnormal protein levels, which may severely limit fetal growth. Genes can be packaged into viruses or artificial carrying systems (vectors), which insert into host cells. The incorporated genes work within the cell to correct abnormal gene function or produce a therapeutic effect (gene therapy). Stem cells can regenerate, providing never-ending supplies of specialist cells, and can be modified by gene therapy before transplantation (stem cell gene therapy). Alternatively, proteins or drugs can be provided to the mother or fetus to produce a therapeutic effect. Delivering proteins, stem cells or gene therapy early in pregnancy, before the immune system has fully matured, may prevent the baby from developing antibodies against the vector, allowing it to function for longer.

We are targeting a range of life-threatening conditions that begin before birth, for prenatal treatment. Thalassaemia is the most common genetic disorder in many countries, and many affected individuals die in the womb or as teenagers. Metabolic liver disorders are associated with significant morbidity and mortality in the neonatal period (e.g. Ornithine Trans-Carbamylase Deficiency) or later in life (eg Wilson's disease). Approximately 1:10 babies fail to achieve their growth potential in the uterus (growth restricted) usually because of a lack of maternal blood flow to the uterus and placenta, limiting the supply of nutrients and oxygen. Sometimes mothers develop gestational diabetes leading babies to put on too much weight, a risk associated with stillbirth and preterm birth. Alternatively in some pregnancies, the membranes around the baby rupture early leading to problems of lung development and preterm birth. In these pregnancy conditions, fetal growth restriction, gestational diabetes and preterm premature rupture of the membranes, babies may be born preterm leading to conditions such as chronic lung disease, infections or cerebral palsy. Delivering treatment to the fetus or mother to treat or prevent these pregnancy conditions requires excellent diagnosis and safe, accurate imaging.

If successful, these therapies will transform fetal medicine and neonatal care, since there are currently no effective treatments for these conditions. Parents of affected fetuses are faced with two options: to terminate the pregnancy or to continue, knowing the baby will be severely affected growing up, or may die before birth. Prenatal therapy presents a third option to these parents.

Our aims are fourfold:

To identify the best stem cells, viral vectors and drugs, and determine when and how they should be given.

To deliver these therapies to animals with congenital or generated models of diseases such as thalassaemia, metabolic liver disease,, fetal growth restriction and gestational diabetes to establish which are the most effective for treatment.

To determine the long term effect of these therapies on fetuses born after therapy.

To develop new and improved ways to safely image the fetus in order to correctly diagnose and treat within the womb and to assess the effects of treatment.

Vectors, stem cells and proteins will be studied in the lab on cells, before being used in any animals, to reduce animal numbers. For these studies we will use congenital mouse models of human disease (up to 3950 animals in total) to demonstrate efficacy of therapy. We will also use guinea pigs (up to 300 animals) because their placental development is the most similar to humans when compared to other mammals, and rats (up to 400 animals) in which pregnancy complications can be generated. Finally, sheep (up to 250 animals), will be used as a way to demonstrate safety and efficacy as they have many similarities to humans in terms of fetal size, dependent on the breed, and development and a longer length of pregnancy than smaller animals such as rabbits. Where possible, vectors, stem cells and/or proteins will be delivered using clinically relevant minimally invasive ultrasound guided injection, that reduces animal suffering compared to large surgical cuts. We will use implanted catheters to monitor heart rate and blood pressure continuously, and which can transmit the data wirelessly to a nearby computer, allowing the animal to roam freely in their enclosure.

What outputs do you think you will see at the end of this project?

Many conditions that affect the fetus (baby in the womb) are currently untreatable. Collectively these conditions lead to a large burden of disease. Some of these conditions are genetic and life-threatening to the fetus and the newborn, such as haemophilia and thalassaemia that affect the blood, or inherited liver disease. Others severe conditions are obstetric disorders that develop in pregnancy. These include severe fetal growth restriction (FGR) where the baby is extremely small, gestational diabetes (GDM) where the baby grows too big, or preterm premature rupture of the membranes (PPROM) leading to preterm birth (PTB) before 37 weeks of gestation.

For many of these disorders, the only option for parents when a diagnosis is made, is to terminate the pregnancy or to accept an affected child. Our work will provide parents and healthcare givers with a third option, namely to treat the fetus before birth.

Preliminary work in small animal models has demonstrated cure of some severe genetic disorders using gene therapy before birth. Gene therapy involves the introduction of normal genes into cells in place of missing or defective ones in order to correct genetic disorders. Prenatal gene therapy would aim to provide treatment before birth. There may be risks involved in giving gene therapy to the whole fetus and this project licence will provide data on what those risks are. Alternative prenatal treatments include giving stem cells either on their own or in combination with gene therapy to the fetus. This project licence will therefore also tell us how effective these alternative treatments may be at curing severe genetic disease.

For obstetric disorders, work in small and large animals has shown that giving gene therapy to the mother's blood supply to the womb can improve fetal growth before birth. This project licence will provide us with safety and efficacy data to support a clinical trial of this new type of therapy. We will also find out how effective are patches to seal the fetal membranes, to prevent preterm birth after fetal treatment or PPROM, and if we can improve excess fetal growth in gestational diabetes.
Finally all diseases in the fetus need better ways to image and make a diagnosis. We will be testing out the accuracy and safety of new imaging techniques to improve our ability to identify diseases before birth.

Overall the work in this PPL will advance the field of knowledge further in fetal therapy, with significant outputs in terms of publications, patents, conference presentations and

data for regulators to support the clinical development of new devices and drugs for fetal treatment.

Who or what will benefit from these outputs, and how?

The likely beneficiaries of this research are patients, i.e., both parents and fetuses/newborns, that are subject to a pregnancy complicated by genetic, obstetric and vascular disorders like Fetal Growth Restriction (FGR), Gestational Diabetes (GDM), Haemophilia, Metabolic Liver Disease, preterm premature rupture of the membranes (PPROM) for example.

For FGR, we are currently developing a first-in-human clinical trial (phase I/IIa) to assess the safety and efficacy of a new drug to improve growth of very small fetuses before birth. FGR complicates around 8% of all pregnancies and is severe in around 1 in 500. We have already demonstrated in FGR sheep and guinea pig pregnancy that this drug improves growth without any safety concerns. The pharmaceutical regulatory authorities (EMEA and MHRA) have reviewed our plans to translate the VEGF gene therapy into man. Before we do so we have been advised by the Medical Research Council to whom we have successfully applied for funding, to test out the proposed clinical Drug Product in further FGR guinea pig pregnancies. This will generate further safety and efficacy data with the Drug Product that will be used in the clinical trial and to better understand the dose response.
Further data on the mechanism of action in mouse models of FGR will improve the chances of this therapy getting through the regulatory procedures. The clinical trial would commence in 2 years' time if successful. The beneficiaries would be fetuses, newborns with FGR and their parents.

For genetic diseases such as haemophilia and thalassaemia, we are working with collaborators who have small and large animal models of disease. If cure is demonstrated, we will apply for stem cell developmental pathway funding support (MRC) to develop the toxicology package and first in man study, with a timeline of 5 years. We will also investigate the therapeutic potential of stem cell and gene therapy in congenital metabolic liver disease including disorders of the urea cycle (e.g. Ornithine Trans-Carbamylase Deficiency; OTCD), the arthrogryposis, renal dysfunction and cholestasis (ARC) syndrome, mucopolysaccharidosis (MPS) and Wilson’s disease. Treatment of these conditions is currently limited to newborn gene or stem cell therapy if available, or palliative enzyme replacement which does not improve outcome. Because the pathology of these conditions begins before birth, newborn treatment is too late. Increasingly clinicians are considering treating the fetus before birth. This is particularly because non-invasive prenatal diagnosis is becoming available for many congenital disorders, which increases the safety of diagnosis. Mouse models of OTCD, ARC syndrome and MPS are available locally, and we have established a collaboration with a US group that have extensive experience with fetal gene therapy in murine Wilson’s disease. If a beneficial effect of stem cell and gene therapy is demonstrated in this setting (timeline 3 years), we plan to investigate these interventions in large animal models of liver disease (sheep).
For amniotic membrane rupture, currently during fetal surgical procedures we use small needles or telescopes called fetoscopes to apply therapy to the fetus. It is possible to plug the defect in the amniotic membrane after surgery with human platelets. But this is associated with a 16% stillbirth rate and the seal often does not work, leading to ruptured membranes or PPROM. This complicates around 30% of fetal surgeries and results in preterm birth. We would like to develop a better approach using a novel protein system that rapidly coalesces with amniotic fluid to form a seal. If successful, we would need to

get regulatory approval for this approach and test out safety in humans, with a timeline of 5-8 years.

To improve fetal therapy we have developed some novel needle tracking devices which can more easily identify the needle tip when it is placed into the fetus during ultrasound-guided fetal surgery. We are also studying a new way to image small blood vessels in the placenta, to improve diagnosis and treatment of placental disorders in twin pregnancies.

How will you look to maximise the outputs of this work?

We aim to maximise the outputs from this work by collaborating with a wide variety of experts both in the UK and internationally to avoid duplication of effort. We will be seeking feedback/inputs from the regulatory authorities such as MHRA at all steps towards clinical translation with the ultimate aim of taking these therapies and devices into the clinic.

We will disseminate the knowledge gained from these studies in conference proceedings, publications and will also publish unsuccessful experiments/methodologies. Our research team frequently publishes in high impact journals (Stem Cells Development, Molecular Therapy etc) and we have regular meetings with a patient public engagement group via the GIFT-Surg project (Wellcome Trust/Engineering and Physical Sciences Research Council funded) at which we present the findings of the research into optimising imaging and prenatal therapy. With them we take into consideration their advice on how best to translate findings into the clinic.

Species and numbers of animals expected to be used

- Sheep: 250
- Mice: 3950
- Rats: 400
- Guinea pigs: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using various types of animals (mice, rats, guinea pigs and sheep) to develop novel clinical therapies to treat serious congenital (inherited) disease and diseases affecting pregnancy. We have chosen specific types of animals because they provide particular advantages and have similarities to human pregnancy and fetal development in the womb before birth.
Many genetic (inherited) models of human disease can be generated in mice making it possible to test out how effective a novel treatment might be, before moving to clinical trials in humans.

Specific types of pregnancy complications such as fetal growth restriction can be generated in mice, rats and guinea pigs. In addition, the guinea pig placenta has the closest structure to the human placenta of all small mammals. This means that experiments in guinea pig pregnancy provide invaluable data on how effective a treatment

might be on the human placenta. Such data can also be used to inform the regulatory authorities about the safety of a new treatment.

Finally pregnant sheep have a much longer length of pregnancy than rodents (maximum 65 days) which is closer to the length of pregnancy in humans (145 days in sheep versus 266 days in humans). They also tend to have only one or two offspring, similar to humans, whereas rodents usually have at least 3-5 pups. The physiology of fetal development in the sheep is also very similar to human fetal development. Therefore data on fetal development, fetal growth and gestational age at delivery are highly relevant in answering how safe and effective a potential clinical treatment might be in humans.

We plan to study pregnant animals as we are developing treatments for diseases of the fetus, placenta and mother in pregnancy. We shall also study the offspring of these treated pregnancies to get important data on long term safety and effectiveness.

Typically, what will be done to an animal used in your project?

Typically animals will undergo procedures under general anaesthetic. Before a procedure, sheep will not eat overnight to reduce the chance of vomiting. For guinea pigs where there is a risk of vomiting, access to food will be restricted for a few hours only to limit any harms. Animals will have free access to water. Pain relief will be given to aid recovery of the animal after surgery. This will include local anaesthetic injected subcutaneously to the wound and buried sutures to reduce pain. Animals will receive intravenous antibiotics to reduce the risk of infection.

Specifically in Protocols 1 and 2 we will study the effect of stem cells, gene therapy or drugs/proteins that can improve their effect in pregnant sheep (ewe) or fetal sheep. The stem cell and gene therapy treatments will be delivered to the ewe or fetus using either ultrasound image-guided needle injection or surgical procedures under general anaesthesia. In Protocols 1 and 2 some ewes with their fetuses will be humanely killed before birth.

Some ewes will deliver their lambs and these lambs will undergo further minor procedures in Protocol 3 to understand about the safety and effectiveness of the stem cell or gene therapy after birth (blood sampling, liver and bone marrow biopsy, immune response, semen collection). These procedures are either associated with minor short-term pain (blood sampling, immune response, semen collection) or are performed by needle biopsy under local anaesthesia (liver and bone marrow biopsy). All lambs will be humanely killed by two years of age.

For Protocol 4 we are studying the effect of novel treatments in fetal sheep to seal the amniotic membrane around the fetus in utero to try to prevent preterm birth. Under general anaesthesia we will create small holes in the amniotic membrane either using small telescope instruments or through surgery. We will then test sealing of the hole / defect using tissue-engineered cells in combination with drugs, materials, nano-particles or other substances to improve stem cell engraftment or patch incorporation into the membrane. In Protocol 4 ewes and their fetuses will be humanely killed before birth.
In Protocol 9 we will test out novel minimally invasive imaging, sensing, and tracking devices in pregnant sheep to improve the safety and effectiveness of fetal therapy. Procedures will be done under general anaesthesia with analgesia and antibiotics to prevent infection, and all ewes and their fetuses will be humanely killed before birth.

For all the sheep protocols (1-4 and 9), image-guided needle injections take only a few minutes to perform and rarely cause maternal or fetal post-operative pain, post-operative infection and stress. The surgical procedures will involve either placement of catheters through small holes or by making incisions in the animal to deliver the interventions. This is associated with maternal post-operative pain, infection and stress in <5% of animals. The fetal complications are infection, procedure related mortality of <5% and preterm birth of around 5-10%. Sheep will receive pain-relief and antibiotics during and after the procedures to reduce these harms.

Specifically in Protocol 5, we will generate obstetric complications such as fetal growth restriction (FGR), pre-eclampsia (PET) and gestational diabetes (GDM) in pregnant mice, rat or guinea pig dams, either because they occur through a genetic mutation in the mouse or by techniques such as reducing or increasing dietary intake, reducing oxygen level or reducing blood flow to the uterus, or administration of some drug substances. Under general anaesthesia we will then test out gene therapy or drugs that may increase fetal growth, reduce maternal blood pressure and poor sugar metabolism to try to improve both maternal and fetal outcome. In Protocol 5 some dams and their fetuses will be humanely killed before birth.

In Protocol 6, we will study pregnant mice dams with genetic mutations that recapitulate severe human genetic diseases. These genetically altered pregnant mice will be bred under Protocol 8. Under general anaesthesia we will then deliver stem cells to the fetuses to try to improve both maternal and fetal outcome. In Protocol 6 some dams and their fetuses will be humanely killed before birth.

In Protocols 5 and 6 minor degrees of maternal post-operative pain, post-operative infection and stress may occur in <5% of animals. The fetal complications are procedure related mortality, infection, vector or stem-cell related toxicity, pain and stress, which are likely to affect up to 10% of animals.

Some dams from Protocols 5 and 6 will deliver their pups to allow long term monitoring of the safety and effectiveness of treatments in these offspring under Protocol 7. Animals will undergo blood sampling or intravenous catheterisation which carries minimal harm and pain. Some animals may undergo ultrasound, magnetic resonance, X ray and bioluminescence imaging procedures under short general anaesthesia which is associated with minimal harms such as stress. Some animals may undergo short surgical procedures under general anaesthesia to place catheters for monitoring or one liver biopsy. Potential associated harms are post-operative pain, infection and stress in <5% of animals which will be relieved using analgesia and antibiotics. Pups will be followed up to one year of age before being humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Major maternal complications are short-term and are related to anaesthesia such as cardio-respiratory depression, inhalation of regurgitated rumen contents and dehydration. Minor degrees of maternal post-operative pain, post-operative infection and stress may occur medium term (eg 1-2 days). Long-term effects (weeks to months) are not expected to occur.

The short-term fetal complications are procedure related pain, mortality and miscarriage (most commonly due to infection). The fetus may experience medium or long-term adverse effects related to gene therapy or stem cell related toxicity, pain and stress.

The Named Veterinary Surgeon will be advised of any major adverse events and advice will be taken on suitable management.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities are moderate for most protocols in sheep, rats, mice and guinea pigs that undergo surgical interventions. For the protocols that include neonates born from other protocols, the severity is mainly mild.

On the basis of past experience, we anticipate that maternal complications in sheep, guinea pigs, rats and mice will occur in less than 5% of procedures. Fetal survival varies according to the protocol and will be >95% in large animal experiments, >85% for guinea pig and around 50-60% for transgenic mouse experiments.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We consider the use of animals to be unavoidable. It is not possible to test our hypotheses in cell culture since we are testing an effect on for example, fetal growth and size, or for example, an increase in circulating concentrations of clotting factors, rather than individual cells in culture. Similarly data on safety of our potential therapeutics needs to be done in animals so as to measure both short term (eg bleeding) and long term (eg apoptosis, inflammation, organ damage) effects. This needs to be done in live animals to achieve our aims.

Similarly, the use of animals to establish device and technology performance of novel technologies is critical to inform development of next-generation medical technologies and to prove functionality prior to translation to the clinical arena. Our benchtop testing using tissue-mimicking phantoms is world- leading, yet elements of device function within the biological environment remain extremely challenging to satisfactorily assess without the use of animals. This includes the performance of elements in the blood pool, the system performance as well as assessing components in as close an environment to that of a clinical situation as possible. Only once such benchtop experiments are performed will we move to deliver our technologies to animal studies in vivo. Likewise, these animal studies are required before devices and technologies are delivered to human patients.

Which non-animal alternatives did you consider for use in this project?

We will be optimising drugs, vectors, stem cells and devices for this project first outside animals (in vitro culture, ex vivo tissues, tissue-mimicking phantoms) as much as possible, so as to reduce the use of animals.

All gene transfer vectors are extensively tested in vitro first, to determine if the vectors can infect cells and express the transgenic proteins. Initial testing is in immortalised mouse or human cell lines followed by testing in primary mouse cells and, where possible, primary human cells, after which there is testing in tissues taken from sheep or guinea pigs before moving to in vivo vectors application.
Similarly, with stem cells we will test these first in culture to determine their growth and differentiation characteristics. Only then will we move to deliver these to animals in vivo.

For the studies with devices we are able to perform detailed and comprehensive assessments of the performance of systems prior to approaching animal work. We will first test devices out in tissue- mimicking phantoms that have been 3D printed from organs, or use animal or human tissues. For example we have access to human placenta after birth via our hospital in which we have ethical approval to test out devices in the placenta ex vivo. We have also constructed phantoms using chicken or beef tissues from butchers.

Why were they not suitable?

Non-animal alternatives are not suitable for all our aims because our experimental readouts can only be obtained from living beings.

It is not possible to test our hypotheses in cell culture since we are testing an effect on for example, fetal growth and size, or for example, an increase in circulating clotting factors, rather than individual cells in culture. Cells in culture can give us focussed information on the effectiveness of a potential therapeutic in specific cells but not in the whole organ or animal.

For devices, we will need information on safety in live tissues such as tissue damage, inflammation, apoptosis thus ex vivo tissue is unsuitable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animal used include pregnant adults and lambs or pups born from those pregnancies that undergo postnatal follow up.

Sample size calculations have been conducted with statistical help from our clinical trials unit for experiments on fetal growth restriction, and will be based on previous observations of uterine artery blood flow and fetal size in sheep and guinea pigs. The calculation will include consideration of litter number and litter sex and will be based on the number of dams used rather than the number of fetuses treated, as recommended. This is because in these experiments the unit of treatment is the mother/dam and not the fetus. Where

possible, larger experiments using a contemporaneous control group are preferred to smaller experiments where a control group is used from the past.

In large animal experiments where the unit of treatment is the fetus and not the dam/mother, an initial experiment using five dams per group will be performed if we do not have data from previous experimental analyses for these transgenic animals. A retrospective power calculation will then be performed to test whether sufficient animals have been used per group. The experiment may then be repeated in order to provide sufficient power. The statistical test used will take into consideration factors such as litter size, and the number of homozygote affected fetuses or neonates. Generally where we are using gene therapy containing a human protein, the animal does not express the human protein. Therefore we expect an "all or nothing" response where either all animals express or none do. In this case n=10 animals is usually sufficient.

For transgenic small animal experiments we have done calculations on effect sizes based on previous data in these animal models. We will compare with contemporaneous control animals that do not have the genetic abnormality but have the same background.

For imaging and device and technologies developments, an individual animal can provide a wealth of data. Thus by carefully constructing operating procedures and protocols we are able to minimise the numbers of animals used for each experimental series. An initial series of experiments aiming to show technology functionality and informing future device iterations will be performed for each major technology development. 4 animals per group will be used for this initial experiment. Device design and functionality will be informed by these and new iterations extensively tested on the benchtop before returning to animal work. Experimental protocols will be performed on up to a further 10 animals to establish functional reproducibility and measurement consistency in vivo, thus establishing robust proof-of-principle and enabling planning for translation to the clinic.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, larger experiments using the same control group are preferred to smaller experiments where a control group is included each time.

In transgenic animal experiments, where we do not have pilot data, we will perform an initial pilot experiment using five dams per group and a retrospective power calculation will then be performed so as to refine /reduce the number of animals being used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have longstanding experience of working with pregnant animals for experimental use and will use our optimised breeding programs, that take care to ensure that animals are only bred when they reach their optimal weight and age.

For device and technologies developments, an individual animal experiment may be used to test a variety of devices in a carefully conducted series of experiments so as to minimise the numbers of animals used. Where possible we will also take tissues from a few animals (sharing of tissue) to use to test out devices ex vivo in the lab, so as to reduce animal numbers.

In addition to adopting efficient breeding strategies, we will maximise on the experimental readouts that we can obtain from each animal; such as harvesting/sampling tissues and organs widely and banking them so that they may be used for multiple studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We propose using the sheep fetus because the similarities between the sheep and human fetus in size and function make it the most widely used animal for studying fetal physiology and give clinical relevance to these experiments. Much developmental work has been done using cultured cells and rodents, but these data require validation before translation into clinical practice. However, issues such as gene therapy toxicity, length of gene expression and distribution of the resulting expressed protein can often not be addressed in small animals. We have extensive experience in working with pregnant sheep (22 years) and guinea pigs (14 years). During this time, we have refined the experiments to reduce morbidity, for example in sheep and guinea pigs we will minimise the animal suffering by using telemetric "remote" monitoring of implanted flow probes or catheters to measure blood flow or cardiovascular indices longitudinally. This allow animals the freedom to move around their environment without being troubled by monitoring devices. We have also developed ways to enhance the speed of recovery after general anaesthesia in sheep and guinea pigs by keeping our procedures short and by providing dietary enhancements (fresh lettuce for guinea pigs and nuts for sheep) to encourage eating after the anaesthesia.
For clinical application it is important to find minimally-invasive injection techniques to deliver gene, cell or drug therapy safely with minimal damage to the mother and fetus. This can only be achieved in a large animal of similar size to humans such as the sheep. Because these delivery techniques will be designed to produce the least trauma to the mother and fetus, there will be minimum suffering to the animals involved. It is likely that a total of 250 sheep will be used for this project over 5 years. In our experience fewer than 1 in 10 mothers or fetuses will experience some adverse event such as bleeding, infection or miscarriage. This has been achieved by paying attention to close clipping of the fleece and triple cleaning of the abdomen to reduce infection, providing intravenous fluids during surgery, and ensuring good analgesia through local subcutaneous anaesthetic to skin wounds. Lambs born after prenatal gene or stem cell therapy are usually healthy, and show no signs of having undergone any procedure. We will encourage the mother to suckle the lambs, but if unsuccessful we have access to frozen colostrum and can bottle feed them.

Fetal growth restriction (FGR) and gestational diabetes can be created in small animals and the underlying placental problem in these affected animals is similar to the human condition. It is not possible to study the effect on fetal growth in computer simulations or in cell culture and therefore animals are required. Suffering will be minimised by having a relatively mild nutrient restriction, in which we have found that animals often still have food

remaining in their cages. Although nutrient restricted guinea pigs are housed singly to ensure that the dietary intervention is correctly applied, we place the cages together so that the animals can see each other. We also provide straw to encourage nesting behaviours. The pups born after the FGR pregnancies are only moderately small and they catch up neonatally.

Pre-eclampsia mouse models experience moderate high blood pressure and some protein in the urine but no other adverse effects. Their pups may be slightly growth restricted but catch up postnatally. Gestational diabetes mouse models have pups that are slightly larger than normal pups, and they may develop moderate high blood pressure in adulthood, but no other adverse effects. We will try wherever possible to use less invasive techniques such as oral delivery rather than intravenous or intraperitoneal injection, and to avoid anaesthesia for non-invasive imaging such as echocardiography using ultrasound in guinea pigs. Refinements to our experiments in mice and rats include ensuring that general anaesthesia and surgeries are short, for example we will try to keep the total time for stem cell injections to no more than 30 minutes as we have found this reduces the fetal loss rate. We will also give local anaesthesia subcutaneously to abdominal wounds to improve pain relief and prevent the animals from pulling at the wound.

Heterozygote mice that carry the trait for congenital blood disorders do not show any abnormalities apart from a mild anaemia (thalassaemia mouse) and slightly prolonged clotting time (hFIX mouse). Homozygote thalassaemia mice (that carry both abnormal traits such as the humanized mouse model, are anaemic at birth but can be rescued by newborn blood transfusion, as in the human condition.
Homozygote haemophilia B mice are well unless they undergo trauma or surgery, in which case they require hFIX protein supplementation.

Heterozygote mice that carry the trait for metabolic liver disease (e.g. the ARC syndrome, MPS, Wilson’s disease) appear to be normal and exhibit no clinical (including ascites), biochemical or histological evidence of disease. Heterozygous females from the mouse model of OTCD are also normal (no clinical, biochemical or histological evidence of disease), but a few die soon after giving birth (due to the increased metabolic demands of the perinatal/postnatal period). Heterozygous OTCD mothers will be fed wet mash prior to parturition (from E16 onwards), and will be closely monitored in the early postnatal period (1-2 weeks). If there is any evidence of distress and/or weight loss (more than 10% of body weight) dams will be humanely killed.

In order to realistically demonstrate potential clinical functionalities, imaging and tracking technologies and devices must be tested in morphologies and dimensions similar to those found in the clinic. Although small animal models (e.g. rodents) may provide highly valuable data on limited aspects, larger mammalian models are required for complete validation, with distances and organ dimensions similar to that of humans. Sheep have a vascular and circulatory anatomy comparable to that of humans and thereby provide an excellent model. All our device work will be performed with the highest regard to animal welfare and every effort will be taken to minimise suffering and pain. Device experiments will be performed under terminal anaesthesia, with local anaesthesia used for skin incisions to minimise tissue reaction. The principles of the 3Rs (Replacement, Reduction and Refinement) will be adhered to. In particular, benchtop (non-animal and tissue-mimicking phantom) models will be used to the greatest extent possible before we move to animals, and the number of animals used will be kept to a minimum.

Why can’t you use animals that are less sentient?

As a majority of the experiments proposed need to be performed in adult pregnant animals to develop prenatal therapies, we are unable to use them at a less sentient stage of their life. Where possible, some experiments will be performed under terminal anaesthesia but for many we need to follow up animals after interventions to understand the effect of the intervention on their wellbeing, to study pathology and examine long-term outcomes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All experimental animals will be monitored 3 times daily on weekdays and 2 times on weekends. Pre- and post-operative analgesia (pain relief) regimens will be an integral component of all procedures, to keep animal suffering to a minimum. We will give antibiotics to reduce the risk of infection in animals that undergo major surgery. We will give local anaesthetic under skin wounds to reduce pain and suffering, and bury the stitches under the skin to avoid irritation.

We will try wherever possible to use less invasive techniques such as oral delivery rather than injecting the veins or peritoneal cavity. We will as far as possible avoid anaesthesia for non-invasive imaging such as ultrasound of the heart (echocardiography) in guinea pigs.

In each protocol, animals will be humanely killed if there are any signs of distress and/or significant reduction in body weight to avoid any distress secondary to deterioration in liver function or anaemia for example.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the published ARRIVE guidelines (https://arriveguidelines.org/arrive-guidelines) to ensure that experiments are conducted in the most refined way.

For example we will use published guidelines to develop the study design (Bate ST and Clark RA (2014). The design and statistical analysis of animal experiments. Cambridge University Press. https://www.cambridge.org/core/books/design-and-statistical-analysis-of-animal- experiments/BDD758F3C49CF5BEB160A9C54ED48706)

We will perform sample size calculations, randomly allocate animals to intervention or control groups, analyse data blind to intervention, use prior setting of outcome measures, use SAMPL guidelines to analyse and present data statistically (Basic statistical reporting for articles published in Biomedical Journals: The “Statistical Analyses and Methods in the Published Literature” or the SAMPL Guidelines; Michel MC, Murphy TJ and Motulsky HJ (2020). New author guidelines for displaying data and reporting data analysis and statistical methods in experimental biology. Mol. Pharmacol. doi: 10.1124/mol.119.118927).

We will report experiments according to ARRIVE version 2.0 (Reporting animal research: Explanation and elaboration for the ARRIVE guidelines 2.0 (Reporting animal research: Explanation and elaboration for the ARRIVE guidelines 2.0 https://journals.plos.org/plosbiology/article? id=10.1371/journal.pbio.3000411)

For best animal welfare we will follow the NC3Rs guidelines for all the rodent animals that we intend to use:

https://www.nc3rs.org.uk/3rs-resources/housing-and-husbandry-guinea-pig
https://www.nc3rs.org.uk/3rs-resources/housing-and-husbandry-mouse
https://www.nc3rs.org.uk/3rs-resources/housing-and-husbandry-rat
For sheep we will refer to RSPCA guidelines as NC3Rs only contains minimal guidance pertaining to blood sampling.
https://www.rspca.org.uk/documents/1494935/9042554/RSPCA+welfare+standards+for+sheep+%28P DF+10.3MB%29.pdf/e91f2d1e-4a04-30cd-5ed8-8f55da4513c6?t=1594889570996

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed of advances in 3Rs via the Home Office Liaison, as well as via the NC3Rs website and attending relevant seminars/talks. Wherever we find an opportunity to improve our technique/experimental design to minimise animal numbers and/or suffering, we will rapidly incorporate it into our protocols. We closely work with the BSUs at the establishments to discuss how we can improve our animal care, which ultimately improves our results.

175. Improving ruminant livestock production efficiency, quality, health and welfare

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
- Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

animal welfare, product quality, environmental protection, nutrients use efficiency, livestock production

Animal types	Life stages
Cattle	juvenile, adult, pregnant
Animal types	Life stages
Sheep	juvenile, adult, pregnant
Goats	juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project seeks to examine ways of optimising efficiency of ruminant meat production from predominately forage-based systems and the associated health and welfare of the livestock. It will examine methods of enhancing product quality, particularly in terms of healthiness, shelf life, hygienic quality, flavour, at the same time as reducing the impact of

these systems on the environment and ensuring farm-based strategies improve animal health and welfare.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Livestock farming, and particularly ruminants (sheep and cattle), is a major component of rural landscapes providing vital services to society through high quality nutrition, soil health, land management for biodiversity and leisure activities and supporting rural communities. But it also polarises society, more so than ever, with debate over animal welfare, impact of animal product consumption on human health and on the environmental footprint of livestock production. This debate is central to the sustainability of livestock farming systems with economic (e.g. production efficiency), environmental (e.g. methane emissions) and social (e.g. animal welfare) parameters and trade-offs widely used to define sustainability. With this project, we aim to address ways of making livestock farming more sustainable in all dimensions to contribute to the "net zero" target for 2050 and with healthier animals and more efficient farms.

What outputs do you think you will see at the end of this project?

Product quality

The research will contribute towards the production of healthier food in terms of a leaner product and which will contain lower quantities of saturated fatty acids and increased content of specific beneficial compounds (i.e. minerals, vitamins and n-3 PUFA) in meat. The role of meat in particular as a vehicle to deliver beneficial minerals, vitamins and fatty acids through to humans. Improved knowledge of the interrelationships between growth of an animal, its production conditions (e.g. grazing system) and subsequent effects on the eating quality of the meat (for example taste and colour) will improve the quality of the product, which is of benefit to the producer and the consumer.

Production efficiency and reduction of greenhouse gases

This work will contribute directly to the overall objective of reducing the output of waste (potential pollutants such as greenhouse gases) per unit of useful product.

Health and welfare

Improving our understanding of livestock systems, including animal health and welfare, has the potential to inform the development of best practice methods of farming. Methods that find synergies between health/welfare, economics, the environment, and society. Regular health and welfare checks will provide insight into risk factors across different systems, animals, and grazing management strategies.

Over the five-year period of the licence, we would envisage the production of 2-3 scientific abstracts to be presented at national and international conferences per year which in turn would be submitted to high impact journals with a total of 10-12 during the life of the project. We envisage the development of 2-3 specific product quality projects related to this licence, 3-4 on production efficiency and 1-2 on health/welfare which would, in turn,

have a pathway to impact for implementation by the farming community – such as decision support tools. We would hope to see these developed during the life of the licence, but some may take longer to implement.

Who or what will benefit from these outputs, and how?

Currently animal agriculture is perceived as inefficient and wasteful in terms of land and nutrient use, this programme of work will improve the efficiency of animal production systems and the quality of the final product. The outputs of this project are targeted and relevant at various levels of the food chain from, the farmer producer, to the meat processor, the retailer and the consumer. In particular, the improved ability to (1) feed ruminants under high forage input systems or sustainable protein systems (2) predict nutrient supply and (3) to manipulate production response will lead to improvements in agricultural efficiency both in terms of use of natural resources and in farm profitability (4) systems can be developed which will reduce incidence of animal disease and associated food pathogens. This will contribute to a reduced reliance on imported feeds, particularly imported protein sources, which is especially prudent following the recent and on-going problems in our industry. Improved knowledge of the interrelationships between growth of an animal and subsequent effects on eating quality (for example tenderness) will improve the quality of the product, which is of benefit to the producer and the consumer. This work will be also particularly important to (but not limited to) ruminant nutritionists (in academia and the livestock industry), agricultural and environmental research scientists, microbiologists and policy makers.

How will you look to maximise the outputs of this work?

The new knowledge generated as a result of this work will be disseminated to the scientific community by publication in peer-reviewed journals and presentation at national and/or international meetings. This will be disseminated to the funding agents, livestock bodies and major meat processors and retailers. We are part of a global network of research farms and we disseminate our findings in international workshops, webinars and conferences.

Data once published in high impact journals will be reported to funding agents to be used in future accreditation schemes and to develop farm-based interventions to improve the quality of meat, production efficiency and animal health/welfare– this could be in the form of decision support tools for the farming community. In particular, the improved ability to (1) determine sustainable supplies of protein to livestock industries, (2) predict nutrient supply and (3) to manipulate production response will lead to improvements in agricultural efficiency both in terms of use of natural resources and in farm profitability. This will contribute to a reduced reliance on imported feeds, particularly imported protein sources, which is especially prudent following the emission targets for 2050. Dissemination to the farming community will occur through interactions at farming events and shows, and through direct interactions with farmers through technology interaction events and farm visits. The translation of scientific results into practical on-farm applications is a key part of the work to be carried out.

Species and numbers of animals expected to be used

- Cattle: 1000
- Sheep: 600
- Goats: 60

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For some of this work there is a requirement to measure various combinations of feed intake, rumen fermentation parameters, product quality, animal health and welfare indicators, and nutrients partitioning between productive (growth and product) and excretion (urine and faeces) purposes. These data can only be collected from live animals, and for the purposes of measuring parameters in relation to meat production there is a clear need to use ruminant livestock (cattle, sheep, goat) in the growing and breeding phase.

Typically, what will be done to an animal used in your project?

Typically, (70%) animals under objectives covering growth performance and product quality and production efficiency will receive 3-4 of the steps stated in the protocol, in rarer cases (10%) animals will experience 4-6 of the steps stated in the protocol or in extreme cases (<5%) animals will have greater than 6 steps. Typically, (80%) of the animals under the health and welfare objective will have a greater number of invasive steps from 4-5, and rarer occasion (10%) 6-7 steps.

The steps are as follows:

Altered housing: animals may be single housed or individually penned, housed in individual 'Chamber', or housed on slatted floors, for a maximum of 12 weeks with a minimum of a days rest for every day penned before the animal can be considered for re-penning. Animals will have sight and sound of other animals

Withdrawal of blood by superficial venepuncture – may be from a one-off sampling for DNA extraction to typically one sampling at the beginning of the assessment period and at the end, with some samplings potentially taking place in the middle

Application of electronic ear tags for monitoring location (GPS) and/or behaviour.

Variation in the composition, constituents, quantity or availability of feed, variation in the composition or constituents of water - typically up to 12 weeks of assessment followed by a resting period of at least two weeks

Administration of substances (e.g. digestive markers, gas tracer, additives) in feed, drinking water, bolus, using a dosing gun for boluses or drench (dosing one bolus up to twice a day for up to two weeks, drenching once a day for up to 9 weeks)

Attachment of harness and separation apparatuses for the collection of urine and faeces - typically for short periods of up to 5 days followed by a resting period of at least one week

Attachment of halters/collars for emissions measurement or tracking position - typically halters for emissions measurement will be attached for periods of up 2-3 weeks followed by a resting period of at least two weeks; collars with GPS sensors can be attached for up to 8 months (during the grazing season).

Manual grab sampling of faeces from the rectum - a maximum of twice a day for up to five days, followed by a resting period of four weeks

What are the expected impacts and/or adverse effects for the animals during your project?

Altered housing: animals may not adapt to the altered housing and may suffer acute stress in the short term until they adapt to the new environment (up to 100% of the animals). Animals may show signs of distress (up to 100% of animals) or stiffness from the slatted floor of the refinement pens (<5% of animals), temporary foot problems or pressure sores from hard floors (<5% of animals).

Withdrawal of blood by superficial venepuncture: in rare cases haematoma formation may occur (<1%).

Application of electronic ear tags: in rare cases haematoma formation may occur (<1%).

Variation in the composition, constituents, quantity or availability of feed, variation in the composition or constituents of water: animals may lose weight (>10% BW) and fitness (<1%).

Administration of substances (e.g. digestive markers or additives) in feed, drinking water, bolus, via dosing gun or drench: animals may show signs of metabolic disorders as a result of the substances (<1%).

Attachment of harness and separation apparatus for the collection of urine and faeces: animals will initially show signs of distress and discomfort (100%).

Attachment of halters/collars for emissions measurement or tracing position: animals getting sores/infection where poor fitting halter/collar causes abrasion of the skin (<5%).

Manual grab sampling of faeces from the rectum: damage to the anal sphincter may occur on rare occasions (<1%).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of the animals will experience little more than standard farming procedures. All procedures are not expected to exceed mild in severity (e.g. blood sampling, nasal swabbing and faecal grab sampling). At the end of the trial animals will be signed off the Animals Act before being returned to flocks/herds or sent for commercial slaughter.

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For some of this work there is a requirement to measure various combinations of feed intake, rumen fermentation parameters, product quality, animal health and welfare and mineral (particularly N) partitioning between productive (growth and product) and excretion (urine and faeces) purposes. These data can only be collected from live animals, and for the purposes of measuring parameters in relation to meat production there is a clear need to use ruminant livestock.

Which non-animal alternatives did you consider for use in this project?

For other areas of work in relation to ruminants for screening additives for their impact on rumen metabolism or pathogens or digestibility of feeds, in vitro measurements of rumen function will be carried. In vitro rumen function studies are carried out using gas production [Theodorou et al., 1994] and rumen simulation techniques [Czerkawski and Breckenridge, 1977]. Much of this work is being carried out as a direct replacement for use of live animals with rumen fluid obtained from an abattoir. Therefore, the use of in vitro analysis replaces the need for greater numbers of animals for direct measurements of rumen function.

Why were they not suitable?

No answer provided

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on the number of cattle used in the Project License no P592D2677 (just below 1000 animals) I consider a similar number will be required for the next five years. For the sheep, I have considered an average of 120 sheep per year which is aligned with the capacity we have in our Small Ruminant Facility (SRF) for detailed intake and nutrients use efficiency studies (three or four trials a year of 24 sheep each in the BioControl pens) with some sheep being assessed outdoor with gas tracers and halters for measuring methane. For goats I have used the maximum capacity of the SRF for hosting goat in one year.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We operate standard quality assurance procedures (i.e. the BBSRC/Defra/FSA Joint Code of Practice) and we have incorporated PREPARE and ARRIVE guidelines for preparing and reporting research activities. Statistical advice is sought (from statisticians) on all experimental protocols to ensure that maximum information is obtained from the minimum

resource. An experimental protocol is prepared for each experiment as part of good laboratory practice, and amongst other information each protocol includes:

a statement of objective(s) a description of the experimental procedures, covering matters such as the number of animals required for the experiment, a description of experimental treatments, and the arrangement of treatment allocations (statistical design)

an outline of how data will be collected, and an indication of the analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Some experiments will comprise a combination of in vivo and in vitro techniques to enable more detailed studies of rumen fermentation to be carried out without the use of animals beyond the provision of rumen fluid. In vitro work is essential when using genetically modified plant material, because this cannot be fed to animals due to legislation and because the small amounts of plant material typically available for study are most suited to in vitro study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For much of the work to be carried the effects of treatments on feed intake, production, animal health and welfare, composition, and/or nitrogen and methane excretion in/from specific animal groups (e.g. sheep or cattle) is required. The use of specific breeds will be governed by current practices in the UK so that the results represent current farming. Therefore, these animals are most suitable and refined for use in this work. Before selecting specific animals for trial work their temperament will be assessed as noted by farm staff to ensure the most appropriate individuals are selected to minimise distress whilst on trial.

Why can’t you use animals that are less sentient?

For some of this work there is a requirement to measure various combinations of feed intake, rumen fermentation parameters, product quality, animal health and welfare and nutrients partitioning between productive (growth and product) and excretion (urine and faeces) purposes. These data can only be collected from live animals, and for the purposes of measuring parameters in relation to meat production there is a clear need to use ruminant livestock.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As soon as the animals arrive on site and have acclimatised to their new environment, they will be frequently handled to minimise any stress caused by sampling during the experiment. The handling facilities, weighing platform and crush to be used for the procedural interventions, e.g. blood sampling, faecal grab sampling, bolusing, are close to the animals' housing or where they will be grazing so minimal stress will be incurred moving animals. The animals will be acclimatised to going through the handling facilities and crush without anything occurring to minimise stress when procedures are actually carried out. The cattle and sheep will be trained to halters and any other piece of equipment fitted to the animals (e.g canisters, tubing, GPS sensors) for the purpose of measuring greenhouse gas emissions and tracking location.

All sampling will be conducted on as few occasions as possible consistent with the scientific objectives of the project. Animals will be assessed daily for health and well-being, as determined by alertness, feed and water intake. Any sign of ill health will be reported to the Veterinary surgeon with the animal being removed from trial if symptoms persist and appropriate treatment provided.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow NC3Rs, PREPARE and ARRIVE guidelines.

Also, Norecopa maintains a "Refinement Wiki" (https://wiki.norecopa.no/index.php/Main_Page) with contributions from scientists and animal carers worldwide, which provides a platform where methods for the refinement of animal experiments can be published. This webpage will provide up to date refinement options.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will periodically check the relevant websites and platforms supporting and promoting the "3Rs" (e.g. https://nc3rs.org.uk). I will keep the relevant guidelines ARRIVE and PREPARE at hand and will circulate them among the researchers and technicians taking part of the project.

I will make all the staff involved in the research activities carried out under this project of the latest guidelines and recommendations issued by the relevant sources (e.g. RSPCA, Home Office, Royal Society of Biology, NC3RS). All the research protocols designed for any specific experiment will have a section of Reduction, Replacement and Refinement to be assessed by the PPL, PIL, NACWO, NVS and the Statistician.

176. Crosstalk between inflammation, cell death and cancer

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cell death, autoimmunity, inflammation, cancer, therapy

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To investigate how small messenger molecules called cytokines and immune signalling pathways are contributing to inflammatory diseases and tumorigenesis and how inhibitors affect these pathways.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cell death and inflammation are important processes which are constantly happening in our body. Yet, they need to be well regulated and require a tight control so that their beneficial effect is not turning into a maleficent happening. Upon infections or mechanical damage such as injury of skin or organs our immune system reacts by causing an inflammation and immune response against that damage and the tissue repair system will

eventually restore normal conditions after the healing process is accomplished. Cell death which can occur either unwanted as a negative side effect in an organ/skin injury scenario or as a wanted process to kill e.g., viral infected cells, plays an important role in this process. Too much cell death or an overshooting immune response in our body can result in a reaction against itself and thus can cause a variety of diseases such as autoimmunity, autoinflammation and cancer. Still, the mechanisms leading to these deregulated events mentioned above are poorly understood. In order to develop new drugs for these diseases, it is essential to understand their origin i.e., what is causing the deregulation of events and to characterise the key components involved in this, their activities and how they interplay. To this end we will study how inflammatory and immune pathways correlate with cell death and genes controlling the formation of cancer. In addition, we intend to evaluate the effect of potential inhibitors for specific proteins or activities within a protein that are key for the regulation of such pathways.

What outputs do you think you will see at the end of this project?

The major benefit of this project is that the gain of knowledge on the involvement of tumour necrosis factor (TNF) and other cytokines and immune receptor signalling in the development and/or treatment of cancer and auto-immune diseases such as Crohn's Disease (CD), psoriasis or Rheumatoid Arthritis (RA), and immunity to infections is likely to result in the development of new therapies for cancer as well as chronic inflammatory, auto-immune, and infectious diseases. This project will lead to high impact factor scientific publications that will directly impact the basic research field of immunity, inflammation and cancer by providing mechanistic insight into the molecular pathways regulating key physiological functions such as cell death, survival and associated inflammation.

Moreover, findings of this project will provide fundamental insights for drug development and will consequently impact the clinical field in the long term. Furthermore, these findings could be used diagnostically to predict whether certain immune stimuli, cytokines, immune receptors, or molecules involved in their signalling pathways should be blocked or whether they should instead be employed together with other drugs to reach beneficial therapeutic effects in the above-mentioned diseases.

Overall, the study of genetically modified mouse models with defined oncogenic and/or immune signalling mutations is of great importance for medical research as findings from this project could be harnessed therapeutically in the future.

Who or what will benefit from these outputs, and how?

In order to prevent or reverse life threatening diseases such as chronic inflammation, autoimmunity and cancer new therapeutic treatments are needed. The use of genetic mouse models is crucial to understand these pathways and to test potential inhibitors that could increase human and animal welfare and even be lifesaving.

How will you look to maximise the outputs of this work?

We will be proactive in reading new literature for any new technologies or refinements to existing procedures/experiments. We will publish any new technologies or refinements to experiments we come across during our work. The studies undertaken under this project licence are often collaborations with people, across the UK, and Worldwide. If new collaboration opportunities arise then we will pursue them if they are the best fit for the experimental outcome. We will disseminate the studies undertaken under this project

licence to the scientific community through collaborations, peer-reviewed publications and talks at conferences.

Species and numbers of animals expected to be used

- Mice: 35000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For all investigational work in this project mice are the species of choice. This is due to the fact that the murine immune system and the different modes of cell death happening in mice are well-studied and many features are comparable to the human system. Furthermore, numerous well-defined models for all of the diseases we are aiming to investigate in this project are available. Using genetically altered (transgenic) mouse strains is currently the most effective way to investigate a specific gene function at the level of the whole animal. The application of commercially available products (specific inhibitors for different proteins, small molecules etc.) in our transgenic mice will allow us to investigate the murine immune system and its reaction/response at the most refined level currently possible and to translate our results into the human system.

Typically, what will be done to an animal used in your project?

Mice that have inducible genes that can be switched on or off, will be given inducers such as tamoxifen, either by topically, intravenous or subcutaneous, by gavage or drinking water, that enables gene expression control. Typically, this will be done once, up to several times, over consecutive days, before mice are engaged in the relevant experiment.

Therapeutic substances will typically be administered through routes such as oral gavage, injection or in the food or drink as required.

During survival studies, mice, including those that develop cancer, will be kept for their entire lifespan; that is, up until the humane endpoint - for example, maximum tumour size or the limit of acceptable deterioration of health through observable body scoring. Therapeutics may be given through routes such as oral gavage, injection or in the food or drink and at specific time points mice will be culled by schedule 1 or nonrecovery anaesthesia so that blood and tissue samples can be collected for examination. These can then be processed and analysed to determine whether genetic alteration or administered therapeutics have had any effect on the progression of the disease. Blood samples may also be taken periodically from these mice for pharmacokinetic studies.

Immune-deficient mice may also be injected with cancer cells, for example subcutaneously, and treated with therapeutics. These studies generally last 2 to 3 months and allow us to study the treatment and progression of cancers and the role of the immune system in cancer.
Mice that undergo a surgical procedure, are expected to make a rapid and unremarkable recovery from surgery, within 48hrs. Mice will be given analgesics to alleviate any pain

prior and post-surgery to aid recovery. Surgery will be performed only once unless an animal needs to be re-sutured.

Mice will also undergo relevant imaging modalities depending on the need they may undergo several imaging sessions. This means they will undergo several rounds of anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Weight loss - gradual over several weeks or more quickly over a few days. Not more than 15% of starting weight within deviation from the start of experiment.

Deterioration in general health caused by progression of disease such as inflammation or cancer as assessed by body scoring. For example, staring coat, laboured breathing and hunchback position that would last for no longer than 24hrs.

Some of the animal models we intend to use spontaneously develop an inflammation of the skin also known as dermatitis. If we are not able to revert this condition by genetic experiments or chemical/biological treatments the animals will be humanely killed as soon as they start to show signs of distress (hunchback position, excessive scratching, etc).

Other animals develop swollen lymph nodes; this condition is not harmful for the animal, and they will be either bred or used in experiments. Animals will be humanely killed as soon as enlarged nodules restrict movement or any other physiological condition. Some other adverse effects may arise by the application of chemical or biological substances into the mice. The animals will be closely monitored during these procedures and will be humanely killed as soon as they start to show signs of distress (hunchback position, lack of grooming, excessive loss weight, etc).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding and maintenance of genetically altered mice should generally cause no more than sub- threshold severity in the case of mice that produce phenotypes that have no clinical manifestation. In the case where phenotypes show clinical signs, they are generally mild and in the case of harmful mutants where tumours arise, mice will be culled before the onset of clinical signs such that breeding mice will not experience severity greater than mild or in a rare case moderate.

In the case where mice are injected with inflammatory substances, injected with cancer cells or develop spontaneous phenotypes with clinical manifestation, then mice will suffer no more than moderate signs of distress if the scientific endpoint is reached before the humane endpoint.

We should be able to generate and collect most of our data under a mild severity. However, if further data is required, then mice will be allowed to reach a humane endpoint where they will experience moderate signs of distress for no more than a day or two.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

All of the planned work with mice is generally preceded by intensive studies done in the laboratory with cell lines and organoids. Before carrying out any experiments in the mouse we will make sure to monitor for as many physiological conditions as possible in our various cell lines and organoids. Yet, although the in vitro work can provide important molecular and cell physiological insight it unfortunately cannot fully recapitulate the complexity of a pathophysiological situation in the context of inflammation and cancer in a mouse or a human.

Which non-animal alternatives did you consider for use in this project?

All of the planned in vivo work is generally preceded by intensive in vitro studies. Cell lines have been generated from the transgenic mouse strains. These include Mouse Embryonic Fibroblasts (MEF) from knockout mice and tumour-derived cell lines as well as tumour-derived organoids from GA mice engineered to express activated oncogenes and inactivated tumour suppressor genes. Human cancer cell lines and organoids with defined genetic alterations are also present. They will be monitored for migration, proliferation, and apoptosis as well as long term survival. Then, cytokine-of-interest blocking agents as well as RNA interference of particular factors will be tested on the cell lines and organoids. The use of matrigel in transwell assays can simulate extracellular matrix in an invasion assay.

Why were they not suitable?

The use of 2D and 3D cellular systems as well as co-culture with different types of immune cells, fibroblasts and endothelial cells cannot fully recapitulate the pathophysiological situation in the tumour microenvironment. However, it can provide important molecular and cell physiological insight and a justification for further in vivo work. In addition, the evaluation of the morbidity caused by inflammation in vivo is irreplaceable with the in vitro studies since the cell lines do not completely recapitulate the inflammatory circumstances in the tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice we would like to use for the experiments would primarily have been based on previous experiments or those performed in the literature or by collaborators. We have also looked at statistical analysis for numbers of animals in experiments. In this way we are confident to produce meaningful scientific data with the least number of mice possible.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our preceding in vitro experiments are going to limit the number of animals required for the in vivo investigation as key components involved in inflammation and oncogene-driven cancer can be identified in 2D and 3D cell culture systems.

Mouse colonies will be closely managed by members of the group to avoid excessive breeding.

For every in vivo experiment we write a protocol which includes a statement of the objectives, a description of the experiment listing experimental treatments, number of mice per treatment group and the experimental material needed. Further reductions in the number of mice will be achieved by improved study design and statistical methods which will allow us to integrate and aggregate the data across multiple experiments thus achieving a statistical conclusion which makes additional experiments with animals superfluous.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Experiments will be conducted using inbred and gene-targeted mice on a C57BL/6 background, which is the most common and well-described strain. We have planned mouse crossings which are aimed at providing us with mice that carry up to seven different transgenes. In order to receive statistically significant numbers of mice carrying the respective phenotypes we calculated probabilities according to Mendelian ratios. We will cancel the breeding pair once the new litter will give us the mice with desirable genotypes. Long term experiments will be done using sufficiently large groups of mice per phenotype to reach statistically significant results. As the different groups will in some cases be composed of mice from subsequent litters from the same breeding pair, following cumulative analysis of the mice in each consecutive litter we will be able to determine statistical significance following final double-blinded analysis of each litter. Thereby we will perform the experiments using 4-25 mice per experimental group depending on the experimental design, in order to obtain statistically significant results. The data generated from regular monitoring of the mice (primary tumour formation or occurrence of inflammatory lesion, incidence, progression, metastasis formation, clinical score, inflammatory phenotype) will be analysed using the Log rank test on Kaplan-Meier representation. Data generated from tissue analysis will compare mutant mice to wild type littermates and will be evaluated by student t test. The proposed experimental design and methods of analysis of the results will be further discussed in detail with the Statistical Services Unit.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the

procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The overall plan of this work is to first, understand what leads to deregulated cell death, inflammation and inappropriate immune responses which can result in autoinflammation, autoimmune diseases and/or cancer and second, to develop novel therapies to benefit human health in targeting these diseases. For all investigational work in this project mice are the species of choice. Furthermore, numerous well-defined models for all of the diseases we are aiming to investigate in this project are available. Using genetically altered (transgenic) mouse strains is currently the most effective way to investigate a specific gene function at the level of the whole animal. The application of commercially available products (specific inhibitors for different proteins, small molecules etc.) in our transgenic mice will allow us to investigate the murine immune system and its reaction/response at the most refined level currently possible and to translate our results into the human system.

All of our procedures are designed to minimise pain to the animal as much as possible. Yet, certain procedures will have a moderate impact on the wellbeing of the animal. Thus, we have developed pre- defined endpoints to pre-empt and avoid the onset of any adverse effects and to keep the negative impact on their welfare as low as possible. These pre-defined endpoints take different parameters into account such as behavioural changes, body weight etc.

In the procedures where we induce tumours for instance the pre-defined endpoint is reached as soon as the tumour burden appears to impair its mobility and the mice show signs of distress such as lack of grooming and separation from the group.

In every procedure we try to keep the length of time for each experiment to a minimum.

Additionally, a close monitoring of animals throughout any kind of treatment or of those which are genetically prone to develop a phenotype will guarantee that they are not suffering excessive adverse effects.

Concerning the mice which are prone to develop diseases due to their genotype (e.g. the mice which develop inflammation of the skin), we have established a breeding strategy which allows us in many cases to delay or completely prevent the onset of disease by combining certain gene mutations thus contributing to the welfare of the animal.

In addition, the institute in which the animal procedures are carried out, runs a comprehensive health- monitoring programme. Animal health and welfare records are maintained to include any adverse effects that may develop, particularly in genetically altered and spontaneous mutant strains. Signs consistently associated with a particular phenotype/genotype will be recorded on the respective “information sheet” in the breeding area and the mice will be maintained under conditions where their health status can be protected as far as it is reasonably practicable.

Why can’t you use animals that are less sentient?

Mice are the species of choice in this project as the murine immune system and the different modes of cell death happening in mice are well-studied and many features are comparable to the human system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For protocols that require surgery, procedures will be carried out aseptically and post-operative analgesia will be given after surgical procedures to manage any pain.

Where the immune status of the animals might compromise health, they will be held in a barrier environment.

During breeding and experimental scenarios arise where mice find themselves individually housed (for example, litters with only one male, if mice need to be culled at different time, according to the humane endpoints points, during experiments). To minimise this from occurring, weaning will be managed to avoid singly housed animals wherever possible and mice that are of no scientific interest or are not required for breeding will be culled. In cases where singly housed males are to be kept for experimental or breeding purposes, post productive females will be sought as cage companions.

Breeding calculations will be used to maximise breeding schedules and minimize the number of animals needed for maintenance and experiments.

If protocols require anaesthesia, this will involve agents and methods suitable for the species as advised by the NVS. Depending on the anaesthetic regime used, animals will be ambulatory within a few minutes to 1hr of the end of anaesthesia. Supplemental heat and analgesia will be provided as advised by the NVS during surgery and recovery. Any animal which has not resumed normal mobility, eating and drinking by the end of the working day of surgery will be killed.

Mice will be observed to monitor the onset of any phenotype; weight, piloerection, abnormal breathing rate, skin turgor, behaviour, eye discharge and mobility will be checked as indicators of suffering. Any deviations from the norm, including the timing of the onset of suffering, will be monitored and used to predict future occurrences. If sufficient scientific data is obtained before the humane end point of the experiment is reached mice will be culled to prevent further suffering.

Suitable administered volumes and doses of therapeutics, immunogenic substances or cells will be determined by referring to our own, collaborators and published data. If suitable doses and volumes are not known, then pilot studies will be initially carried out. Pilot studies will consist of injecting one animal with a low dose and increasing the dose stepwise in other animals, until the desired scientific endpoint is reached, or before a moderate degree of suffering is reached, whichever is lowest – this will dictate the maximum dose for the experiment. The effects of each dose will be evaluated before adopting a stepwise approach to higher doses, such that the humane endpoints are not breached.

During cancer studies, animals will be observed for signs of tumour growth for their entire lifespan by blood sampling and calliper measurements of external tumours. For animals with internal tumours experiments will be carried out with routine necropsies taken to determine the growth rate of the tumours and its effect on the welfare of the animals. This will enable the timing of scientific and humane endpoints to be determined.

Other than in terminally anaesthetised animals, dosing and sampling procedures will be undertaken by a person competent in the relevant technique, in accordance with good practice using a combination of volumes, routes and frequencies that will result in no more than transient discomfort and no lasting harm and are the minimum compatible with the scientific objectives.

The latest procedures that cause the least suffering to mice will be used to replace older, outdated methods. Unless otherwise stated in the protocol. Ongoing training will be given in new and existing procedures to ensure best practice is occurring.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best guidance practice published on websites such as NC3Rs and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By literature searches and staying up to date with the NC3rs website and attending NC3rs symposiums. Checking with the NVS, NACWO and BSU staff before any procedure is carried so that we can implement these techniques effectively. Collaborating with researchers who have carried out this work before.

177. Role of blood vessels in bone health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

blood vessels, bone, ageing, haematopoiesis, microenvironment

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how blood vessels inside the bone help to regulate specific microenvironments that contribute to bone physiology during growth and ageing. We want to do this so we can develop new strategies to improve bone health in the ageing population.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Age-related bone loss and other bone conditions, such as osteoporosis and delayed fracture repair, are extremely prevalent among the ageing population. With increasing life expectancy and lifestyle and demography changes, it is important to tackle

musculoskeletal conditions for healthy ageing. In addition to bone loss and fracture risk, re-establishment of healthy bone marrow in patients following chemotherapy or radiotherapy is crucial to maximise the treatment outcome of bone marrow (BM) transplantations.

The bone interacts with other organs in the body to tightly regulate whole-body health. Changes in bone mass are linked to ageing and diseases such as diabetes, hypothyroidism etc. These changes involve modifications in smaller localised 'microenvironments' within the bone. Blood vessels in the bone play a key role in regulating these microenvironments, and are important for supporting these microenvironments for the healthy formation of bone and production of blood cells within the bone marrow. Despite their importance, bone blood vessels and their microenvironments have not been well- understood. In this programme, we investigate blood vessels and their specialised microenvironments to explore their functions in bone health, repair and disease, and to develop new therapeutic strategies for managing bone and blood diseases in the future.

What outputs do you think you will see at the end of this project?

The ultimate aim of this project is to understand blood vessel functions in skeletal physiology. We hope to better understand how blood vessels in the bone interact with other cells in the bone to affect bone formation and blood cell production. Importantly, our findings in this project could identify new strategies which target blood vessels to treat patients with bone and blood diseases.

This research will generate data which will be published in peer-reviewed journals, contributing to the advancement of knowledge in this field. We plan to publish this research in the highest quality journals (where it is well-cited and influential) and at international conferences, ensuring that it reaches the widest possible audience. Our data on bone health and diseases will also be communicated to the public through accessible presentations and innovative workshop formats.

Who or what will benefit from these outputs, and how?

My team will constantly discuss our findings with collaborators and the UK scientific community from the beginning of this project. We will disseminate important findings and techniques which are beneficial to other labs around the world who are carrying out research in the field. We will discuss our findings and observations with clinicians, to maximise the potential of our work to be applied to help patients with bone diseases in the future.

We believe new suitable pharmacological targets for treatment of bone conditions would be proposed in the next five years. These findings would potentially benefit clinics in the next 10-15 years. We will also constantly interact with the public through presentations and workshops which would benefit the public by providing essential knowledge on lifestyle for healthy living.

How will you look to maximise the outputs of this work?

My team and myself will be constantly involved in the dissemination of the findings to the scientific community and will also make these findings accessible to non-specialized audiences every year through public engagement activities. In addition to research collaborations, I am establishing clinical collaborations to take our findings to clinics, which

will maximise the development of effective therapeutics for patients. We are also interacting with industrial partners to design/screen drugs to target specific cell types or functions. We will present our findings in scientific meetings, discuss the benefits with the public and publish the work in high impact journals to disseminate the knowledge and maximise the outputs of this work.

Species and numbers of animals expected to be used

- Mice: 12500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

As this research investigates blood vessels and the skeletal system in the context of whole-body physiology, the use of a mammalian model system is a fundamental requisite. Importantly, the unavailability of an artificial model system mimicking human blood vessel functions is the primary motivation to perform this study on animal models. Mus Musculus (laboratory mouse) is the most commonly used mammalian model system. The mouse genome is sequenced, and it shows similarity to the human genome. The relevance of genetic and physiological context to the human system makes it the appropriate model system to investigate systemic physiology. In particular, mice have a skeletal system that looks, ages and develops diseases that resemble humans. Thus, the physiological interaction of the cardiovascular and skeletal systems in health and disease can be efficiently studied using mouse models. In addition to being the smallest mammalian model, the availability of a wide variety of genetic models, short reproduction cycles, and low maintenance costs compared to other models make the mouse the best mammalian model system available. Moreover, it is a powerful system to manipulate genes in a tissue-specific and time-dependent manner to study cell-specific functions and understand age-associated molecular mechanisms.

Most of our experiments use the postnatal development stage to understand the mechanisms that regulate anabolic mechanisms in the bone. We then use these findings at this stage to manipulate aged and diseased mouse models.

Typically, what will be done to an animal used in your project?

Typically, we target blood vessels using various strategies and disease models to understand their functions. We breed and generate genetically altered (GA) mice which will then be administered with inducible substances orally or injections usually five consecutive days to induce genetic changes. The mice will be humanely killed at the end of the experiment usually after 2 weeks to study functions of genes. Similarly, we also use wildtype mice to administer substances (dosage and route depending on the substance) to induce disease models or to inhibit blood vessels. Sometimes both wildtype and GA mice are allowed to age (>1 year) and performed genetic alterations by inducible manner (as explained earlier) to study age-related changes in the bone. Mice will be humanely killed at the end of the procedure to determine changes in bone, circulating blood and blood vessels.

We also use GA mice to visualise blood vessels in a living mouse. Mice will be anaesthetised and maintained under continuous anaesthesia during imaging process. Mice will be humanely killed at the end of the procedure without regaining consciousness.

What are the expected impacts and/or adverse effects for the animals during your project?

Although no adverse effect is expected after genetic manipulation, deletion of some genes may result in unexpected traits. In this case, induced mice will be closely monitored and the termination time of the experiment will be brought forward as required. Therefore, mice will be carefully monitored for adverse effects and will be killed if the condition is prolonged for more than 24 hours. In general, we will always seek advice from the local Named Animal Care and Welfare Office (NAWCO) and Named Veterinary Surgeon (NVS) if any mouse shows adverse changes.

In ageing experiments, mice older than 15 months will be closely monitored for the severity of age- related symptoms. Generally, mice will be used before they reach 18 months of age.

In general, if the administration of any pharmacological drugs or their solutions causes local rashes/irritation/inflammation/infection or any unexpected adversities, we will immediately seek the advice of NVS and NACWOs to manage those animals and future experiments.

Whole-body irradiation damages primarily cells dividing at a high rate such as blood cells and gut cells. Adverse effects of whole-body irradiation are noticed in less than 1% of animals undergoing the procedure. Irradiation commonly affects pigment production leading to dark furred mice producing grey/white coats which has no adverse effects on the animal.

To minimise the presence of potentially pathogenic agents, mice of the cleanest available health status are used, held within clean housing conditions (such as isolator, filter cages, clean enclosure rooms or at least maximal hygienic measures) at all times. Any mouse receiving a single dose of radioactivity will be maintained on antibiotic treatment for at least 5 weeks after the last irradiation dose to prevent diarrhoea or weight loss possibly arising through cells damage in the intestines. Any animal showing abrupt weight loss of pre-irradiation body weight, and/or other signs of illness will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of our experiments, the actual level of severity involved in the procedures is mild. Based on our last year record, minimum 80% of mice undergo mild procedures and the maximum of 20% of mice will be in moderate level.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed study investigates the physiology of blood vessels in the skeletal system and their relevance to ageing. Animal models have proven to be more relevant to investigate blood vessels in organ- and whole-body physiology. Importantly, the unavailability of an in-vitro model system mimicking human vascular functions is the primary motivation to perform this study on animal models. Mus musculus (laboratory mouse) is one of the best model systems available to study the mammalian physiology and pathophysiology of blood vessels and the skeletal system. Though some details can be studied on cultured cells, endothelial cells do not represent the way they behave in intact animals, e.g. transport of blood. They do not demonstrate the diversity in function and structure observed in intact animals. There are no cell culture models available that can replicate the system in vitro. Therefore, the use of animal models is inevitable for this programme, which dwells in the systemic understanding of skeletal physiology. Animal models can provide systemic insights into the ageing process that cannot be addressed by in vitro model systems. Moreover, the experimental findings from this animal work can be generalised and beneficial to understanding human physiology and disease.

Which non-animal alternatives did you consider for use in this project?

Where possible, we make use of cultured cell lines to carry out pilot experiments to gain some information about the behaviour of gene constructs before hypotheses are tested in mice. In addition, culturing of cells isolated from genetically altered mice constitute replacement as they replace procedures that would otherwise be carried out in mice. To note, we are also developing a novel three-dimensional culture system to replicate a bone microenvironment in a dish. If we establish this method, it would reduce the number of mice used in bone research not only in our lab, around the world.

Why were they not suitable?

In vitro systems cannot provide systemic insights into blood vessel functions and ageing of the skeletal system. In general, the basic research is at its initial stages of understanding blood vessels formation and structure. We are still unable to generate functional blood vessels of a particular organ system in vitro. Therefore, we do not have an alternative system to study vascular function in skeletal ageing.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice was estimated considering the scientific objectives outlined in the programme of work and anticipated numbers of experiments and mice. The estimates are based on similar studies conducted in the past using similar protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

At every stage in our experiments, consideration will be given to ways in which we can reduce the number of animals. Several of the protocols that we use are designed in such a way as to obtain the maximum possible data from a single animal. In my team, all animal experiments are planned and designed to reduce animal usage and increase maximum output. We use tissues from a single animal for multiple analyses that involve advanced cellular and molecular techniques. This is evident from the current animal use data in my project license.

Genetically altered (GA) mouse models will be generated by the highly experienced staff of our dedicated transgenic facility. Best practice will be followed but it is difficult to predict how many animals will be required as this depends on the expression profile of different constructs. Where GA animals are generated in house, established breeding practices will be followed that are designed to generate the minimum number of animals.

We will consult with statistical experts within the institute. We will use appropriate statistical tools to assist in planning or designing experiments to calculate the number of mice needed to generate meaningful data. Otherwise, we will use the least number of animals to provide an adequate description, generally on the basis of previous experience. In terms of the numbers of animals required, usually 6-10 animals per treatment group are sufficient to obtain the required results. In addition, we will use the Animal Research: Reporting In Vivo Experiments (ARRIVE) guidelines issued by National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) in reporting our results, and in considering the design of our experiments (e.g., allocation of animals to groups, blinding, etc).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Sharing of tissues is well established in my team; every team member coordinates with others in best and maximum use of every single mouse in our experiments for e.g. we use genotypically unsuitable mice from our breedings for in vitro studies.

Our expertise and more than a decade of experience in transgenic mice allow us to efficiently reduce unnecessary mouse breedings for our experiments. Mice sharing strategy in our lab permits efficient use of genetically unsuitable mice from the breedings.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the procedures in this licence are classified as either mild or moderate and are done under local or general anaesthesia, where appropriate, to minimise stress and suffering of the animals.

We will use wildtype and genetic altered mouse models to induce changes in the blood vessels and bone, to understand the mechanisms involved in bone physiology. To study gene functions, we use inducible cell-specific mouse models which do not induce genetic changes in the whole body reducing the harm and stress experienced by the animals. Scientifically, it will allow us to study cell specific functions of a gene without altering other cell types. We will also administer pharmacological substances to target particular molecular pathways in the bone. There is the potential for suffering when substances are administered to conscious animals. Animal suffering is minimised by following careful aseptic techniques and handling by skilled scientists. In general, these genetic alterations and substances are not expected to cause distress or lasting harm to the animals. We will administer the minimum doses required and minimise the length of experimental conditions (most lasting 2 weeks or less), to minimise stress and inflict the minimum pain.

Why can’t you use animals that are less sentient?

We need to use mice because we need to work with mammals since they have bones, blood and a circulatory system that function similar to humans’. Non-protected animals (e.g. invertebrates such as insects, decapods, nematodes) or less sentient animals (e.g. zebrafish) have different physiologies, so cannot be used for this study. We also need to work with adults and ageing mice because we are studying how and why ageing affects bones and blood vessels.

Mice are the simplest and most humane mammalian model we can use to study bone physiology. Because all mammals are sentient, we follow methods to reduce distress, pain, suffering or any harm to mice in our experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In general, we provide extra care and closely monitor the experimental mice to minimise any welfare issues. If any unexpected signs of distress are observed, we will stop the experiment early and humanely kill the affected animal. We will try to make all animals as comfortable as possible, whether or not they are undergoing experimental procedures, e.g. by providing an enriched environment and careful handling to minismise stress. We will get mice used to people and handling from a young age, to reduce their stress levels during protocols where they may be handled frequently. When appropriate, analgesia will be provided.

To administer pharmacological treatments, and especially when medium-long term treatment is needed, multiple injections will be replaced by osmotic minipumps, whenever possible. Dose-response and time course analysis for induction of gene manipulations will be performed to maximise research outcomes, but with a minimum consequence to the animal’s health. Animals will be kept warm and monitored regularly during and after anaesthesia. We will regularly consult with the NACWOs, NVS and colleagues about best practices and potential further refinement of our procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the guidelines mentioned in Animal Research: Reporting In Vivo Experiments (ARRIVE) and Laboratory Animal Science Association (LASA). We also refer to LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery, and Laboratory Animals Limited (LAL) for progressing the care, husbandry and management of ageing mice used in scientific studies.

For best practices in severity limits, we take guidance from the following published literature:

Jones HRP, Oates J, Trussell BA: An applied approach to the assessment of severity. In: Humane endpoints in animal experiments for biomedical research. Proceedings of the international conference, 22-25 November 1998, Zeist, The Netherlands, edited by CFM Hendriksen and DBMorton, pp. 40-47, 1999.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I and my team will be in regular contact with the local facility technicians, NACWOs and NVS to review current approaches and any new opportunities in the Replacement, Refinement and Reduction of animals in research. We also follow NC3Rs newsletter to get information on recent advances, opportunities and events. We will follow NC3R events, symposia and events to get more information about tools and technologies at the other institutes.

178. Embryonic origins of heart disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words
embryonic, cardiovascular, heart, circulation, development

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine some of the mechanisms via which adverse conditions during prenatal development trigger embryonic origins of heart disease

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To diminish the burden of cardiovascular disease by understanding mechanisms better in order to identify plausible therapies for intervention

What outputs do you think you will see at the end of this project?

The outputs that we will see at the end of the project will be:

Data relating to cardiovascular function, cardiovascular morphology (structure) and underlying molecular pathways in chicken embryos incubated under control of challenged

conditions (e.g. lower than normal oxygenation or hypoxia) with and without treatment (e.g. antioxidants);

Data relating to cardiovascular function, cardiovascular morphology and underlying molecular pathways in hatchlings raised from fertilised eggs incubated under control of challenged conditions (e.g. hypoxia) with and without treatment (e.g. antioxidants);

Data relating to cardiovascular function, cardiovascular morphology and underlying molecular pathways in juvenile/adult birds raised from fertilised eggs incubated under control of challenged conditions (e.g. hypoxia) with and without treatment (e.g. antioxidants);

Data relating to cardiovascular function, cardiovascular morphology and underlying molecular pathways in first and second generation birds raised from fertilised eggs incubated under control of challenged conditions (e.g. hypoxia) with and without treatment (e.g. antioxidants).

Publications as abstract, papers, reviews and book chapters of Points 1-4;

Dissemination of unsuccessful approaches or negative findings.

Who or what will benefit from these outputs, and how?

The work in this project licence is to be done in the chicken. The reason is because in contrast to all mammals (except primitive mammals that lay eggs or monotremes), the chicken permits some of the direct effects of adverse conditions during development on the embryo to be isolated, independent of effects on the mother and/or the placenta. Establishing direct effects on the developing heart and circulation means we can better identify mechanisms involved. This will improve intervention to guide future translation into human clinical practice.

In the short-term term (1-3 years), the data outputs of this project licence (e.g. changes in arterial blood pressure, heart rate, cardiac function) will inform us how adverse conditions during early life may increase the risk of cardiovascular dysfunction later on in the adult offspring. For instance, is the heart affected more than the vasculature? Which is worse and which may contribute more to triggering cardiovascular disease?

In the medium-term (3-5 years), the effects of the experiments in chickens will also inform our programmes of work and those of other researchers in other species, such as in the mouse, rat and the sheep. It will tell us which are the areas to focus on, and what similarities and differences there are between species. The idea is then to create a layered approach of understanding on the effects of adverse conditions during development on the cardiovascular system across the life course in different species. This will help to better translate our findings to the human clinical situation. For example, knowledge of common effects of an adverse condition in early life on the heart of the chicken, mouse and sheep may precipitate human benefit by designing a treatment with protection across species and thereby likely to be as efficient in humans.

How will you look to maximise the outputs of this work?
The outputs of this work, including the dissemination of unsuccessful approaches or findings, will be maximised at several levels:

Scientific advancement and collaboration: In the longer term (>4 years), the data will benefit the design of therapies in higher vertebrate models of adverse pregnancy with a view to human translation and the design of clinical trials. This will be achieved via collaboration with experts in different fields within and outside the university. Therefore, the proposed work in this new project licence may hasten translation to relatively simple but novel human clinical interventions to not only treat the mother, but also her progeny. This will contribute to a reduction in the burden of developmental origins of heart disease, thereby having a positive clinical, economic and societal impact on health.

Dissemination of new knowledge. Other pathways to further increase impact will include contacting the funders and the University communications office to alert them of the potential influence for human health of the scientific findings. This will lead to press releases, which will be supported by radio and television interviews. In addition, the data will benefit the design of cures to protect the health of the unborn child. The proposed research is therefore likely to be of significant interest and benefit not only to researchers carrying out similar or related research in the field, but also to national and international researchers in other disciplines, such as biochemistry, pharmacology and nanotechnology, as well as cross-disciplinary teams in the pharmaceutical industry. To deliver translational benefit to the nation’s health, wealth and culture we will adopt a number of strategies such as seeking patent protection for any new therapies or diagnostic biomarkers revealed by the research as well as actively engage with the commercial pharmaceutical and healthcare sectors to exploit our research at the earliest opportunity.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The chicken is the ideal animal for the project as it permits isolation of the direct effects of adverse conditions during development on the cardiovascular system, independent of confounding effects of these challenges on the mother and the placenta (as in mammals). This will help us better isolate the direct effects of challenges to development, underlying mechanisms and therefore the improved design of possible cures.

The studies will focus on the chicken embryo, the hatchling and the juvenile/adult bird as the project is designed to determine the effects of adverse conditions on the cardiovascular system of the progeny across the life-course, from embryonic stages through to the adult offspring.

Typically, what will be done to an animal used in your project?

The project focusses on three life-stages of the life-course: the chicken embryo, the hatchling and the juvenile/adult bird.

In the chicken embryo studies, typically a fertilised egg will be exposed to control (e.g. normal air or normoxia) or challenged conditions (e.g. lower than normal oxygenation or

hypoxia) during incubation and the chicken embryo studied in late incubation (e.g. at day 20 out of 21-day incubation period). The majority of the studies will be ex vivo (after death), i.e. in tissues isolated from animals followig Schedule 1 killing. A minority of studies will investigate the function of the heart and circulation under terminal or recoverable anaesthesia following surgery. Under terminal or recoverable anaesthesia, typically 1 experiment will be performed in any one embryo, lasting approximately 5 hours.

In studies in the hatchling, juvenile or adult bird, typically a fertilised egg will be exposed to control (e.g. normoxia) or challenged conditions (e.g. hypoxia) during incubation and the chicken embryo will be allowed to hatch. The majority of the studies in the hatchling (typically 1-2 weeks of age) or in the juvenile or adult bird (typically 12 weeks to 1 year of age) will be ex vivo, i.e. in tissues isolated from animals following Schedule 1 killing. A minority of studies will investigate the function of the heart and circulation under terminal or recoverable anaesthesia following surgery. Under terminal anaesthesia, typically 1 experiment will be performed in any one animal, lasting approximately 5 hours. Under recoverable anaesthesia, typically 3 experiments will be performed in any one animal, with 1 day rest in between. Each experiment will typically last 3 hours.

What are the expected impacts and/or adverse effects for the animals during your project?

It is well established that incubation of fertilised chicken eggs in adverse developmental conditions, such as lower than normal oxygenation or exposure to glucocorticoids (steroids) can reduce embryonic growth and survival. Our own experience is that about 15% of eggs are not fertile (checked by candling) and about 10% of embryos incubated artificially under optimal and normoxic (normal air)
conditions die normally, usually stopping development within the first 5 days of incubation. Exposure to 14% hypoxia (lower than normal oxygenation) between day 1-19 of incubation reduces the survival further by ca. 40% and hatchability by 50%. Relative to embryos incubated under normoxic conditions, surviving embryos of hypoxic incubations show a ca. 25% reduction in body weight. Our experience with glucocorticoid therapy is that treatment of the chicken embryo with synthetic steroid hormones, such as dexamethasone or betamethasone reduces survival by 20% and it decreases fetal body weight by 20% by the end of the incubation period. Therefore, we expect similar adverse effects of incubations with periods of lower than normal oxygenation or treatment with glucocorticoids during the tenure of this project licence. We do not expect other adverse effects of experiments at the chicken embryo stage of the life-course.

We do not expect any adverse effects of topical administration of substances (e.g. antioxidants or vehicle) onto the chorioallantoic membrane (membrane that separates the embryo from the air cell within the egg) between day 1-20 of incubation, via a 1 mm hole drilled into the eggshell. The hole in the egg shell will be covered by a small piece of tape after substance administration. We have plenty of experience with this route of administration and we have not seen problems, such as infection, for instance in 5 years.

Conversely, between day 15-20 of incubation, administration for example of antioxidants, or vehicle via intravenous, intramuscular or intraperitoneal may cause bleeding. Intraperitoneal injection in birds also increases risk from flooding one of the air sacs. If air sacs are compromised and /or bleeding on any one day is estimated to be >10% of the estimated embryonic blood volume, the animal will be killed by a Schedule 1 method. Similarly, if blood loss could not be controlled, the animal will be killed by a Schedule 1 method. Embryonic blood volume can be estimated from comparison of the size of the

embryo to our own historical library of sizes and weights of embryos at different stages of the incubation period.

Following hatching, growth of hatchlings of incubations under adverse conditions may also be slower compared to controls. For instance, our own experience is that the weight gain of hatchlings from hypoxic incubations at 6 months of age is reduced by an average of 1-2 g/day. Therefore, we expect similar adverse effects of incubations under sub-optimal oxygenation on post-hatching growth with or without embryonic and/or post-hatching treatment with glucocorticoids during the tenure of this project licence. Conversely, we expect hatchlings exposed to an obesogenic diet (a diet that makes you gain weight) to put more weight on than controls as they grow to adulthood.

Some protocols require treatment of hatchling/juvenile/adult birds with intramuscular injections (in the muscle). Intramuscular injections in juvenile/adult birds will be given in the pectoral muscle. This may cause transient pain.

Exposure of hatchling/juvenile/adult birds to an obesogenic diet may lead to fatty liver. We do not expect that this will affect the wellbeing or behaviour of the animal during the tenure of the protocol.

While under terminal anaesthesia, some protocols may require surgical implantation of probes or occluders, or the application of vessel occlusion. Some of these procedures may lead to unexpected bleeding. If more than 10% of the estimated blood volume of the animal is lost, then the animal will be killed by a Schedule 1 method.

A minority of experiments in the hatchling/juvenile/adult birds require surgery under recoverable anaesthesia. All surgical procedures will be carried according to the Home Office Minimum Standards for Aseptic Surgery. Through previous work, we have gained significant experience with work on birds following surgery. Pain killers will be administered as required, judging from the animal behaviour. In some animals, arterial catheters will be placed which allow for blood sampling. The health of the bird can then be monitored through measurements of blood gases. For example, we will be able to ask if oxygen levels in blood are normal?

Some protocols require study of the bird after removal of the nerve that is attached to the carotid body (denervation of the carotid bodies) or removal of the adrenal glands. Denervation of the carotid bodies does not produce any resultant harm. In fact, carotid body denervation is currently being trialled in human patients to treat hypertension. In contrast, removal of the adrenal glands can trigger adverse effects on blood volume and blood pressure over prolonged periods of time. Adrenal insufficiency in man and other animals is known as Addison’s disease and these individuals through hormone insufficiency can develop low blood pressure over a period of months. To minimise this possibility, no animal will be studied and kept for longer than 1 month after surgical removal of the adrenal glands.
In the event of post-operative complications, such as a catheter being removed, birds will be killed unless such complications can be remedied promptly and successfully using no more than minor interventions. In the case of wound dehiscence (bursting open), uninfected wounds may be re-closed on one occasion.

We estimate that about 10% of birds will not be able to weight bear on one or both legs after one day's recovery from surgery. In this instance, the animal will be given supportive care via a sling and it will be monitored closely by taking morning and afternoon arterial blood samples. The animal's food intake and ability to pass faeces will also be closely

monitored at least twice daily. Any birds that cannot weight bear on two legs for 72 hours despite continued pain killer care, appropriate food intake, defecation and blood glucose concentration will be killed by a Schedule 1 method or earlier if its condition deteriorates before this point.

For studies involving a scan of the heart in the conscious bird, the plucking of feathers under gentle restraint to expose any area will be minimised. Feathers will be plucked in the direction of their insertion into the skin to avoid skin rupture and discomfort.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Species: Chicken Mild: 90%
Moderate: 10%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In some experiments, we must use whole animals or organs isolated from animals because function, for instance in the cardiovascular system, is regulated by complex networks, none of which have been reconstituted completely in computer models. The overall system is not well enough understood to make mathematical modelling useful.

Which non-animal alternatives did you consider for use in this project?

There are no suitable non-animal alternatives to use in this project.

Why were they not suitable?
No non-animal alternatives are suitable to use in this project as none can model the effects of adverse conditions during embryonic development in programming an increased risk of cardiovascular disease in the adult progeny.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals that we will use in this licence from experienced use of animals, as detailed in more than one retrospective review using this species.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental design was created with the NC3R's Experimental Design Assistant to ensure reproducibility using the least number of animals to satisfy statistical power for anyone measurable output.

To ensure the minimum number of animals is used in this project to address all objectives, we have considered the choice of species very carefully. The real ethical, biological and economic value of the avian relative to other experimental animal models, such as rats and mice, can be best appreciated by considering the lack of need for surrogate mothers or for control of the effects of litter variation or the effects on lactation, as is needed in mammals that give birth to litters and suckle their young. For example, in rodents, one litter irrespective of the number of pups in that litter, is considered as the experimental unit for many statistical comparisons. In addition, adverse pregnancy in mammals may affect the quality of the mother's milk. Therefore, additional control animals, such as surrogate mothers for newborn pups, are needed to understand these effects better. By using the bird as the species of choice to address the project objectives, this markedly reduces the number of animal groups, as there is no need to control for litters or maternal milk. Therefore, this significantly contributes to the 3Rs principle of reduction as enshrined in EU Directive 2010/63.

Where relevant, multiple experimental designs will be used, rather than the one-thing-at-a-time approach, to maximise the information obtained from the minimum resource. For most experiments, the study design will adopt methods of analysis previously published extensively by our group, which compares 4 groups: control and experimental groups with and without a treatment or intervention. For example, outcomes from normoxic (normal air) or hypoxic (lower than normal oxygenation) incubations with and without treatment with an antioxidant. Control groups treated and untreated are necessary, as the treatment may affect normal and complicated incubations differentially.

Sex differences are an important consideration in the risk of developing cardiovascular disease. Therefore, assuming a 1:1 ratio of males to females, the number of animals required per outcome variable will be doubled to be able to address sex differences. In such cases, statistical analysis able to compare three factors comparing treatment, intervention and sex will be adopted (e.g. a Generalised Mixed Linear Model; SPSS).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will optimise the number of animals used in this project from 1) pilot data and 2) by using multiple data obtained from the same animal. For instance, we will obtain data from the living organism as well as from tissues isolated from them after death. In addition, we routinely share tissues generated from projects for collaborative studies by other investigators. About 20% of our publication output is derived from such collaborative studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The work will be done in the chicken, which has several advantages. First, it permits isolation of the effect of adverse developmental conditions directly on the fetal heart and circulation independent of effects on the mother and the placenta. This helps better identify potential direct mechanisms and interventions on the developing individual. Secondly, most of the work will be done in the chicken embryo pre-hatching rather than in the post-hatching animal. Thirdly, the work is of greater relevance to humans than using rodents because the development of the heart and circulation is much more similar in humans and chickens, compared with humans and rodents. Fourthly, we can apply interventions in greater numbers of chicken embryos at any one time within one incubator, allowing for contemporaneous comparison and thereby minimising confounding effects of increased variability (e.g. experiments affected by seasonality, effects that sometimes cannot be avoided in longer living species).

A much larger component of the work can be achieved by investigating isolated organs and tissues. For example, after death, the function of the isolated heart and vessels can still be investigated, as well as experiments at the level of the cell and molecule. Comparatively smaller components of the work will involve studying whole living animals under terminal anaesthesia, or conscious animals which have been surgically prepared under general anaesthesia. In some cases, it is necessary to study conscious animals, as anaesthesia can impair normal cardiovascular function. Experiments will only be performed following appropriate post-surgical recovery. We will keep suffering to the minimum by using procedures with the least possible severity, and by subsequent monitoring with veterinary advice.

Why can’t you use animals that are less sentient?

The development of the cardiovascular system in less sentient species, such as in worms or flies is very different than in humans. In addition, the regulatory mechanisms of cardiovascular function in such species is not well understood.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

With experience from previous work, we have streamlined and refined surgical procedures that reduce bleeding, shorten anaesthetic exposure and improve port-surgical recovery. For example, we have slightly raised the bird's head during general anaesthesia to prevent inhalation of any crop reflux. We have also used a different surgical approach to refine procedures. For example, in some preparations, we will need to catheterise the femoral artery of the adult bird. We now do so by isolating the vessel on the outside of the leg muscles rather than through an inguinal approach. From past experience, we have found that this refined surgical approach markedly reduces the disruption of circulation, reduces bleeding and improves the post-surgical recovery of the bird.

In some birds, under recoverable anaesthesia and using strict aseptic conditions, catheters will be placed in one leg and a flow probe in the other. Following 5 days of postoperative recovery, experiments lasting 7-10 days will be performed in these chronically instrumented birds. Approximately 80% can stand following surgery, 15% are reluctant to stand but can stand and weight bear when prompted and 5% are unable to stand. A score sheet has been developed to assess mobility and behaviour to guide decisions, and it will continue to be used and improved as appropriate. The score sheet will be trialled for 6 months and it will be refined thereafter with the input from the Named Veterinary Surgeon.

Bedding in the animal holding areas has also been improved. Some forms of past bedding used in the facility created a lot of dust in the animal's environment. The new bedding material generated much less dust.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure experiments are conducted in the most refined way, we follow the NC3Rs' ARRIVE guidelines, the LASA guidelines and the PREPARE guidelines.

For example, we will refer to the latest edition of the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery 2017, at the time of preparing this project licence application.

The Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE) guidelines issued by NORECOPA (https://norecopa.no/prepare) covers all stages of quality assurance, from the management of an animal facility or population to the individual procedures which form part ofa study.

We will refer to specific guidance or position papers from the Laboratory Animal Science Association, (LASA) https://www.lasa.co.uk/current_publications/. For example: Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T (2018) PREPARE: guidelines for planning animal research and testing. Lab Animal 52(2): 135-141. doi: 10.1177/0023677217724823.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We visit the NC3Rs website frequently and have subscribed to their newsletters.

Project licence holders are ultimately responsible for implementing the 3Rs within their work. Therefore, the project licence holder will have regular discussions with the Named Persons and animal technicians to review current approaches and whether there are any new 3Rs opportunities.

We will access our local NC3Rs Regional Programme Manager. We will maintain contact to obtain an informal route to 3Rs advice, developments, and best practice.

We will use of other resources, such as Norecopa https://norecopa.no/databases-guidelines. Regular consideration and reflection of the latest practical guidance from Laboratory Animal Science Association (LASA) will provide additional sources of new recommendations and advances in animal techniques.

179. Maintenance of gerbils with filariasis

Project duration

1 years 0 months

Project purpose

- Basic research

Key words

parasitology

Animal types	Life stages
Gerbils	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To maintain infected gerbils with the human filarial worm parasite *Brugia malayi*

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have continuously maintained a specific isolate of a human filarial worm parasite, *Brugia malayi,* in our laboratory by routine passage between gerbils and mosquitoes since 2012. This lab isolate has been used in a variety of basic and translational research including drug discovery and development for human filariasis. The use of this specific licence will be to continue the propogation of our filarial worm parasite life cycle

What outputs do you think you will see at the end of this project?

The only benefit will be the continued resource of our specific isolate of *B. malayi* which we intend to utilise in the near future for a variety of basic and translational research.

Who or what will benefit from these outputs, and how?

Our laboratory will benefit from continued maintenance of this specific strain of *B. malayi,* in order to carry out future basic and translational research studies

How will you look to maximise the outputs of this work?

This licence will allow us to prolong the life cycle of Brugia malayi so that we may apply for a more extensive licence to cover our next five year research programmes in new anti-filarial drugs and diagnostics

Species and numbers of animals expected to be used

- Gerbils: 10

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult gerbils are the lowest outbred vertebrate susceptible to *B. malayi.* Male gerbils are more susceptible to infection. Male gerbils tolerate infections in the peritoneum without overt pathology. Length of infection/age is limited to 18/24 months to mitigate against decline in welfare due to ageing.

Typically, what will be done to an animal used in your project?

The gerbils have been infected with *B. malayi* on another project licence. The gerbils will be transferred to this licence and maintained. The gerbils will either be humanely destroyed for isolation of parasites or transferred onto a subsequent licence for continued use.

What are the expected impacts and/or adverse effects for the animals during your project?

No expected overt clinical signs or adverse effects due to infection with Brugia malayi via the peritoneal route. Gerbils may decline in welfare due to age, reflective of the long-term maintenance. This may include decline in mobility, weight loss and potential risk of skin bacterial infection. We will monitor any decline in welfare routinely, take remedial actions such as wet food, topical antibiotics and other treatments where appropriate and not allow any animal to suffer more than a mild severity before humanely culling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

mild, 10 gerbils (100% of procedures)

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Brugia malayi has a complex life cycle and requires a mammalian and insect host to develop and reproduce. With NC3R funding we have attempted to culture infectious larvae derived from mosquitoes to grow outside of the body. Our attempts using co-cultures with various mammalian cells has failed to support the growth of these parasites to a reproductive adult stage.

Which non-animal alternatives did you consider for use in this project?

advanced 2D, 3D and organoid *in vitro* cultures to propogate *B. malayi* from infectious stage to mature reproductively active adult worms.

Why were they not suitable?

We have in the past trialled several methods to grow the mammalian life cycle stages of *B. malayi* in complex co-culture systems. These attempts have proven unsuccessful. Whilst we have developed methods to prolong adult *B. malayi* worm survival *ex vivo,* this still requires an animal host to provide a source of parasites. It might be possible in the future, with advancements in *in vitro* organoid models of the lymphatic system (the natural parasitic niche of this parasite), to establish an environment to propogate reproductively active adult *B. malayi.* However, such studies have not been placed in the public domain and we are not currently funded to undertake such expensive and high-risk experimentation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will require maintenance of 10 gerbils in total over a maximum period of 12 months

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

NA

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

NA

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Gerbils are the lowest outbred vertebrate susceptible to Brugia filarial worms. Gerbils tolerate these infections within the peritoneum without signs of disease or ill health. Length of infection/age is limited to 18/24 months to avoid decline in welfare due to ageing.

Why can’t you use animals that are less sentient?

The long life cycle of and requirements to maintain Brugia parasites long term precludes less sentient alternatives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimize development of any welfare issues due to ageing, gerbils will be maintained for a maximum period of +18 months post infection / +24 months of age (whichever is sooner). Through ten years experience, not exceeding these time frames safeguards against the majority of age-related loss of welfare issues which arise. When loss of welfare does arise we will not allow an animal to exceed a mild level of suffering before humanely culling, judged by appearance, behaviour any specific clinical symptoms and/or weight loss.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow best practice guidance for handling, housing and husbandry of gerbils: https://nc3rs.org.uk/3rs-resources/housing-and-husbandry-gerbil

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?
I am an NC3R grantee, an NC3R panel member and chair the institutional AWERB. Through these activities I and receive regular communications from stakeholders such as LASA, NC3Rs and RSCPA. Our AWERB members are proactive in attending off-site seminars on aspects of 3Rs and report back to practicioners. Similarly I receive information and advice from the secondary establishment biological services unit on best practice.

180. Development and regulation of Immunity

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immune cells, Therapy, Inflammation, Autoimmunity, Infectious diseases

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We are trying to understand the fundamental processes by which the body's immune system normally develops the ability to fight infections but avoids causing the sort of "friendly fire" that sometimes leads to diseases like rheumatoid arthritis and insulin-dependent diabetes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We need to understand how the immune system responds to infections, why it fails in some patients and how we might modify in a range of diseases. One outcome of our research will be an understanding of how to improve the treatment for cancer by triggering a mild form of friendly fire to tumours and new ways to turn off immunity in diseases like rheumatoid arthritis. We expect to be able help families with rare forms of immune deficiency and our study of these diseases may ultimately inform the design of vaccines.

What outputs do you think you will see at the end of this project?

We will publish information about how the immune system works to fight infection and prevent autoimmune diseases, and our work will help to develop new treatments for human disease. The immune system is directly involved or implicated in multiple forms of human disease, ranging from cancer treatment, to heart disease, schizophrenia and dementia - so our fundamental research will have broad benefits.

Our approaches are designed to gain as much information as possible from the mice, the vast majority of which are used for breeding, so we can select the most informative experiments. These approaches are published and adopted elsewhere.

Who or what will benefit from these outputs, and how?

The beneficiaries of our work in the short term will include the scientific and commercial sectors generating new treatments for human disease; and in the long term the beneficiaries will include patients. Our work is published in scientific journals and at conferences, where it will be read or otherwise communicated and contribute to new approaches for treating disease. Our work contributes to the develoment of new drugs that can be used in the treatment of disease and to new approaches to diagnosis, which may be transferred to human samples generated in the NHS. We also communicate our work through public engagement.

How will you look to maximise the outputs of this work?

We will maximise the outputs by disseminating knowledge through publication, collaboration, lectures and public-speaking. We will continue to publish in top scientific journals and attend conferences where we can explain our findings and exchange ideas withouther scientists. Our collaborations are widespread in the UK and overseas, and our work is also widely read. We will continue a variety of forms of public engagement, including webinars and short films.

Species and numbers of animals expected to be used

- Mice: 50,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in these experiments will be mice, which are the most appropriate fully developed model of the human immune system - accurate in all important respects but the least sentient. Some of these animals will be genetically modified strains, carrying spontaneous or induced, targeted mutations or transgenes. We will be using mainly adults but occasionally neonates or foetuses, because we also want to understand how the immune system develops in early life.

Typically, what will be done to an animal used in your project?

Some mice will be immunised and rarely mice may be challenged with self-limiting viral infections, such as influenza, to check their immune response. Some mice will also be irradiated to destroy the immune system, followed by rescue with donor cells. Some will be used to model inflammatory disease - such as kidney inflammation - and bone marrow transplantation; and in these models we may test new drugs to ameliorate disease.

The majority of mice used in these projects will kept for breeding, where they do not suffer harm. The other procedures are time-limited with most animals used within 6-18 weeks of full adulthood. Mice will be closely monitored during this period/

Mice used in the regulated proedures are subject to vaccination We expect to use approximately 50,000 mice in 5 years.

What are the expected impacts and/or adverse effects for the animals during your project?

Most experiments (>95%) will not cause any adverse effects. Other experiments may result in mild or occasionally moderate harmful side effects, such as weight loss or transient changes in behaviour due to the immune response brought about by injection of the animals with vaccines or other substances affecting the immune function, vaccination, irradiation, or autoinflammatory processes following infection of autoimmune reactions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

60% subthreshold

15% mild

25% moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are particularly interested in how the macrophages, dendritic, T and B cells that orchestrate the immune response attack infectious particles and how these cells are regulated. Discovering how this happens is a challenge because most of the immune response occurs in inaccessible parts of the body like the spleen, so many of the key advances in this field have been made in mice. The mouse and human immune systems are very similar and share conserved regulatory pathways; and the mouse genome is very

similar to the human, meaning that it is possible to translate findings in genetics between both species.

Which non-animal alternatives did you consider for use in this project?

As far as possible we use model systems using immune cells in vitro to model the effects we want to investigate.

Some of the work leading up to this project was based on the use of in vitro non-animal alternatives, including cell lines; however these lines have been grown without selection for many generations and have accummulated mutations, which make them unreliable. Moreover, these model systems cannot replicate the complexity involved in the immune response, which is seen in animals.

Many of the reagents used in the study - for example, antibodies - are generated in animals but maintained in cell lines; and we use similar model systems to develop our approaches before applying them in animal experiments.

Why were they not suitable?

The normal development of immune cells, which depend on the local environment, and the complex interactions of different cells in different organs during an immune response can only be studied in vivo. In our experiments we are exploring disease processes that occur in the setting of animals and the development of immune cells in the setting of particular tissue environments, such as the bone marrow and spleen. Our experiments are also focused on the effect of genetics on disease, which occurs by natural inheritance. It is not possible to replicated these processes in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on our experience and, since the majority of the animals are used in breeding, our plans for generating strains of mice with particular characteristics that can be used to answer specific questions in our experiments. In other experiments, we make calculations that are based on expected differences to work out the numbers of mice required to get a meaningful result - for example, the number of mice to be given and not given a particular intervention.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the smallest possible group sizes that are still informative for a thorough statistical analysis and logical progression to the next step. Advice is sought, and we use various tools and experts in statistics to support these aspects of the programme - for example the NC3R's Experimental Design Assistant. We are very careful to reduce variation by housing the mice together and ensuring that they are genetically identical. Several new

approaches reduce the need for as much breeding, including the use of small number of mice that are first irradiated and then have different bone marrow transplants, so we can compare the immune system that develops from the bone marrow in multiple animals without further breeding; and the maintenance of strains combining multiple genetic differences where these are not harmful. We conduct our experiments in compliance with the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We optimise our colony management to keep breeding cages to a minimum and use a single database to assist us in tracking and managing the breeding strategy. We use ANOVA and other statistical tools to maximise our ability to detect difference in groups with uneven numbers. We use small pilot studies to ensure that projects are feasible and to reinforce our ability to detect difference. We share tissues to make the most of mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of experiments require us to breed and then compare tissues from mice that are normal (wild-type) or genetically targeted to recapitulate human diseases, or to establish the role of proteins and biochemical pathways in immune function. The disease models recapitulate human autoimmune disease like systemic lupus erythematosis, graft-versus-host disease, or kidney disease due to inflammation; or they model human immune deficiency, where this is due to mutations affecting the development of immune cells. These enable us to investigate the underlying mechanisms and possible treatments of the same conditions in humans. The pathways may be perturbed in human disease or be potential targets for therapy. The breeding protocols cause minimal or no distress. Other experiments are designed to deliver statistically significant results in the least harmful way by making power calculations and focusing only measurable differences in well matched mice and controls. We use bone marrow transplantation, which is well tolerated, as a way of generating several well-matched mice with identical immune systems, without the need for excessive breeding, and we use models for infection, inflammation and autoimmunity when these have been very well characterised. In the bone marrow chimeras, we frequently mixed wild-type and mutant bone marrow, so we can compare the development of cells side-by-side in single mice. In our experience this is an extremely sensitive way to pick up differences and the refinement results in a reduction in total mice. We continually seek ways to improve these assays and reduce the level of suffering to the animals.

Why can’t you use animals that are less sentient?
Mice are the least sentient animals available with multiple reagents for conducting experiments and exploring hypotheses, including transgenic and knockout strains, for studying a complex adaptive immune system that is similar to humans. Non-mammals do

not recapitulate the human immune system as well as mice, which only diverged from us 80 million years ago in evolution.We study the development of the immune system in neonatal and adult mice and the response to antigens (vaccination) and self-tolerance in adult mice, which requires us to observe live individual animals over several days or weeks.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will review our procedures on a regular basis in our weekly lab meetings and share information with other groups and through our NC3R committee to establish best practice and continue to minimise the harm to the animals. We refine our work by reading the literature, listening to presentations in the field, and through this process of sharing and our weekly lab meetings. Examples include taking the data from one experiment and using it to revise the number of animals and the schedules of interventions and monitoring in the subsequent tests.

We will review the cost: benefit of all our experiments throughout the lifetime of the licence.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow published protocols which are assessed by our AWERBs in consultation with our veterinary surgeons. Some of the other resources we use include www.nc3rs.org.uk; https://norecopa.no; https://www.lasa.co.uk.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We follow and contribute to our local NC3R committee and attend committees for local users, where we share data and methods. We follow activity at www.nc3rs.org.uk and https://science.rspca.org.uk. We will follow best practice as it evolves. We monitor our animals closely. We will exchange information on animal welfare by engaging with NACWOs, Veterinary Surgeons and other investigators in our institute and outside it. We seek advice from our colleagues. We keep careful records so we can refine our protocols to be more efficient over time. We keep our training up to date and adopt new methods when they will improve animal care.

181. Mechanisms and rescue of absence seizures and their psychiatric comorbidities

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

non-convulsive seizures, cortico-thalamic networks, cortico-hippocampal networks, pharmacological therapy, psychiatric comorbidities

Animal types	Life stages
Mice	neonate, juvenile, adult, embryo, pregnant
Rats	neonate, juvenile, adult, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterize the mechanisms of generation, propagation and termination of absence seizures and their neuropsychiatric comorbidities.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Absence seizures are genetic generalized seizures that consist of sudden, relatively brief lapses of consciousness, lack of voluntary movements, a blank stare and 2.5-4Hz spike/polyspike-wave discharges in the electroencephalogram. Absence seizures are the only clinical symptom in childhood absence epilepsy, highly prevalent in paediatric/juvenile populations and often present with other seizure types in many age-dependent and age-independent epilepsies with greater severity and less positive clinical outcome.

Absence seizures are still considered relatively benign because of their non-convulsive nature and relatively high remittance rate in early adulthood. However, recent studies in large childhood absence epilepsy cohorts have shown that 30% of these children are pharmaco-resistant (a rate similar to that of more severe seizures), leading to polytherapy and consequent increase in drug adverse effects.
Moreover, 60% of children with absence seizures suffer from psychiatric comorbidities, including deficits in memory and attention that can persist after full pharmacological control of the seizures and be aggravated by some anti-absence drug. Notably, it is not known whether these comorbidities are causally linked to absence seizures or develop independently from the epileptic phenotype.

Thus, there is a compelling clinical need to discover novel therapeutic targets that may control both absence seizures and their comorbidities. However, though advances have been made in recent years to understand the pathophysiological mechanisms of these non-convulsive seizures, we still do not have a full picture of the mechanisms that control their generation and termination. Moreover, very few studies have addressed the origin and mechanisms of the comorbid psychiatric impairments that are present in children, teenagers and adults with absence seizures.

What outputs do you think you will see at the end of this project?

The primary output of this project will be the characterization of the mechanisms of generation and termination of absence seizures and their psychiatric comorbidities. Moreover, this project will identify targets that control both absence seizures and their comorbidities, leading to the development of single pharmacological entities that could rescue both the primary and secondary phenotypes of this neurological disease.

Who or what will benefit from these outputs, and how?

We expect early-stage (Phase 1) clinical studies on the use of endogenous substances against absence seizures and their comorbidities to be initiated towards the end of this project, whereas the synthesis and testing of novel exogenous substances may require longer efforts (5-10 years). Children, teenagers and adults with absence seizures will be the main cohorts benefiting from this project, including individuals with childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, epilepsy with myoclonic absences, Dravet syndrome and Lennox-Gastaut syndrome.

How will you look to maximise the outputs of this work?

The primary output of this project will be the publication of original papers in high impact journals describing the technical and scientific discoveries that we will make. Any potential improvements in the 3Rs will also be similarly publicized in relevant journals. Moreover, both technical, scientific and 3Rs output will also be disseminated at international neuroscience and epilepsy conferences.

Species and numbers of animals expected to be used

- Mice: 4000
- Rats: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

We will use the best available genetic mouse and rat models of absence seizures, that have strong face-, construct- and content-validity. Some work will be done in juvenile animals but other experiments will be performed in animals older than 3 months of age when absence seizures are fully developed.

Typically, what will be done to an animal used in your project?

Animals (~40%) will be terminally anaesthetized for *in vitro* histological, immunological and biochemical analyses of their brain.

Animals (~30%) will be implanted with EEG electrodes (under general anaesthesia) to test the effect on absence seizures of endogenous substances, anti-epileptic medications or drugs that modulate neuronal ion channels, transmitter receptors and transporters.

Animal (~30%) will undergo a series of behavioural tests to assess their memory and learning deficits and the effect on these impairments of endogenous substances, anti-epileptic medications and drugs that modulate neuronal ion channels, transmitter receptors and transporters.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect major long-lasting adverse effects resulting from the proposed procedures, though some temporary post-surgery discomfort may occur in some animals. Injection of a substance may also cause minor temporary discomfort. All substances to be used in these experiments will have been already tested in normal, i.e. non-epileptic, animals to confirm and establish their site and mechanism of action.

Fifty percent of the genetically altered mice may experience moderate harms due to an ataxia phenotype which involves loss of balance and coordination.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

30% of animals will experience subthreshold harms only - breeding without harmful phenotypes and genotyping by an unregulated method

20% of animals will experience non-recovery harms - due to anaesthesia induction

20% of animals will experience harms of a mild maximal severity due to surgery and/or drug injections. 25% of animals will experience harms of a moderate maximal severity due to an ataxia phenotype
5% of animals will experience harms of a moderate maximal severity due to surgery and/or drug injection.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Existing computer-programs that simulate the rhythmic electrical activity underlying absence seizures are highly inadequate in describing absence seizure firing patterns and associated membrane potential changes, because they lack data on single-neuron biophysics and network-wide firing interactions, i.e. the very same knowledge that our project aims to collect. Absence seizures cannot be reproduced in cultures of immortalized human cell lines or in primary animal neuronal cultures.

Though the technology for differentiating human fibroblasts and stem cells into excitatory and inhibitory (mainly cortical and mesencephalic) neurons are at present being developed, the complexity of absence seizure generation would require the differentiation and culturing, and successful interaction, of many different neuronal and astrocytic cell types from various brain regions: this, unfortunately, is still not available.

Which non-animal alternatives did you consider for use in this project?

In silico (i.e. computer-based) experiments, work in immortalized human cell lines and stem-cell- differentiated cell cultures. As indicated in the previous answer, these are all inappropriate for this project.

Why were they not suitable?

They are unable to reproduce absence seizures and their psychiatric comorbidities.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animals has been mainly derived from our 40 years' experience with similar types of animal experiments that were supported by previous Project Licences. Our current funds support three main research lines within the general "umbrella" of the "pathophysiology of absence seizures". Successful completion of one of these research lines earlier than anticipated may result in a reduction of this estimate.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3R's Experimental Design Assistant and the ARRIVE guidelines have been used, together with our long-standing experience in this field, to reduce the expected number of animals.

Notably, the epilepsy research-selective guidelines (whose publication I contributed to) were also used in the planning of the experimental design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible, the biochemical, histological and immunocytochemical analysis will be carried out on brain tissue harvested from animals that have completed other tests.

Our 40 years experience of using rat and mouse models of absence seizures has led to a very efficient breeding of these colonies with minimal waste.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The vast majority of the experiments will be carried out in the best available mouse and rat models of absence seizures, i.e the stargazer STG mice and the inbred Genetic Absence Epilepsy Rats from Strasbourg (GAERS), both of which have been shown to have strong face-, construct- and content- validity, i.e. to be valid models of this neurological disorder.'

The GAERS rats are superior to other available rat models since they have their own inbred control, non-epileptic strain (generally referred to as the NEC rat strain) to be used for comparative results. Moreover, the discovery of the cortical regions where absence seizures originate (before becoming generalized) was made in GAERS rats before being observed in children with absence seizures.

STG mice, as all other single-mutation mouse models of absence seizures, have a mild ataxia (problems with balance and movement coordination) phenotype.

The most selective drugs, the best transgenic species and strains are always selected even they are often expensive to purchase and maintain, respectively.

In vivo experiments are never carried out until we have solid *in vitro* data, thus ensuring optimal use of the *in vivo* preparations.

Why can't you use animals that are less sentient?

Absence seizures are developmentally regulated (both in humans and in animal models), i.e. so that they can only be appropriately studied in mice and rats that are older than 3 months.

Terminally anaesthetized animals cannot be used since both in humans and in experimental animals absence seizures are fully blocked by by general anaesthesia. New-born and juvenile animals will be used when assessing the developmental profile of abnormalities in brain receptors, ion channels and transporters.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Continuous monitoring and advice from animal care staff and NVS will ensure optimal housing and welfare conditions, in particular for the chronically implanted animals.

A high standard of environmental enrichment are consistently provided before and after any procedure, except in special cases, i.e. in chronically implanted animals.

Pre- and post-operative pharmacological control of pain and inflammation is consistently implemented.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I was instrumental in setting up a working group on the best practices for animal experiments in epilepsy. The working group included UK researchers in epilepsy, NC3Rs representatives, experienced NVSs from different national institutions, and world experts in epilepsy research from Europe and the USA. Moreover, Home Office inspectors attended, and provided input to, some of this group's meetings. I will follow the guidance that this committee published at the end of their work since it still represents the newest guidelines in epilepsy research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I received continuous updates from the NC3Rs newsletter and via the local Regional Programme Manager. Any advance in refinement techniques and methods will be carefully considered for implementation in consultation with local animal welfare personnel, provided their implementation would still allow comparison of results with previously obtained data.

182. Animal models of fibrotic diseases

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Fibrosis, Liver, Kidney, Experimental therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to provide a demand-led service for the delivery of new treatments for patients with fibrosis. This project will test the efficacy of antifibrotic drugs in validated rodent models, to refine and optimise the use of therapeutics for the treatment of fibrosis in humans. The data generated from our studies will impact the drug development process, support new drug applications, and allow drugs to progress to the clinical trials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fibrosis occurs in response to injury when the tissue repair response becomes uncontrolled, leading to thickening and scarring of the tissue, and organ dysfunction over time. Fibrosis can affect any organ, including, skin, lung, liver and kidney. It is a major cause of death worldwide and it is often seen in chronic inflammatory disorders, such as metabolic syndrome and cardiovascular disease.

Unfortunately, to date, only two drugs are available for the treatment of lung fibrosis, and no treatment has yet been approved for liver or kidney fibrosis.

Despite substantial progress in our understanding of the nature of fibrosis, a gap remains between the identification of antifibrotic targets and conversion of this knowledge into effective treatments in humans. Therefore, our preclinical data will pave the way to predict successful clinical trials and help pharmaceutical companies decide which drug(s) to develop.

What outputs do you think you will see at the end of this project?

This project will provide data from various pre-clinical models to biotech and pharmaceutical industries, to identify those compounds most likely to have the greatest clinical potential and highlight those with limited efficacy results.

The drug development in the field of fibrosis remains limited, hence offering this work as a service, represents an extraordinary opportunity to yield new discoveries and drive a new era of precision medicine in the treatment of chronic fibrotic diseases. In the long run, the project's potential outputs are human health improvement, thus reducing the burden on healthcare.

Who or what will benefit from these outputs, and how?

The principal benefit of this project is to identify promising next generation treatments for fibrotic disorders benefiting patients with multiple fibrotic conditions. The short-term benefit of the data generated from studies is to facilitate the drug development process. In medium-term the data generated is used to support new drug applications, and the long-term is to enable drug treatments to progress to the clinical trials.

How will you look to maximise the outputs of this work?

To maximise the outputs of this work, we will share the results of the project through publications and preprints when appropriate and possible, in line with the establishment policy for the use of animals in research. We will also look into building new relationships, both in the field of fibrosis and beyond, as the knowledge generated through this project can be easily applied to other diseases.

We have an extensive in-house experience of drug testing *in vivo*. We can provide to our commercial sponsors our in-depth knowledge of fibrosis and *ex vivo* tissue analysis to identify biochemical markers that better correlate with disease outcome. This will maximise the quality of the data and provide a broad census of cells involved in fibrosis. Crucially, this data will support our sponsors with increased diagnostic accuracy and prognosis in clinical trials.

Species and numbers of animals expected to be used

- Mice: 2400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The programme requires that models are used, which closely mirror the human biological system and can capture the potential therapeutic effects on fibrosis and inflammation. Adult mice are suitable for these studies as the work cannot be conducted in lower vertebrates, invertebrates, or cell lines due to the poor resemblance of these options to the clinical setting.

Typically, what will be done to an animal used in your project?

The bulk of the animals in this protocol will undergo at least one or two (100%), or up to four (50%) of the following procedures listed below:

Animals will be obtained from established providers and acclimatised for at least 1 week before studies are initiated.

Animals will be treated with agents that cause liver and kidney fibrosis. For all models, animals will be monitored daily and weighed at least 2-3 times a week, unless more frequent weighing is warranted.

Test Item (or the same solvent without any drug, if using controls) will be administered via a known route, and at a volume, concentration and schedule that is known to be well tolerated.

Blood samples may be collected periodically via a tail vein bleed in conscious animals. We will always follow the NC3Rs guidelines/limits for peripheral blood sampling. We may collect urine samples so that we can measure changes in kidney function associated with fibrosis (e.g., presence of different chemicals in the urine and urine volume). We will employ the most refined method of collection of urine, to include urine droplet, but where collection over 24 hours is required, mice may need to be kept in 'metabolic' cages.

In some instances, tissues from animals may be collected for studies in the laboratory (*ex vivo* studies) under terminal anaesthesia.

Fibrosis of the liver may be induced by injection of carbon tetrachloride into the abdominal cavity. This chemical is metabolised in the liver and converted to a highly reactive form, that causes liver damage, resulting in inflammation and fibrosis. This model of advanced chronic liver disease is one of the most widely performed and can also be used to study fibrosis regression as the damage caused by the chemical is partially reversed when exposure stops. Mice may be given a high fat diet prior to chemical exposure since liver fibrosis often overlaps with obesity. This model is useful to study toxic-mediated liver fibrosis and mimics acute liver injury in humans.

Non-alcoholic steatohepatitis (NASH), is a condition where fat accumulation causes liver inflammation and scarring (fibrosis). In order to mimic this disease, mice may be fed with a nutrient-deficient diet (choline- and L-amino-acid deficient), high-fat and cholesterol diet for a period of 12-16 weeks. Control mice will receive a matching diet. This model is of great significance to understand how lifestyle and nutrition play a role in the development of fibrosis.

Renal fibrosis i.e., fibrosis of the kidney, may be induced by feeding animals a diet rich in adenine for 2-4 weeks. This model allows the study of mechanisms involved in renal

dysfunction, similar to humans with chronic kidney disease. This model is relevant to understand renal fibrosis since inflammation and fibrosis markers can be detected during the progression or resolution of the disease when the diet is switched back to normal.

What are the expected impacts and/or adverse effects for the animals during your project?

Like humans, animals can sustain fibrotic injury for a long period of time with no apparent symptoms. In the rare scenario that an animal shows signs of organ failure we will ensure that the animal does not exceed the severity limits set out in this project. Previous experience has shown that these procedures typically induce mild to moderate adverse effects:

Animals will experience stress due to restraint and transient discomfort from needle insertion and/or anaesthetic injection or inhalation of gaseous anaesthetics (100 % incidence).

Repeated intravenous injection can result in irreversible damage to the vein and very occasionally, a haematoma/bruising may develop.

Intraperitoneal injection (through the abdominal wall) is likely to be painful if the needle injures an abdominal organ or if the substance being injected is an irritant.

Oral administration (gavage) is associated with minor discomfort. Very occasionally damage to the oesophagus may occur or substances may enter the lungs resulting in difficulty in breathing.

Slow-release pellets and osmotic minipumps are small devices implanted under the skin of the mouse and cause minimal effects. Animals may experience a lowered body temperature during anaesthesia required to implant these devices. Animals may experience pain on recovery from anaesthesia.

Animals will experience stress due to restraint and a transient discomfort from blood collection (100% incidence). Animals may become overheated or dehydrated from spending too long in the hotbox.

With all surgical procedures there is some risk of development of infections or wound complications (<1%).

Animals fed with high-fat diet will develop obesity (up to 100%) and greasy coat (up to 100%), which may lead to over-grooming (~25%) and as a result possible skin inflammation/ulceration and infection (expected incidence of <5%).

For a diabetic animal, if diabetes is ongoing, diabetic kidney disease, and high blood sugar will occur (up to 100%). For an obese animal without diabetes, weight gain can result in hypertension and respiratory depression.

Animals with liver or kidney damage may lose 10-15% of body weight (up to 70%).

Mice with kidney disease will show proteinuria (high quantities of protein in the urine) (100%).

Mice with liver disease could show abdominal swelling, although this is rare and extremely variable.

Animals may show cardiovascular or gastrointestinal system dysfunction (<10%).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Given the controls in place, the expected severity for animals under all protocols under the licence is moderate and may be experienced for up to 100% of animals used.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Fibrosis is a highly complex process. Producing a non-animal alternative in the lab, which replicates all aspects of fibrosis, is currently impossible. Due to the complexity and ever-changing physiological environment during fibrosis, the use of mice is necessary as the tissue architecture plays an important role in influencing this process. Currently, it is inconceivable that we will be able to generate computer models that will allow us to study the cell-cell interaction in an ever-changing three-dimensional structure that is required for this study.

The animal models proposed for this study, have been carefully selected to allow effective drug development and reduce animal pain. Although these models are specific for kidney, and liver, other organs such as pancreas, gut, heart, bone marrow, and skin can be analysed in one model. Therefore, this approach can address the current scientific need and minimize the number of animals required in each experiment.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives such as drug testing on liver organoids and *in vitro* assays using fibroblasts, hepatocytes or cell co-cultures are being successfully established in the lab. We have invested heavily in *in vitro* model systems over the last years, purchasing new analysis platforms for the laboratory and fostering collaboration with other laboratories.

This technology has been considered for initial drug screening, which may help to partially replace the number of animals used. We have focused on developing 3D cultures, derived from tissue samples obtained from a range of species, including mouse and human. These cultures allow us to look at how drugs directly affect the digestive system and help us identify potential novel treatments.

Why were they not suitable?

Liver and kidney fibrosis alternatives from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) will be considered. However, cells studied *in vitro* do not offer a true reflection of inflammation and fibrosis that animals can provide. Furthermore, common variations in culture conditions can have large effects on cells or organoids and have to be taken into account when designing experiments and comparing results. Therefore, the use of animal models is vital to facilitate disease study and subsequent drug screening.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Data from previously published studies has been used to estimate the total number of animals in each protocol. To obtain the desired effect, the number of animals estimated has been calculated based on the accumulation of type I collagen. Where possible we will make use of organoids or archived tissue to reduce animal use.

Therapeutic compounds studied under this licence will have demonstrated *in vitro* efficacy and will have some supporting toxicological data. Only those compounds showing reasonable activity and specificity for their intended target will be considered for animal testing.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have greater than 5 years of experience using mice as a model system to study fibrosis. I have used my experience together with statistical advice and online tools such as the NC3R’s to minimise the number of animals used for testing our hypothesis. Furthermore, prior to the experimental design, I used the 3R's site (www.3rs-reduction.co.uk), the PREPARE guidelines (https://norecopa.no/prepare) and had input from statistical experts to minimise the animal used while ensuring high reproducibility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Academic experts and independent companies are consulted to ensure the rigour of our experimental design and analysis. We are promoting multi-user studies to improve the efficiency of animal usage. We will stay informed about advances in the 3Rs (reduction, replacement and refinement), and implement these advances effectively during the project.

We will also have a fibrosis database to ensure that every organ collected will be recorded together with the relevant information (e.g., experiments conducted, age, sex) to ensure that it can be used when needed. In addition, the tissue collected can be used for pilot experiments. Furthermore, we will encourage clients to also share and publish negative

results to avoid unnecessary duplication of studies. Together, this will reduce the overall usage of mice in our experimental procedures while sharing the information with everyone in the university when possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models of fibrosis are well-characterised and demonstrate broad similarities with human disease, regarding symptoms and fibrotic changes. The models included in this project have been selected based on the disease origin. Furthermore, the least damaging models with appropriate translation into human disease are being selected.

There are other models available such as the rodent cafeteria diet (feeding animals a choice of food items to stimulate energy intake) or nutrient-depleted diets (e.g., methionine- choline-deficient diet), but they have not been included in this licence application due to insufficient fibrosis or excessive body weight loss, respectively.

Surgical fibrosis models have not been included due to severe adverse effects and distress. Instead, more refined, and less harmful models have been selected in the interest of maintaining relevance to human pathology.

Why can’t you use animals that are less sentient?

Mouse models are well-characterised and demonstrate broad similarities with human disease, regarding symptoms and fibrotic pathological changes, which non-mammal species do not adequately display.
Animal models have facilitated many discoveries that translated to humans, such as antifibrotic drugs and metabolic regulators of liver health. Examples are the glucagon-like peptide-1 (GLP-1) analogues, the farnesoid X receptor agonists (FXR) and the dual chemokine 2 and 5 receptor antagonist (anti- CCR2/CCR5) that currently are in development for the treatment of liver fibrosis (published studies).

Decades of research have provided substantial standard techniques to evaluate fibrosis in rodents, making mice the most suitable species for the studies proposed for this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animal handing and care will be conducted in a manner that minimise stress whenever possible. Other welfare measures will be:

Gavage: We use specifically designed gavage tubes, and may pre-coat our gavage needles with palatable lubricant, which has been shown to reduce the stress associated with the procedure and reduce gavage time.

Injections: Repeated injections will be not performed on the same site. We will alternate between the right and left side to reduce pain and discomfort. Furthermore, localised administrations and manipulations will reduce the adverse effects that are typically associated with systemic manipulations where multiple organs and cell types are affected at the same time.

Refinement can also be achieved in the type of mice we used. Animal genetic background will be considered to minimise harm. Very sensitive mice strains to the fibrosis model will not be used.

Special care will be given to all animals after a surgical procedure or prior to any animal experimentation where they will be gently handled in order to minimise stress caused by the procedures. This will include increased monitoring after any surgical procedure which includes post-operative care and analgesic if required. In addition, we aim to reduce the duration of all surgical procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure experiments are conducted in the most refined way, we will follow the Animals (Scientific Procedures) Act 1986, the Joint Working Group on Refinement ‘Refining Admin of Subst’ Lab Anim 2001, the PREPARE Guidelines, and the non-technical summaries found in: https://www.gov.uk/guidance/research-and-testing-using-animals. We are keeping up to date with the literature within the field of pre-clinical fibrosis research and are actively looking to implement refinements of our models.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have signed up for newsletters from FRAME, NC3Rs, and www.nlm.nih.gov/toxnet, a cluster of databases on toxicology & hazardous materials, to support our research plan, reduce animal numbers and refine the use of toxic compounds to induce fibrosis. The NORECOPA portal and the PREPARE guidelines will be regularly consulted for design planning.

183. Neural Mechanisms of Autonomic Control

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Autonomic control, Hypothalamus, Torpor, Critical Care, Homeostasis

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, aged, embryo
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify neural mechanisms that regulate autonomic function with a particular focus on torpor, and to develop strategies to modulate these circuits with the aim of improving patient care during critical illness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the United Kingdom around 200,000 critically ill patients are admitted to an intensive care unit (ICU) annually (www.icnarc.org). Of these patients almost 40% require life support involving mechanical ventilation under anaesthesia. During the current COVID-19 pandemic the UK demand for ICU beds increased 2.5 fold, with 72% of the COVID-19 patients requiring mechanical ventilation.

Admission to the ICU for organ support represents a state in which the demand for oxygen and nutrients is either unmet, due to respiratory or circulatory failure, or else oxygen and nutrients cannot be utilized by cells due to bioenergetic failure. Traditionally, ICU treatment has focused on redressing this imbalance by increasing oxygen and nutrient supply through fluid infusion, blood transfusion, cardiac support with drugs and mechanical support of ventilation. These approaches are far from perfect and frequently result in harm as efforts are made to increase supply to normal or even above normal levels.

An alternative approach, which balances the limitations in supply against the demand by reducing the metabolic requirement of the body could be beneficial in the treatment of many conditions seen in ICU. By reducing metabolic demand, patients may better tolerate critical illness avoiding the need for invasive interventions such as mechanical ventilation. As well as potentially preventing some of the harms from organ support, by reducing the intensity of the care required, this approach would also result in a reduction on the demand for ICU beds and staff.

Our understanding of the autonomic responses to the physiological challenge of critical illness is incomplete. We do not know which responses are beneficial and which are harmful. This lack of knowledge represents a fundamental challenge to optimising the management of life support for patients.

Torpor is a naturally occurring state that is like a short term hibernation (animals become cold, have a very low metabolic rate and appear to sleep), which in mice serves as a protective response to environmental challenge (such as food scarcity). The work conducted under this licence aims to advance understanding of the neural basis of the control of torpor. In so doing, we aim to identify the mechanisms behind beneficial, protective autonomic responses, with the ultimate aim of translating that understanding to develop better strategies for the treatment of critically ill patients. The findings of these studies will be of value to neuroscientists, patients, clinicians, and industry.

What outputs do you think you will see at the end of this project?

This study will advance understanding of:

The neural pathways within the CNS involved in thermoregulation, metabolism, and cardiorespiratory control.

Neuronal mechanisms of torpor control, and the extent to which analogous circuits exist in species for which torpor is not an extant behaviour.

The reciprocal interactions between physiological states such as torpor and circadian rhythms.

and to relay the knowledge gained to scientist and clinicians through publications in the scientific literature and conference presentations. In so doing the work aims to identify protective autonomic nervous system responses that may be manipulated to improve outcomes in clinical situations such as major surgery or critical illness.

Who or what will benefit from these outputs, and how?

The chief beneficiaries of the study outputs will be the academic, clinical, and industrial research communities, who will use the knowledge to drive future research and deploy new therapeutic approaches. Data generated will be published in high impact peer-

reviewed journals (as well as on preprint servers such as BioRxiv) and presented to appropriate audiences at national and international meetings. We will communicate our findings at public and patient engagement events and include patients as partners during the development of our research strategies. We expect in the long term that our outputs will benefit surgical and critically ill patients, and the wider society.

How will you look to maximise the outputs of this work?

We will continue to collaborate with academic research colleagues at both a national and international level to best exploit our research findings – a large part of our work involves international collaborations. We will disseminate our research through traditional peer reviewed publication and scientific meetings but will also publish our research (successful or otherwise) as open access pre- prints and will share the data via appropriate repositories. We will present to the public and at patient engagement events. We will protect any intellectual property so that it can be developed commercially and turned into treatments.

Species and numbers of animals expected to be used

- Mice: 1330
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents have been chosen for these studies because they have the least neurophysiological sensitivity of species within which mammalian autonomic control can be modelled, including the natural display of torpor. Rodents share many of the anatomical and physiological aspect of the human nervous system and consequently have been used extensively in similar studies worldwide. Non- mammalian species (e.g. arthropods and fish) are not appropriate as they either lack the brain structures of interest or, if present, lack the organisation and connectivity with higher centres that we seek to understand. Additionally, they have different neurochemical mediators and distinct receptors, so their pharmacology is often not directly comparable to human.

Both mice and rats will be used for these studies. Mice offer the advantage of naturally displaying torpor and are easily genetically manipulated. This allows the study of specific populations of neurons to define their role in autonomic control. Rats on the other hand offer the advantage of not naturally displaying torpor, but in many other respects are like mice. This allows investigation of the extent to which protective torpor-inducing circuits that exist in mice are present in species for which torpor is not an extant behaviour. Additionally, their larger size and greater cognitive ability offers advantages for some types of experiments.

Typically, what will be done to an animal used in your project?

The majority of animals used in these studies (~75%) will undergo a surgical procedure. In most cases this will involve the injection of a viral vector into a specific region of the brain.

Following surgery, these animals will be returned to a group housed environment for 2 to 4 weeks to enable sufficient expression of new proteins to allow recording or manipulation of neuronal activity. A subset of animals (20%), will have either a fibre optic cable or electrodes implanted into the brain, and/or implantation of a recording device into the abdomen to allow remote recording of core temperature, activity, blood pressure or brain and heart activity (~10%). These surgical steps may be undertaken together or independently, but no animal will undergo more than two surgical procedures in the course of the study. Following surgery, animals may be temporarily singly housed, while the skin heals, before returning to group housing.

Approximately 40% of animals, most of which will previously have received a viral vector injection, will undergo a period of food restriction lasting for up to 5 days during which food intake will be reduced to 70% normal and delivered at a specific time point, usually at the beginning of the active phase at lights off. In mice, this protocol reliably induces a state of torpor, typically by day 3 or 4. In rats, torpor is not induced but the food restriction activates the associated autonomic control pathways. Welfare and body weight will be assessed daily with weight loss limited to 20% from baseline.

Circadian rhythms will be assessed using a running wheel and/or video or remote recordings (~20%). Animals undergoing circadian rhythm analysis will be exposed to a period of total darkness (up to 5 days) in order to assess the impact on their sleep-wake cycle. A small proportion of animals (<10%) will be sleep-deprived for up to 4 hours (e.g. by introducing novel objects to their cage), which will be followed immediately by a period in which recovery sleep is allowed - this will allow the assessment of whether torpor shares some similarities to the neural circuits that regulate sleep. Another group of animals (5%) may be placed in either a warm (up to 30°C) or cool (16°C) environment for up to 5 days, which will tend to increase or decrease the probability of inducing torpor.

Animals may receive intra-abdominal injection of drugs to selectively induce gene expression or to alter neuronal circuit function.

At the conclusion of the study the animals will be killed, and their tissues further assessed ex-vivo using preparations such as working heart brainstem preparation (~30%), isolated heart function and tolerance (~20%); mitochondrial function assays (<10%), and/or histology (~80%). These ex-vivo experiments will be conducted to better define the neural circuits of torpor and also to identify any protective effects on organs.

What are the expected impacts and/or adverse effects for the animals during your project?

All animals undergoing surgery are expected to experience some pain following recovery from general anaesthesia. To mitigate against this, all animals will be given post-operative pain control, which will be maintained until the animals are showing no further signs of pain. All animals are expected to make an uneventful recovery from surgery and to resume normal behaviour within 24 hours.

Food restriction will induce a temporary state of hunger but is not expected to adversely affect the long- term wellbeing of the animals. Weight loss will be monitored daily and restricted to a maximum of 20%. Animals losing >20% of baseline weight will immediately be given ad-lib access to food, and those not regaining weight will be culled at 24 hours. For mice, entry into torpor is a natural and protective behaviour with no known negative impacts. Studies involving sleep deprivation, circadian rhythm assessment and modulation of the ambient temperature are not expected to generate any adverse effects.

Chemo- or optogenetic manipulations of autonomic function are expected to result in reversible changes to core temperature, cardiorespiratory function, and metabolism. These will all be via activation of endogenous circuits and are not expected to adversely affect the long-term wellbeing of the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Rats: moderate (100%)

Mice: moderate (70%);

Mice Mild (25%)

Mice: non-recovery (5%)

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the work is to advance understanding of the autonomic control of protective responses (such as torpor) with a focus on identifying those with the potential for translation into a clinical setting. It is not possible to studies these control mechanisms without using living animals as they involve integrated processing by many classes of neurons, located both peripherally and centrally, as well as endocrine factors which only exist in intact living animals.

Which non-animal alternatives did you consider for use in this project?

We have considered computer modelling and recordings from cultured cells such as stem cell derived neurons as alternatives. We also considered the use of human models. None of these provide viable alternatives to the use of animals at this stage, although in the future we would hope to translate our findings to humans and build computer models of the neuronal circuit functions.

Why were they not suitable?

Computer modelling requires biological data to build informative models and make accurate predictions – at present there is no adequate model of autonomic neurophysiological control that has any predictive validity. Cell cultures cannot be used to

make inferences about autonomic control as this requires an intact nervous system integrating information from many sources. Human studies have clear limits in the ability to isolate and control the experimental conditions (through exposure, insertion of recording and stimulating electrodes and the use of genetic and pharmacological tools to probe neuronal circuits) to definitively identify neuronal mechanisms, and at present we do not know the neuronal circuit(s) to target in a human setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have considerable experience in the study of autonomic control mechanisms including the use of chemo- and optogenetic paradigms and behavioural assessments. Specifically, we have been conducting torpor experiments over the past 4 years and the effects on physiological parameters of interest are large (like temperature, heart rate and metabolic function). We have used this information, as well as data from published studies, to estimate the numbers of animals needed (and so group sizes are typically between 6-10 animals).

For experiments using novel measures we will use data from the existing literature where available and conduct pilot experiments (n=3-6) to get an estimate of the necessary number of animals for the definitive study.

For the GA colony estimates these animal numbers have been scaled to take account of whether the strain of animals will be homozygous or heterozygous for the gene of interest (wherever possible we will use homozygous breeding lines). We have experience breeding GA lines for use in this type of experiment, and have calculated the number of breeding pairs required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will make extensive use of within animal controls which halves the number of animals needed for a study and reduces the variance so increasing the power to detect effects. We will use inbred strains of animals to further reduce variance. We will use animals of either sex and will stratify on this variable in our analyses to identify any sex specific differences. We use standardised surgical approaches and follow defined protocols for the adjustment of environment or food delivery. We have made use of the NC3Rs experimental design assistant when planning our investigations and making proposals to funders. Following in-vivo studies and killing, we will then use their organs in ex-vivo preparations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Wherever possible we will use homozygote lines of GA mice. We will make use of pilot studies for any new experimental protocols. Tissue from animals will be used for ex vivo

experiments such as the working heart brainstem preparation or in vitro experiments such as mitochondrial oxygen consumption assays.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a well-established protocol for torpor induction by food restriction. This protocol results in less than 20% body weight loss across 5 days, indeed once torpor appears, weight loss plateaus as it is an effective energy conserving strategy. For studies of circadian function, we will induce torpor by calorie restriction or by targeted activation of specific central circuits. To assess the impact on circadian rhythms this will then be followed by monitoring in an environment free of external time clues for up to 5 days, necessitating a deviation from normal housing conditions.

Most animals will undergo injection of viral vectors into the central nervous system (CNS). Where appropriate, animals may be implanted with telemetric devices to enable the recording body temperature, activity etc without needing to handle the animals, thereby minimising distress whilst maximising the data yields. A small number of animals will undergo implantation of cannulae, fibre- optic probes or recording electrodes into the CNS or into a blood vessel to allow delivery of drugs, stimulation and/or recording. These experiments will necessitate periods of tethering during recordings.

A minority of animals will undergo indirect calorimetry (up to 24 hours) and/or spirometry (up to 4 hours), necessitating their placement in a plexiglass box.

In all cases the least severe model, consistent with obtaining the necessary data, will be used. For each protocol we have clearly defined humane end points.
These approaches will allow us to study how the brain controls torpor, and how torpor interacts with other autonomic processes, as well as to study whether torpor-like states can be triggered in animals that do not naturally enter torpor.

Why can’t you use animals that are less sentient?

Rodents have been chosen for these studies because they constitute the least sentient species within which mammalian autonomic responses can be modelled. Non-mammalian species (e.g. arthropods and fish) are not appropriate as they either lack many of the brain structures of interest or, if present, lack the organization and connectivity with higher centres that we seek to understand. Additionally, they have different neurochemical mediators, ion channels and distinct receptors so their pharmacology and physiology are often not directly comparable to human. Rodents share many of the anatomical and physiological aspect of the human nervous system and consequently have been used extensively in similar studies in many other laboratories worldwide. We will make use of ex vivo experiments for some measurements. By using reduced preparations e.g. the working

heart brainstem preparation to address some of the cellular and circuit level questions in combination with targeted genetic approaches we will be able to minimise the numbers of procedures and the burden on sentient animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have refined and developed our approaches over the past 15 years. The animals used in these studies will be acclimatised to the unit prior to any procedure and handled during this period to habituate them to human contact. Surgery will be performed aseptically under general anaesthesia with appropriate post-surgical analgesia. Animals will be closely monitored and allowed to fully recover after surgery before any subsequent intervention. The surgical procedures and implants for our chronic recording experiments have been refined over many years to minimise their severity and to reduce the numbers of animals required to meet our objectives. Animals will be group housed (whenever possible) with environmental enrichment. They will be monitored for signs of distress or excess weight loss and will immediately be removed from the study if these are detected.

We continually seek to refine our experimental approaches to keep up with the state of the art in our research field. We have been early adopters of new methods (such as optogenetics and chemogenetics) that have allowed improved, more powerful experimental designs using within animal comparisons and reduced need for implants. We have also introduced high density neuronal recording systems that has increased data yields and reduced the numbers of animals needed for experiment.
By monitoring spontaneous rather than evoked behaviour and using automated assessments based on video recording we have sought to both reduce stress and make behaviours more naturalistic. During the course of this project licence, we expect this process of continual refinement to be embedded in our thinking about experimental design and methodological improvement. We will consult with NVS/NACWO throughout the duration of the project and will regularly review the options for refinement of our procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidance to improve our reporting of research using animals, maximising information published and minimising unnecessary studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of the Physiological Society, the International Association for the Study of Pain, and Society for Neuroscience, which all have a clear focus on 3Rs and experimental approaches for the study of physiology and autonomic control. I attend and present at 3Rs events along with my research team and am informed by the regular circulation of information from the NC3R's and keep abreast of developments at www.nc3rs.org.uk. Within my institute I am part of a working group on in vivo experimental approaches in Neuroscience.

184. Regulatory Testing of Biological Medicinal Products

Project duration

5 years 0 months

Project purpose

- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Biological Medicinal Products, Regulatory Testing

Animal types	Life stages
Mice	adult, neonate
Guinea pigs	adult
Domestic fowl (Gallus gallus domesticus)	embryo
Rabbits	adult
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project licence is to assess and confirm the safety of Biological Medicinal Products (BMPs) and to produce antiserum for regulatory purposes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work in order that BMPs can be tested and guaranteed to be safe for general use. These BMPs are mainly produced by novel biotechnological processes and include naturally occurring human proteins and hormones (e.g. insulin required by diabetics), blood products (e.g. factor VIII required by haemophiliacs) and

cytokines (e.g. interferons used in the treatment of cancer). Novel viral vaccine antigens (e.g. Ebola and COVID-19) produced by recombinant DNA technology are also tested and all these products are undoubtedly having a profound impact across the entire medical spectrum. Many of these BMPs have added treatment options for diseases which previously had no treatment options. There are however potential safety concerns that arise from the novel processes used in their manufacture and from the complex structural and biological characteristics of the products. Such products therefore require robust testing by in-vitro and in-vivo methods to allow adequate assessment of safety. A risk based approach is commonly taken by regulators depending on the product itself and the manufacturing process. So it is essentially because the products are novel that the robust testing schedule is required (or at least until there is more historical data to confirm that a type of product or a production process is safe).

The protocols used for this work are refined and compliant with the relevant regulatory standards. Furthermore, there is an established track record of excellence in animal care and welfare for studies of this nature.

What outputs do you think you will see at the end of this project?

The primary output is the safe development and release of BMPs.

Who or what will benefit from these outputs, and how?

The short-term benefits from this output are directly related to ensuring the safety and availability of existing products. Each production batch of a BMP must satisfy a defined group of batch release criteria to ensure that the batch is safe and potent. Official batch release of BMPs always involves the review of batch protocols for compliance with the Marketing Authorisation (MA). This is particularly important for biologicals since they can be prone to variability in their production and testing and are administered under particular conditions. The failure of a batch to meet pre-defined criteria will lead to a dialogue with the manufacturer and result in a formal investigation intended to prevent the release of an ineffective or unsafe product onto the market.

The medium and longer-term benefits are primarily related to the testing of products in development such as cell banks and viral seed stocks (required by regulators as detailed under Project Plan).
Without this testing, the pipeline of new products would be severely depleted and would pose a major risk to human health, particularly considering recognised issues of resistance against antibiotics.

The potential impact of the outputs have clear potential to be highly significant in supporting the licensing of human proteins and hormones (e.g. insulin required by diabetics), blood products (e.g. factor VIII required by haemophiliacs) and cytokines (e.g. interferons used in the treatment of cancer and in particular a new BMP with dual mechanisms of action which directly attacks cancer cells and also stimulates the immune system to recognise and destroy cancer cells). Novel viral vaccine antigens (e.g. Ebola, COVID-19, HIV, HPV and Hep B) produced by recombinant DNA technology are also tested and all these products are undoubtedly having a profound impact across the entire medical spectrum. Many of these BMPs have added treatment options for diseases which previously had no treatment options.

This licence will play a key role in getting new BMPs into Stage 3 Clinical Trials and ultimately provide essential data for market authorisation.

How will you look to maximise the outputs of this work?

All the in-vivo tests offered by the company are specified in pharmacopoeial monographs, each with defined pass/fail criteria. A rigorous quality system helps maximise the outputs and for instance a robust and comprehensive 'Out of Specification' or OOS procedure is in place to investigate any failed or invalid tests. This OOS procedure runs in parallel with a 'Corrective and Preventative Action' or CAPA procedure. This dual system allows all information on product type tested (and media components) to be collated and referenced to prevent failed or invalid assays with similar product types. These systems also ensure that the testing service operates with very few repeats and the development and release of BMPs is not stalled or delayed.

Species and numbers of animals expected to be used

- Mice: Approx 6,000 per year
- Guinea pigs: Approx 300 per year
- Rabbits: Approx 24 per year
- Sheep: Approx 8 per year
- Domestic fowl (Gallus gallus domesticus): 50,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Viruses that do not cause cytopathic or other noticeable effects in a cell culture system may be detectable in an animal system. The following animal and life stages are efficient isolation systems for the following viruses:

Suckling mice - Arboviruses, Coxsackie A&B, Herpes Simplex 1&2, Rhabdoviruses, Togaviruses, Junin, Herpes B.

Adult mice - Rhabdoviruses, Togaviruses, LCM.

Adult guinea pigs - Rhabdoviruses, LCM, Lassa, Junin, Marburg, Ebola, Mycobacteria

Embryonated Hen's Eggs - Herpes Simplex 1&2, Rhabdoviruses, Herpes B, Mumps, Influenza, Parainfluenza 1,2&3, Vaccinia (embryonated eggs are also used for the detection of adventitious viruses, the procedures on these animals are carried out, out with the scope of the Act since they are undertaken before the animals are classed as protected, however monitoring of the animals may continue up to 17 days incubation.

The various regulatory guidelines such as EP dictate that testing of BMPs is required in protected animals as well as embryonated eggs. Although there is some crossover in the range of viruses detected in different species, the sensitivity is not uniform and this range of species is considered the lowest risk approach.
Adult rabbits (and occasionally sheep) are used for the production of polyclonal antisera which is used to comply with EP 2.6.16 which describes the in-vivo and in-vitro assays required to detect adventitious agents in viral vaccines for human use. Immunocompetent

adults mount an immune response to multiple epitopes on an immunising antigen and the resultant antiserum can successfully neutralise the majority of viruses.

Typically, what will be done to an animal used in your project?

The vast majority of test articles will contain no adventitious viruses and there will be no adverse effects in the animals. In addition to daily general health observations throughout the study as part of routine husbandry procedures, all animals will be clinically monitored by an experienced person on a daily basis for up to 42 days following inoculation. Any animal exhibiting more than moderate discomfort or loss of condition will be euthanased on humane grounds and a necropsy may be carried out.

There is an expected mortality (<0.01%) for adult mice and guinea pigs. These unexpected deaths can occur occasionally and are often not related to test material. For antiserum production, an animal may be immunised on up to four occasions with adjuvanted antigen. The duration of these studies is normally 56 days and over that time up to four blood samples may be collected. Animals are exsanguinated under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects in safety studies are few and infrequent therefore >99.9% of animals will complete a study without experiencing pain or discomfort except at the time of administration. The occasional animal experiencing pain or discomfort is normally due to toxicity of a medicinal product which the manufacturer was not anticipating. Animals are always euthanased if in any distress or at the end of a study by an approved method.

Adverse effects in antiserum production studies are minimal and all animals should complete a study without experiencing pain or discomfort except at the time of administration or blood sampling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Suckling mice (adventitious agents) - Expected severity is MILD and expectation is 100% but experience is that ~0.01% of animals have exceeded this annually.

Adult mice (adventitious agents) - Expected severity is MILD and expectation is 100% but experience is that ~0.01% of animals have exceeded this annually.

Adult guinea pigs (adventitious agents) - Expected severity is mild and expectation is 100%.

Rabbits (antiserum production) - Expected severity is mild and expectation is 100%.
Sheep (antiserum production) - Expected severity is mild and expectation is 100%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For adventitious agents testing, the safety of new products is being evaluated in animals to comply with regulatory requirements. It is therefore not possible to move towards in-vitro alternatives without approval from governmental regulatory bodies - essentially national and international legislation would have to change.

Which non-animal alternatives did you consider for use in this project?

The use of non-animal alternatives have not been considered for adventitious agents testing for the reason stated above. The use of non-animal-derived antibody technologies have however developed considerably in recent years and clients are encouraged to develop non-animal alternatives through the period when a product is being developed (particularly later stages). Due to complexities relating to the validation of the neutralisation process, this can take considerable time and animal derived antibody is required in the early stages of development. Antiserum production services are not offered for licensed products.

Why were they not suitable?

The use of non-animal derived antibody has been assessed by clients* and considered problematic because often they cannot recapitulate the properties of animal-derived antibody and for instance they may neutralise and impact the detection of other similar viruses and is therefore considered high risk in terms of human safety. That said, generation of system-compatible, neutralising synthetic antibody is technically possible but requires a framework with diversity restricted complementarity-determining regions which is a lengthy process. This should be possible for licensed products but is not feasible when a product is in development. Going forward, the production of neutralising antibody in animals will only be offered for a product in the early stages of development or if neutralisation by synthetic antibody is impossible.

*We were a strategic partner in the release of a COVID-19 vaccine and antiserum was required to neutralise the vaccine's viral vector. In this instance, the use of commercial antibody was not feasible since there was a risk that it neutralised and impacted the detection of other potential adventitious adenoviruses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.
How have you estimated the numbers of animals you will use?

Numbers have been informed by experience under predecessor licences.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Group sizes are set in the various regulatory guidelines and the criteria for test pass or fail are clearly defined in the pharmacopoeial monographs.

Animal studies will only be conducted when there is a reasoned, sustainable justification for the generation of new test data, there is no validated alternative to animal testing and the protocol will generate data which will meet the specified objective, will be scientifically valid and will be acceptable to the relevant regulatory authorities.

Eggs numbers listed are for eggs which will be incubated for up to 17 days.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Steps are taken to ensure that the number of control groups is minimised by running several test groups beside a single control group.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For the detection of adventitious agents, models and methods are set in the various pharmacopoeial monographs.

For the production of polyclonal antiserum a 'double emulsification' procedure is used prior to immunisation to ensure that any local reactions/response to immunisation is minimal. This procedure was developed within the Establishment and positively improves the experience of the animal without compromising the quality of the antibody.

Why can’t you use animals that are less sentient?

For the detection of adventitious agents, life stages and species are set in the various pharmacopoeial monographs.

For the production of polyclonal antiserum, mature animals with fully developed immune systems are required. The final exsunguination is undertaken under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Care is always taken to ensure that increased monitoring is in place if any animals show signs of discomfort or distress (or where it might be anticipated). Veterinary support is also available 24/7 should the need be required.

The provision of environmental enrichment is also a priority for all studies. For example all antiserum production studies in recent years have employed communal floor pens where rabbits have raised areas, tunnels and other items. As a result of the work of the 3R's committee the Establishment has introduced enriched and improved environments for avian species, goats, cattle and also introduced a new welfare-friendly farrowing crate system.

At each meeting of the Establishment AWERB, in addition to other business, specified project licensees, or their representatives are asked to present details of experiments or project licence applications or amendments with particular reference to their continued justification for animal usage. The members of the AWERB are invited to give their comments and advice for any amendments required, with particular relevance to the application of the 3Rs. This licence is therefore under the constant scrutiny of the AWERB.

Refinements and improvements are shared with other licence holders working in similar areas.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The Establishment 3Rs committee produces newsletters and presentations on housing and enrichment for staff working directly or indirectly with experimental animals.

The NC3Rs website is used for guidance and information and this website also provides links to other relevant publications and events.

European Commission reports are also circulated and discussed e.g. EURL ECVAM Status Report (2020) - Non-animal Methods in Science and Regulation and EURL ECVAM Recommendation on Non- Animal-Derived Antibodies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment has a 3Rs committee and one person from the team involved with this licence sits on this committee. There are regular communications and training recommendations from this committee to all personal and project licence holders. The main objectives of the 3Rs committee is as follows:

To provide a framework of people across all departments with an interest and experience in the 3Rs.

To produce a resource of techniques and materials to facilitate Enrichment and Refinement wherever possible.

To provide a vehicle that supports engagement with enrichment and refinement during the ethical review process to include reporting on and discussion of methods employed.

185. Profiling of test agents in rodents in a drug discovery platform

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pharmacokinetics, Drug discovery, Tolerability, Biomarkers, Safety

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to generate data on the pharmacokinetics, pharmacodynamics and tolerability of test agents for the disease areas listed in this licence, and the effect of test agents in rodents over a longer period of dosing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will generate crucial data in the preclinical (before human dosing) development of potential new drugs for the treatment of cancer, cardiovascular diseases and disorders of haemostasis, metabolic diseases, inflammatory diseases and neurological diseases. All of the diseases we work on are diseases were current treatments are not available or need improving upon. These studies will generate important information that

cannot be found without the use of animals. All clients that we work with are developing test agents (potential new drugs) which will hopefully contribute to helping people with various diseases where current treatments are not available or need improving upon.

This project investigates both how the test agents are processed and removed by the body (pharmacokinetics, or PK), and how the test agents affect the function of the body (pharmacodynamics, or PD). This requires information from a whole animal system and cannot be replicated in a cell or a test tube. The project will determine important characteristics of test agents to decide the best dose levels, dose routes (how the drug is taken) and patterns of dosing (how often the drug is taken), whether the test agents have early signs of unwanted side effects, and whether the test agents are likely to work as an effective treatment for disease. This information will be key in decisions regarding which test agents should continue to be developed, and which are unsuitable for further work. Ultimately, this will feed into which test agents make it into clinical trials, where they are tested in humans. Our approach to the work ensures that this is done in the most efficient way possible, and that the use of every animal is maximised.

What outputs do you think you will see at the end of this project?

As part of this project, we expect to test the PK (what the body does to the drug) of at least 30 test agents, of which the majority will be new test agents. We expect at least 10 of these to move onto further work either under this project or other projects. In addition, we expect to run a minimum of 20 longer term studies looking at the safety and tolerability of test agents as well as how they change body function as part of this project.

Data produced by studies under this project may be used to support patent and funding applications by clients. They will also support the design of regulatory preclinical (animal) studies for clients and may be included in applications for regulatory approval. We will also provide valuable information from this project that will halt the further development of several test agents, preventing unnecessary use of animals in studies using test agents that would not be suitable for use in humans. These test agents will be for potential use as a therapeutic in the following disease areas:

Cancer

Cardiovascular diseases

Disorders of haemostasis

Metabolic diseases (including inborn errors of metabolism such as alpha-1 antitrypsin deficiency)

Inflammatory diseases

Neurological diseases

Who or what will benefit from these outputs, and how?

This project will generate important data in the development of potential new drugs.

The PK analysis which determines how much drug gets into the body and what the body does to the drug will enable our clients to select the best test agents (drugs) for further development. These studies show how long it takes for drugs to get into the blood and the

length of time they stay in the blood or tissues (parts of the body) before the body gets rid of them. As well as providing information for key decisions as to whether test agents are likely to make suitable drugs, PK studies provide vital information required to design the longer-term studies needed in drug development. Ultimately, PK studies also feed into the design of clinical trials.

The safety and tolerability work will check that test agents are suitable for repeat dosing over longer time periods and look to see if test agents have any early side effects. These studies will help with working out the best dose for potentially treating disease. They also make sure that we identify any unwanted side effects that mean that they would not be suitable for use as a drug for humans. These studies also help us to design longer term studies in the best way possible to provide the information required about the way the test agent is working.

The longer-term dosing studies in this project will allow us to investigate the effects of the test agents on biomarkers, which are measurable levels of key molecules in the body which tell us whether body function has been altered by the drug. This will provide us with information on whether the test agents are able to alter the levels of biomarkers that are most relevant to the disease that the test agent is designed to treat. If a test agent does not alter the important biomarkers, this may mean it will not be a suitable treatment for disease.

Our focus on using a science-led approach will enable key decisions to be made at each development stage on whether a test agent is likely to become a successful drug. This allows test agents which are not suitable as drugs to be abandoned at an early stage using the fewest number of animals possible for each test agent. The identification of test agents as unsuitable for use in humans at an early stage of development will also ensure a better success rate in the drug discovery process than has previously been seen in the pharmaceutical industry. Ultimately, this project will contribute to the successful development of new drugs, which will benefit patients with the diseases being treated.

Health conditions linked to inflammation are very common and half of deaths worldwide can be linked to diseases involving inflammation. Cardiovascular and metabolic diseases lead to a third of deaths worldwide. Disorders of haemostasis contribute to these deaths where abnormal clotting occurs. In the case of the rarer diseases where clotting is reduced, such as Haemophilia, the diseases reduce life expectancy. Cancer is also sadly a leading cause of death worldwide, with more than a quarter of deaths in the UK involving cancer. With both an aging population and the increasing problems with obesity in society, the occurrence of these diseases is likely to increase. Neurological diseases are also increasing, with Alzheimer's and dementia the leading cause of death in the UK in 2018. There is a lot of overlap between the diseases covered by this project, for example a rise in cardiovascular and metabolic diseases such as heart disease and diabetes increase the risk of stroke and the associated life-changing neurodegeneration. Therefore, it is clear that investigation into potential new drugs for all of these diseases is required to improve chances of survival, but also to improve the quality of life for patients living with the diseases.

How will you look to maximise the outputs of this work?
All studies are designed such that the outputs from each animal are maximised. Expert knowledge is gathered not only from within the preclinical (animal work) team performing the animal studies, but from other teams at our company. This ensures that all relevant work that has been performed in the laboratory is taken into consideration when designing the animal studies. The *in vitro* (in the dish/test tube) and bioanalysis teams at our

company are experts at analysing tissue and blood samples collected from animals, and they help with details of sample collection and storage to ensure that the samples are collected and stored in the best way possible. They are also experts at working with small samples, particularly small blood samples, meaning that they can often analyse lots of different biomarkers and test agent levels from each animal.

In addition, we will seek expertise from our established networks both within our establishment and further afield, to ensure that we make use of any new knowledge or better methods of performing animal studies. We will also use these networks to give information to others about any ways in which we can help via our research. This will include sharing information about unsuccessful approaches in addition to sharing information on any refinements and improvements. We will maintain good communication with managers of the animal facilities to ensure that any tissues from animals being killed that are not required for our work can be made available to other researchers.

Due to the nature of the work undertaken in this project we are unlikely to be able to publish data, as this would put ourselves or our clients at a competitive disadvantage. However, where advances are made in study design, we will publish or share these wherever possible.

Species and numbers of animals expected to be used

- Mice: 3200
- Rats: 1750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Both mice and rats are well established 'models' for use in studies determining the PK and tolerability of new test agents and the effect of test agents on biomarkers. This is due to their similarities to humans, with these 'models' mimicking aspects of human physiology and disease. They are very well characterised, meaning that there is a lot known about how the body works in mice and rats, both when healthy and with diseases. This helps in the interpretation of results from studies using test agents. We are using adult animals in this project as this will reduce the variability in the results and is the life stage most relevant to the majority of test agents. This project will look at test agents for the following disease areas:

Cancer

Cardiovascular diseases
Disorders of haemostasis

Metabolic diseases (including inborn errors of metabolism such as alpha-1 antitrypsin deficiency)

Inflammatory diseases

Neurological diseases

Typically, what will be done to an animal used in your project?

In the majority of studies, test agents will be administered to animals. This dosing will be by a number of different methods. Test agents will be administered intravenously (into a vein), intraperitoneally (into the abdominal body cavity), subcutaneously (under the skin), orally (either using a dosing tube or via adding the test agent to the food or drinking water), intranasally (inhaled into the nose), intracolonically (into the colon) and/or intraduodenally (into the small intestine). Where dosing is performed intranasally or intracolonically, this will be in animals who are anaesthetised. Intravenous injection may also be performed under anaesthesia but will usually be performed in conscious (not anaesthetised) animals.

On occasions a slow-release device will be implanted for the subcutaneous or intraperitoneal administration of drugs.

In PK studies animals will usually be given one dose of test agent and blood samples will be collected multiple times after this dose is given. In some PK studies, we will use animals with a cannula, which is tubing allowing direct access to either a blood vessel or to the gut. These cannulae require surgery to put them in place. This surgery will either be performed by scientists at our company using our in-house expertise, or more commonly performed by an external supplier who are experts in these surgeries.

When using animals with a cannula into a blood vessel, they may be given the same test agent twice, once straight into the blood (intravenous) and once by a different route, with blood samples taken after both doses. There will be enough time between the two doses to make sure that no test agent is left in the body before the second dose. This will allow calculation of how much of the drug given by an extravascular route (not straight into the blood, for example given orally) makes it into the blood.
For safety and tolerability studies, animals will be dosed with test agent(s) over a period of several days or weeks. In some safety studies the dosage will be set at a level predicted to be effective when used as a treatment in animals to check if any side effects are observed. For tolerability studies, the concentration of test agent(s) may be increased during the study to test if higher doses have early side effects. Blood samples may be collected during the study and blood and tissue samples will be collected at the end of the study to make sure as much data as possible is generated from each animal. During safety and tolerability studies, blood samples may also be taken to investigate the PK of the test agents being used, and whether this is changed after the animals have received the test agent for several days.

For dosing studies, animals will be dosed with test agent(s) over a period of several weeks or months. Dosing will usually be daily, but this may vary depending upon the test agent. Blood samples may be collected at regular intervals during the study for the measurement of biomarkers or test agent levels. Other non-regulated procedures such as urine collection may also be performed. Blood and tissue samples will be collected at the end of the study to maximise the data generated from each animal.

Where animals are used only for the collection of blood or tissue samples for *ex vivo* work (work outside of a living body in the laboratory), all procedures will be performed under non-recovery anaesthesia where possible, such that the only procedure the animal experiences is the process of being anesthetised. They will then be kept unconscious under deep anaesthesia whilst blood and/or tissue(s) are collected. On some occasions, animals may be dosed with a substance prior to humane killing, if required for the *ex vivo*

work. Again, where possible this will be performed under non-recovery anaesthesia, but on some occasions it may be necessary to dose animals over a period of weeks prior to blood collection. Terminal blood and tissue samples will be collected immediately before death and rodents humanely killed. Additional tissue samples may be collected after death.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals used for PK studies, longer-term dosing studies and those used for the collection of blood samples for *ex vivo* work should not experience more than transient (short-lasting) pain and discomfort. Those animals with a cannula for PK studies will go through a surgery before the PK study is performed. The surgery will be performed under general anaesthesia, such that the animal will remain in a state of unconsciousness throughout the surgery. Recovery from surgery is expected to be quick, with recovery from anaesthesia within 2 hours. In most cases, the cannulation surgery will be performed by an external supplier who have extensive expertise in these surgeries and reliably perform the surgery without problems. Animals will be allowed to recover for a suitable period determined by the supplier (currently 7 days) prior to shipment to us. For vascular cannulation, we often use vascular access buttons located in the interscapular region. These vascular access buttons connect to the end of the cannula and have a magnetic metal cap to cover the access point, meaning that animals are able to be group housed without the risk of the cannula being damaged by cage mates. In all cases the cannulae do not cause problems with the ability of the animal to move freely and scratching at the cannula site is only observed on very rare occasions. Where a slow-release device is used in longer- term dosing studies, these animals will undergo surgery under general anaesthesia, with quick recovery expected. The location of the slow-release device is not expected to have any effect on the animal's ability to move freely.

The majority of animals undergoing safety and tolerability studies will only experience transient pain and discomfort. However, some animals may experience more significant side effects. These could include weight loss (up to 15%, or 20% when using test agents designed for the treatment of cancer), pain and subdued behaviour. There are two main reasons when these studies may be required to cause more side effects. One of these is where the test agents are designed to treat fatal human diseases, where more side effects are acceptable in humans, for example in the case of chemotherapy for treatment of cancer. The other occasions are studies where it is important to find out what the maximum dose that can be given to animals is. Understanding the maximum dose that can be given is important as it allows decisions to be made on the doses for all future work. In these studies the dosage will be gradually increased until side effects are noticed. Once side effects are observed the dose will be held at that level and the study typically completed within 72 hours. This allows us to see if the animals develop tolerance to the drug and the side effects normalise, or whether the side effects are sustained. Animals will be closely monitored to ensure that they do not suffer excessively.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse - Mild: 66% Mouse - Moderate: 26%
Mouse - Non-recovery: 8% Rat - Mild: 59%
Rat - Moderate: 30% Rat - Non-recovery: 11%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The work to be performed in this project cannot be fully replaced by using models in a laboratory. Wherever possible, work is performed either using cells or tissues taken from an animal before moving into animal studies, to make sure that the animal studies are well designed and that the maximum amount of data is gained from each animal study. However, this project aims to investigate the PK, tolerability and effect on biomarkers after dosing with test agents, which cannot be determined without using animals.

Which non-animal alternatives did you consider for use in this project?

Work can be performed in the laboratory to ensure that test agents are acting as expected before moving into animal studies. These may be using cell lines grown in the lab, or using tissues collected from animals. For example, we have previously performed these types of experiments by running assays (laboratory experiments) looking at how quickly blood clots form in rodent blood, or by looking at the effect of a test agent on liver cells collected from a mouse. We use these studies before moving into animals to make sure that test agents that are unlikely to be useful to humans do not get tested in animals.

Why were they not suitable?

The use of animals is essential to determine how the body acts on test agents, and how test agents act on the body. It is not possible to determine how a drug gets into the blood and how it is broken down and removed from the body without using live animals. Similarly, it is not possible to determine whether a test agent will have side effects using cells or tissues in a laboratory, or to find out the effect a test agent will have on biomarkers.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used has been estimated by analysis of the number of animals used on previous projects, looking at the number of animals required for each type of study. This was then combined with a prediction of likely demand of future projects to give the numbers in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have extensive experience in the design of experiments of the types in this project, which has given us confidence in the number of animals required to ensure that no animals are used unnecessarily, but also that the data generated is reliable. Whilst through experience we do tend to use a standard group size for the majority of our pharmacokinetic (3 per group) and tolerability (5 per group) studies, we regularly refer to the PREPARE and ARRIVE guidelines and make use of the NC3Rs Experimental Design Assistant to ensure that we are using the correct number of animals for every study. When designing experiments for the effect of test agents on biomarkers, we also look at published literature to determine the variability observed in the biomarkers of interest where we have not tested these before. Where information is not available in published literature or from contact with other researchers, pilot studies in a small number of animals will be used first where appropriate to assess the variability of the biomarker to be tested and to determine the appropriate group size for future experiments. We can then use the NC3Rs Experimental Design Assistant to help determine the most appropriate group size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Data from pilot studies and previous experience are used to ensure that the numbers used are both as low as possible, but also large enough to generate reliable data. Within our company, a member of the wider team has generated a tool for performing power calculations and can be consulted as necessary to assist with study design.

Where genetically altered animals are required, these will usually be provided by our breeding project, which will ensure that animals are bred efficiently using as few animals as possible by communicating need with colony managers. Where animals are obtained from external sources, only the number of animals required for the study will be purchased or imported.

Wherever possible, our *in vivo* (animal work) scientists will be blinded to the treatment status of an animal, reducing bias. This enables more reliable information to be gathered from a smaller number of animals. Those who carry out analysis on blood and tissues collected during the study are also blind to any treatment with test agent where possible.

Baseline data (e.g. bodyweight, biomarker levels) are recorded and animals assigned to treatment groups to minimise differences between the groups at the start of the study.

Good planning ensures that within any series of studies we can control for variability that might be introduced. To limit this variability we look at using animals of a similar age/weight range, testing different batches of test agent in the lab first, using the same source of reagents (chemicals used during the experiments), keeping records of observations made and standardising as many components of the *in vivo* model as is practicable.

We will also provide valuable information from this project that will halt the further development of several test agents, preventing unnecessary use of animals in studies using test agents that would not be suitable for use in humans.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use both mice and rats during this project. Some of these will have a genetic alteration that will not cause them harm, but which provides a more appropriate model in which to perform experiments on test agents for particular diseases.

PK studies are generally performed using a low dose of the test agent which reduces the chance of any unwanted side effects. However, when the test agent has not been dosed to animals previously, a small group will be dosed and monitored for 2 hours to ensure that there are no side effects before the test agent is given to the remaining animals. These animals will be further monitored up to 6 hours post dosing to ensure any side effects that occur several hours after dosing are also observed. PK studies involve taking blood at several different periods of time after dosing (time points) from as short as 2 minutes to as long as days after dosing. Where multiple animals are dosed with the same test agent, blood samples will be collected at different time points from the different groups of animals. The animals dosed first will be those for longer time points, with animals for shorter time points dosed subsequently. This means that side effects which are not seen until more than 2 hours have passed will not be relevant to animals dosed later in the day and that it is appropriate to begin dosing additional groups after only 2 hours. If any side effects are observed, the study would be stopped or the dose lowered. If side effects are observed, these would likely be subdued behaviour, piloerection (hair standing on end) or a hunched appearance.

Where it is hard to predict the potential side effects of a test agent, studies will be performed in a small number of animals first who will be monitored for at least 2 hours or overnight in the case of test agents where side effects are likely to take longer to be seen. Where side effects are observed, the dose may be altered to ensure no long-lasting side effects are seen before any longer-term studies are performed.

Dosing will always be performed using the least invasive route (e.g. oral dosing via food or water if possible), and where a needle is required using the smallest needle possible.

Why can’t you use animals that are less sentient?

Mature mice and rats are essential for studying complex diseases, where all systems must be similar enough to humans to find the most effective drugs. The duration of most studies in this project are longer than can be performed under anaesthesia as they span several days or weeks. The anaesthetic drugs themselves may also affect the results of the studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have a demonstrable history of refining our procedures and practices to minimise harm to our experimental animals. For example, we always use the smallest needle possible for dosing to minimise any pain and distress to the animal. We also investigate the suitability

of test agents administered orally to be dosed via the drinking water rather than via oral dosing, where the dose is administered via insertion of a tube down the throat. We recently implemented this for a test agent, allowing us to switch from twice daily oral dosing to dosing via the drinking water. We will also sometimes use a slow-release device for dosing. Whilst this requires an initial surgical procedure, it reduces the need for the stress of regular injections.

During studies that involve repeat dosing, animal condition and bodyweight is monitored regularly, with body weight recorded prior to each dose as a minimum. We are developing a scoring system to monitor any side effects observed due to dosing, which will help us to ensure that these are tracked and acted upon as necessary.

Animals will be housed in social groups in the vast majority of cases, with animals housed alone only where this is absolutely necessary (for example in some animals who have a cannula inserted, where cage mates may dislodge the cannula). Where anaesthesia is used, care will be given to support animals during anaesthesia and recovery, using heat hats to maintain body temperature and providing soft diet and hydrogel to aid recovery as appropriate.

We use microvettes (small capillary blood collection tubes, coated with anticoagulant if appropriate to prevent blood from clotting) to collect small blood samples from animals. This allows us to take small samples in the most efficient way possible. We have also developed methods to be able to use a mixture of blood and water for some of the tests run on rodent blood, which allows us to collect a smaller volume of blood than would be required when using standard methods of preparing plasma from collected blood.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will be using PREPARE guidelines for the planning of studies and follow the latest version (2020) of the ARRIVE guidelines for ultimate reporting of data. The LASA document ‘Guidance on dose level selection for regulatory general toxicology studies for pharmaceuticals’ will be used when planning studies, to help guide study design. This document, particularly the section detailing the report of the FELASA working group on pain and distress has also been used when setting the humane endpoints within this project. Where surgery is performed, we will refer to the LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery. We will also regularly check the current list of LASA publications, to ensure that any relevant to work under this project are taken into consideration.

Similarly, we will regularly reference the NC3Rs to ensure that we are implementing best practice for the techniques undertaken.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

When designing animal studies we consider the appropriate guidelines, including the guidance from LASA, the NC3Rs and the PREPARE and ARRIVE guidelines. This guidance will influence our study design. One example of this is the use of the NC3Rs guidance on the number and volume of bleeds to be taken from rodents in the design of pharmacokinetic studies. We regularly check the NC3Rs website, along with other external resources such as Norecopa and Jax, to ensure that we are using the most refined methods and are aware of any improvements to procedures that have been developed.

186. Vascular cytoprotection during inflammation

Project duration

0 years 8 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

angiogenesis, cardiovascular disease, endothelial homeostasis, inflammation, endothelial transcription

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of our work is to further our understanding of the transcriptional pathways which regulate endothelial homeostatic and protective genes, and modulate the complex process of angiogenesis. The ultimate long-term aim is to define the means to therapeutically target these pathways to: (i) prevent and reverse endothelial dysfunction and atherogenesis, and (ii) specifically enhance or inhibit angiogenesis as required in different disease scenarios.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work? Cardiovascular Disease
Cardiovascular disease, and atherosclerosis (which is the build up of fatty substances in the walls of blood vessels leading to restriction of blood flow to vital organs) in particular,

remains the biggest killer in the developed world and are increasingly common in the emerging economies. Despite this, preventative strategies are relatively ineffective and treatment is often delayed and only initiated after presentation with angina, myocardial infarction or stroke. This in turn results in a huge financial burden to health services. Critically, therapeutic options remain limited and progress has stalled since the introduction of statin therapy. Thus an important challenge remains, namely the development of optimal preventative treatment. We propose that improved understanding of the biology of the vascular endothelium, the single layer of cells that line the surface of all blood vessels, will allow us to identify novel therapeutic targets and ultimately novel therapies aimed at preventing or retarding cardiovascular disease.

Vascular injury and endothelial dysfunction

Vascular endothelial cells (EC), which line all blood vessels, play a central role in the regulation of inflammation, vascular tone, blood clotting (haemostasis), wound healing and new blood vessel formation (angiogenesis). By virtue of its anatomic location the vascular endothelium is continuously exposed to harmful factors including inflammatory mediators circulating in the blood, white blood cells (leukocytes) and activated forms of a cholesterol transporting protein (oxidatively-modified LDL).

Moreover, endothelial injury and dysfunction may contribute to the premature atherosclerosis seen in patients with diabetes, renal failure, systemic lupus erythematosus or rheumatoid arthritis. In order to combat this, cytoprotective pathways have evolved which are activated during inflammatory responses. They act to maintain vascular integrity and assist endothelial repair. An important additional function of the endothelium is angiogenesis, the development of new blood vessels from pre-existing vasculature. This process plays an essential role in vascular repair, wound healing and remodelling.

However, aberrant angiogenesis has also been implicated in a variety of diseases including cancer, rheumatoid arthritis and atherosclerosis. Vascular endothelial injury is the earliest detectable event in atherogenesis and predisposes to endothelial dysfunction. Our initial approach has been to study the molecular mechanisms involved in endothelial homeostasis, vasculoprotection and angiogenesis, with the ultimate aim of therapeutic manipulation. Endothelial dysfunction is characterised by a local inflammatory response, impaired nitric oxide biosynthesis, enhanced oxidative stress and increased permeability to lipids and monocytes. If unchecked this dysfunction leads to endothelial injury and programmed EC death (apoptosis), which occurs preferentially at arterial branches and curvatures, where loss of arterial endothelium and exposure of the underlying extracellular matrix enhance the risk of thrombosis.

What outputs do you think you will see at the end of this project?

The predominant output during the duration of the licence will be in the form of novel scientific data published in peer-reviewed scientific journals with an open-access platform. We will also continue our regular presentations at Local, National and International conferences including the European Vascular Biology Organisation seminars and International Vascular Biology Meetings. We will also engage in meetings aimed at presenting scientific data to the public which are organised by my institution, and funder-supported outreach events and site visits. These data will be available to other researchers both scientific and clinical.

Who or what will benefit from these outputs, and how?

We believe that therapies are required that act to reduce the incidence of atherosclerosis-related disease in those patients known to be at high risk. For example those with diabetes or inflammatory diseases. Our focus is endothelial dysfunction and how we might reverse that. We believe that we have identified pathways that are important for endothelial protection. The current project will seek safe and effective ways to switch the protective pathways on and so enhance endothelial function.
Ultimately if drugs can be developed to mimic these responses then patients shown to have endothelial dysfunction might benefit from these therapies.

How will you look to maximise the outputs of this work?

Our aim in the medium and long-term will be to translate the findings in animals in to human studies and then, either independently or in collaboration with industry. This will be a new step for our group and we will approach our institution's innovations department at this point for help and advice concerning interactions with industry. This will also include attending joint meetings arranged by our institution with potential commercial partners. Our aim will be to develop small molecules that target important endothelial signalling pathways and to test their efficacy as therapeutics. Currently we are particularly focused upon protective pathways regulated by endothelial expressed protein kinases and endothelial transcription factors.

Species and numbers of animals expected to be used

- Mice: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using adult mice for the experimental parts of our project as they are widely available in the genetic form we require and they have a well-researched and understood immune system. There are no other animals that serve this purpose as well as mice. For this project, we will be using mice (with or without associated wild-type controls) that are genetically modified to either inactivate or turn on different genes so that we can study how these genes control important processes such as the body's response to inflammation or how new blood vessels form (a process called angiogenesis). In some instances, mice will also be given a high fat diet in order to study the development of fatty substances or plaques in the blood vessel walls (known as atherosclerosis). The use of these models will however be kept under review, and we will consider refining our approach by moving to an even more informative and clinically relevant model if one becomes available.

Typically, what will be done to an animal used in your project?

Animals may be administered substances such as drugs, proteins, antibodies, nanoparticles, genes or other agents for up to 16 weeks, in order to modify specific outcomes, such as to induce changes in gene expression. This will be carried out using injection of substances or through the use of osmotic pumps or a slow release pellet, or by incorporating substances into the animal's food or water. Animals may subsequently be fed a high fat diet for periods of up to 4 months. Mice may be injected with substances in

order to induce inflammation or we may inject them with a basement membrane matrix (e.g. Matrigel) in order to study how newly formed blood vessels are affected by changes in gene expression or dietary modification. Performing studies using genetically modified mice will allow us to study the effect of the progression and regression of disease using these models.

Blood sampling may occur at certain stages.

Animals may be injected with targeting agents for imaging. Under general anaesthesia animals may have their hair removed using shaver and special creams, and then be scanned using positron emission tomography (PET), ultrasound or optical imaging, computed tomography (CT), or magnetic resonance imaging (MRI).

What are the expected impacts and/or adverse effects for the animals during your project?

All expected impacts or adverse effects (such as ruffled fur, hunched posture, reluctance to feed or move, weight loss >20%) will be monitored carefully by a licensed member of our team alongside a named veterinary surgeon and named animal care and welfare officer.

Potential adverse effects include: skin damage from high fat diet, infection from administration of treatments, blood loss from blood sampling. However we will carefully monitor these and where possible reduce these impacts.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All mice used within this license are expected to fall under the mild (~70 %) or moderate (~30%) severity categories.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A detailed understanding of the cellular mechanisms underlying endothelial homeostasis, vascular protection against injury and regeneration will lead to novel therapies for human disease. Where possible, our laboratory performs experiments *in vitro*, using cultured human endothelial cell (EC), to replace *in vivo* studies. However, the complex nature of blood vessels cannot be fully recapitulated *in vitro* and it may be necessary for some experiments (such as *in vivo* analysis of vessel development) to be carried out using murine models. These assays are well established in the group with clear end points and

will be used to test the hypotheses generated by the detailed in vitro experiments. In this way we will minimise the number of animals required and any associated suffering.

Which non-animal alternatives did you consider for use in this project?

We are constantly seeking non-animal models in the published scientific literature, we attend relevant scientific conferences and we discuss alternative options with collaborators. In addition we have searched PubMed and EURL-ECVAM databases. We have established an *in vitro* flow apparatus to model the impact of shear stress exerted by blood on human endothelium. We are developing 3D organ-on-a-chip and microfluidic angiogenesis models with human cells. We have perfected methods for the isolation and culture of late outgrowth endothelial colony forming cells (ECFC) from human blood. We have generated conditionally-immortalised EC lines from genetically engineered animals to minimise animal usage.

Why were they not suitable?

Chronic inflammation, endothelial dysfunction, angiogenesis and vascular injury are complex multicellular responses that cannot fully be modelled in vitro. At the present time, *in vivo* models are the only definitive way of studying the efficacy of novel therapies and testing hypotheses generated from *in vitro* data.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Over 10 years we have developed protocols to minimise animal numbers required, while ensuring with statistical advice that rigour is maintained.

Principles of experimental design and data analysis.

We use detailed *in vitro* analysis to frame a clear question and then plan the key *in vivo* experiments:
As part of experimental planning we use guidance from our previous experiments and/or those in the literature.
To minimise variation we use matched littermate controls.

To randomise, animals are sequentially allocated from single cages to test or control groups.

For these established protocols we aim to achieve 80-90% power, $p<0.05$, and 25-50% differences, and use the analysis of variance statistical analysis with a post-hoc test if required. From our previous experience we expect that groups of 6-8 animals per treatment group should be sufficient to obtain the required results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The models of inflammatory disease or angiogenesis we have developed are extremely reliable and reproducible, so we can accurately calculate the numbers of mice required for each treatment group in order to obtain scientifically significant results from small groups of animals. We combine experiments where possible to make maximum use of controls and so further limit experimental variation. We have also developed approaches to maximise use of tissues from each animal, for example by collecting multiple tissues after death. This ensures that we get as much data as possible from each mouse which thereby limits the number of mice needed.

We have designed the experiments and the methods of analysis to allow the results to be published in accordance with the NC3Rs' ARRIVE guidelines (Kilkenny et al. PLOS Biol 8(6): e1000412).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Further aspects of experimental design to ensure the minimum number of animals:

Use of differentially labelled antibodies which allows data on different molecules to be obtained from single tissue specimens.

Introduction of non-invasive imaging strategies which allow accurate longitudinal analysis, so reducing animal numbers.

Harvesting and storage of post-mortem tissues allows subsequent use in different experiments/ projects, so optimising data output and reducing the total number of animals required.

To maximise data output from the sub-cutaneous air pouch model, above and beyond analysis of leukocyte migration in to the pouch, we dissect out the pouch tissue at the end of the experiment and prepare RNA from this. We can then analyse changes in adhesion molecule expression in the blood vessels lining the pouch. In parallel some tissue is conserved for subsequent comparative confocal microscopy analysis. This has increased the data obtained and optimised interpretation of the mechanism underlying the changes in leukocyte trafficking

We use freezing of embryos to avoid unnecessary breeding of genetically-modified mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice have proved invaluable for our studies, largely due to the availability of genetically-engineered strains to model human disease. For example, LdlR knockout mice represent a good model for human atherosclerosis with minimal animal suffering.

Genetic manipulation or specific molecular targeting of signalling molecules allows specific analysis of the role of these molecules without needing to treat animals with pharmacological inhibitors, which are less specific and often toxic.

Our protocols have been devised and refined so that they are all mild or moderate. Examples include the subcutaneous air pouch and peritonitis models of inflammation and the Matrigel model of angiogenesis. The local models of inflammation e.g. sub-cutaneous air-pouch and peritonitis have minimal impact and do not require analgesia in contrast to the foot pad model which we no longer employ. These two models have also reduced our use of systemic inflammatory models.

Why can’t you use animals that are less sentient?

Mouse models of atherosclerosis or for inflammation research are common and well validated. There are no high fidelity animal models for these processes in less sentient animals. Larger animal models (such as pigs or rabbits) are well validated, but are even more sentient than mice. Therefore, using mice is the best possible option for exploring experimental models of atherosclerosis, inflammation or angiogenesis in high fidelity models.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedures are all reviewed by ourselves and by NACWO and NVS to ensure we are minimising animal welfare harms. Where recovery from surgery is required, the animals are recovered in a warmed cabinet and analgesia administered as standard following advice of the local NACWO and NVS. Animals asleep under general anaesthesia have the depth of anaesthesia monitored closely to ensure appropriate level of sleep. This is performed by checking toe pinch reflexes as well as respiratory rate monitoring and general inspection. Following any procedure with the potential to cause harm, our team and the technicians that closely work alongside the animals, regularly monitor the mice to check for signs of ill-health, pain or distress and poor welfare.

We regularly consult the NC3Rs website to see whether any techniques that we are using can be refined. We will also continue to use the general approaches we have demonstrated above to ensure our experiments are the upmost refined and animal welfare costs are minimised.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R guidance available from https://nc3rs.org.uk/3rs-resources

Procedure related guidance available from https://researchanimaltraining.com/

Laboratory Animal Science Association (LASA) guidelines: https://www.lasa.co.uk/current_publications/ FRAME experimental design workflows: https://frame.org.uk/resources/experimental-design/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly view the NC3Rs website (https://www.nc3rs.org.uk/) to stay on top of advancement in 3Rs, as well as attending seminars as appropriate. We are in regular discussions with NACWOs and NVS to ensure our experimental methods are the best possible.

187. Genes, diseases and lifestyle influences on the musculoskeletal system

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Bones, Joints, Bone Cancer, Arthritis, Secondary Bone Cancer

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant
Rats	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to improve the understanding of how genes, diseases and lifestyle influences musculoskeletal health. The ultimate aim is to identify and develop new drug targets to maintain a healthy skeleton throughout the life course, and/or combat the detrimental physiological changes that occur in diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Musculoskeletal disease is the second greatest cause of disability world-wide, affecting over 1.7 billion people, and having the fourth greatest impact on overall health. In the UK, one in two women and one in five men over the age of 50 will break a bone because of osteoporosis and 1/3 of older fracture patients die within 6 months of hospital admission. Osteoarthritis (OA) has undergone a substantial increase in incidence, with the prevalent disease burden of hip OA alone meaning that between 30 and 40 million European citizens suffering pain and disability. In the context of cancer, once a primary cancer (i.e. breast or prostate) metastasises to bone it becomes incurable, whilst the brutal treatment and poor survival statistics for primary bone cancer has not change in the past 40 years. These staggering facts makes it important for us to undertake this work to try and find new treatments and cures for Musculoskeletal diseases.

What outputs do you think you will see at the end of this project?

Outputs will include new information that will advance the scientific understanding of how our genes and our lifestyle affect musculoskeletal health and development of diseases that effect the skeleton. We are hoping to generate new information on how and why musculoskeletal diseases occur - in particular we are focused on disease such as osteoporosis, osteo- and rheumatoid arthritis, primary bone cancers such as osteosarcoma, Ewing Sarcoma and Chrondrosarcoma and secondary cancers that also affect the skeleton such as secondary breast and prostate cancer. This new information could include; identifying how our diet or our activity levels/exercise affect these diseases; how genes affect the ability of diseases to develop; how proteins in our bodies might also affect our skeleton and disease development. We will share this new information via scientific publications and press releases, and to also generate other outputs such as patents for new drugs.

Who or what will benefit from these outputs, and how?

In the short term the academic, medical and pharmaceutical community will benefit from this work with the publication of new knowledge. In the longer term this will translate to benefit for patients and the wider public (due to the socio-economic impact of reducing disease burden on society) as new and better treatments are developed. This has the potential for considerable impact as musculoskeletal disease which are the second greatest cause of disability world-wide, affecting over 1.7 billion people, and having the fourth greatest impact on overall health.

How will you look to maximise the outputs of this work?

We already collaborate with other academics nationally and internationally and we will seek to increase our network of collaborators during the course of this project. We will also seek to establish collaborations with the pharma industry and clinicians to help translate the outputs of this work. We will regularly disseminate new knowledge via presentations and scientific and patient focused conferences as well as publishing our work in scientific journals and in the popular media via press releases blog/website articles (both TUoS and those of our funders).

Species and numbers of animals expected to be used

- Mice: 7500

- Rats: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice and rats in this project as they are the smallest mammals with musculoskeletal systems and genes similar to humans. The models we are proposing to use are already established and considerably refined. Rodents also have the added advantage of being amenable to genetic manipulation allowing the functional characterisation of specific gene products.

Typically, what will be done to an animal used in your project?

Animals may undergo injection of substances, surgical procedures, injection and establishment of tumours, alteration in diet and bone loading (either passive or via increased exercise i.e. treadmill running).

The duration of the experiment will not exceed that required to obtain meaningful results (can vary from one week to establish tumour take to several months due to slow growing tumours ie chondrosarcoma).

Number of procedures: mice 5200, rats 1100

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects for the animals during the project include those associated with anaesthesiology and surgery (i.e. pain, infection, wound dehiscence) which will be brief/for the duration of that step in the procedure. Mechanical loading/implants may impact the animals due to mild lameness which may persist for the duration of the procedure (2weeks+) but that does not impede the animal’s ability to eat and drink. Repeated anaesthesia and recovery periods may result in weight loss due to preventing normal feeding. Development of tumours in the animals may cause low level pain or again mild lameness if located on the hindlegs and which may persist for the duration of the procedure (2weeks+) but that does not impede the animal’s ability to eat and drink. Alterations to diet to specifically mimic a nutritional deficiency may result in a significant and easily detectable disturbance of an animal's normal state. The presence of tumours may also induce weight loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity will not exceed moderate in the vast majority of cases/procedures in each category of animal.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Modelling the complex interaction between bone and or tumour cells and the environments in which they grow in patients as well as the effect of lifestyle choices (i.e. diet and exercise) is simply not possible in cell culture. The interventions and procedures needed to understand these interactions cannot be used in patients themselves. Where possible when the effects of agents on single populations of cells (bone or tumour cells) are evaluated, this will be done in vitro.

Which non-animal alternatives did you consider for use in this project?

We have considered and do use in vitro cell culture and modelling to predict interactions and outcomes in this project. We are constantly developing better in vitro models (ie multi-cell line cultures, organoids and we will use these as much as possible to ensure that we only use animal models when absolutely necessary for the project in question.

Zebrafish have been used by many researchers as an alternative to mouse studies, and we have considered this and where appropriate we would collaborate with colleagues who are experts in this field.

Why were they not suitable?

The alternatives are at the single cell (or at best tri-cell) level and do not fully recapitulate the intact animal and the complex interactions that takes place locally and systemically, nor do they consider the endocrine and paracrine influence therefore minimizing their clinical relevance.

Zebrafish are evolutionarily more distant from humans than mice and have some significant differences that mean they are not suitable for the majority of the aims of our project. Zebrafish bones only show few bones with trabeculae, long bones are absent and whilst Zebrafish do have growth plates, only a small portion of chondrocytes become hypertrophic - this makes them unsuitable for studying primary bone cancer as it predominantly occurs in long bones and especially during growth spurts involving the growth plate and chondrocyte hypertophy. Zebrafish bone marrow is fatty and does not harbour a site for haematopoiesis - again this make them an unsuitable model for looking at bone cancer metastasis as we, and others, believe and have demonstrated that cancer cells may hijack the haematopoietic niche to enable metastatic spread and as part of the seeding of distant organs (pre-metastatic niche).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers are based on previous use over a 5-year period and predicted use in the coming 5 years taking into account planned research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The systems we are using have been used in previous studies and we have done statistical calculations to define the minimum numbers of animals required to obtain significant data. All experiments are designed using the NC3Rs Experimental Design Assistant a nd or an individual study protocol to fully consider the numbers of animals needed. Where possible we will also use repeated in vivo measurements (i.e. in vivo CT, BLI of tumour burden) over time where possible to reduce the number of animals needed to obtain statistically meaningful results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies were necessary to optimise the number of animals we need where we do not already have this information. We also have an aim to use computer modelling to help us to reduce the use and number of animals in our studies. In addition, we will share samples with other projects –this is common practice within our laboratory/institution.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice and rats in our project and well-established experiment models for the diseases we are researching. The main animal models we are using have all been previously validated and published before, and we have refined the protocols over many years of experience, and we are using protocols that cause the least pain suffering and distress.

Why can’t you use animals that are less sentient?

Mice and rats as they are the lowest order of mammal that is still physiologically, anatomically and genetically similar to the human. As we are investigating lifestyle influences (ie diet and exercise) we can't use animals that have been terminally anaesthetised. Most of the disease we are researching also occur later in life (with the exception of primary bone cancer although this is still post-natal) and so we cannot use animals at a more immature life stage.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The main animal models we are using have all been previously validated and published before, and we have refined the protocols over many years of experience. The welfare of the mice and rats will be strictly monitored (i.e. enhanced monitoring post-operatively, daily welfare monitoring and the use of the mouse grimace scale for assessing pain). Appropriate pain relief during our protocols will be achieved through appropriate levels of analgesia.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the LASA "Guiding Principles for Preparing for and Undertaking Aseptic Surgery". Procedures for establishment and monitoring of tumour growth, metastasis and animal welfare we will follow best practice as outlined in "Guidelines for the welfare and use of animals in cancer research" Workman et al., British Journal of Cancer, 2010.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly receive updates from our NC3Rs Regional Programme Manager and we will attend local, national and international workshops and conferences; and read current peer-reviewed literature to stay informed of new advances. Our Named Veterinary Surgeon also provides regular updates to project holders on best practice and advances in the 3RS. We will actively engage in implementing these advances in our practices during the project.

188. Immune cross-talk between the oral and distant mucosal barriers

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Periodontitis, Immune response, Mucosal Immuntiy, Inflammation, T cells

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine immune mechanisms that drive oral inflammation and better understand how oral inflammation contributes to the pathogenesis of inflammation at distinct mucosal barriers. Mucosal barriers are sites that separate the internal body from external environment and include sites such as the gastrointestinal tract, lung and skin.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Periodontitis, is commonly referred to as "gum disease" and the most severe form of oral inflammation. It is the most common chronic inflammatory disorder of mankind; affecting

almost 50% of the global population. Moreover, it has been predicted that almost 80% of the global population exhibit less severe forms of oral inflammation, such as gingivitis. Not only is oral inflammation therefore an incredibly prevalent pathology, but periodontitis has been associated with many other systemic diseases. For example, individuals with periodontitis have been shown to exhibit increased severity and/or incidence of rheumatoid arthritis, cardiovascular diseases, Alzheimer's Disease, diabetes, chronic obstructive pulmonary disease (COPD) and inflammatory bowel diseases (IBD). Thus, better delineating the immune mechanisms that contribute to the maintenance of oral health would not only promote the development of better therapies for periodontitis, but may also have implications for the treatment of other inflammatory conditions.

This work investigates the immune mechanisms which reinforce health within the oral cavity, defining how they become un-controlled during oral inflammation. Moreover, our work will outline how immune dysfunction within the oral cavity and initiation of periodontitis can contribute to the development or exacerbation of inflammation at distal mucosal barriers.

What outputs do you think you will see at the end of this project?

Two key outputs will emerge from this project that will advance our knowledge of oral inflammation and its systemic consequences. First, information generated from these studies will contribute to our understanding of how immune responses are appropriately controlled at the mucosal barriers of the mouth, yielding key information on important pathways that can go wrong during the development of oral inflammation, and more specifically periodontitis. Secondly these studies will provide some of the first mechanistic insights into the immune-based communication between the oral and distant mucosal barriers, as our approaches will outline how oral inflammation can contribute to extra-oral inflammatory diseases such as inflammatory bowel disease (IBD). We predict that the data generated within these studies will have a positive impact on the treatment of both periodontitis and as well as other diseases such as IBD, providing not only novel treatment options but also suggest mechanisms to stratify patients or identify patients at risk of developing both of these two, hugely impacting disease.

To maximise these benefits data generated from the studies undertaken will be effectively disseminated to the research community, (including academic and industrial researchers, medical and dental clinicians). This will be achieved through; i) publication of data in academic journals; ii) presentation of data at seminars and conferences and iii) through public engagement events. In this way data generated within this project will rapidly inform the work of others and promote scientific discovery within our research community.

There is a key secondary benefit that will also arise from undertaking this work; our work will advance research methods, through refinement and/or enhancement of current methods as well as through the possible development of new transgenic lines.

Who or what will benefit from these outputs, and how?

Scientific Community: This programme of work will generate new data, research tools and advance research methods which will be shared with the scientific community with the ultimate effect of promoting scientific discovery. This impact will occur in both the short term - following publication or talks but, overall support scientific advancement worldwide in the long term. Data generate will benefit researchers who focus on immunology and oral and gastrointestinal inflammatory diseases. However, our work will be more broadly applicable to other fields including microbiology, development and systems biology.

Healthcare Sector: Outputs from this research will, in the longer-term, have the potential to impact the healthcare sector, both medical and dental clinicians. This work will provide basic biological insights into the drivers of periodontitis and the mechanisms by which this disease impacts distant mucosal barriers, such as the gut or lung. It is hoped our studies will provide novel therapeutic targets for the treatment of oral, gut and lung pathologies targeted at the very accessible oral cavity. We also hypothesize that our studies could support the development of better mechanisms of patient stratification.

Biomedical Industry: Data generated from this project will also support the biomedical industry, as findings from our research are translated into the clinic. This impact will occur in the longer-term as novel therapeutics and/or treatment strategies emerge from our data sets.

General Public: The importance of oral health is often overlooked in the face of pathologies which drive more considerable suffering or lead more obviously to shorten life-spans or life-quality.
Information obtained from this project can be used to engage the general in the vital importance of oral health, highlighting the impact poor oral health, and subsequent development of oral inflammation, could have on completely distal organs.

How will you look to maximise the outputs of this work?

Dissemination of new knowledge: Output from this work will be published in highly visible (high- impact) journals which are read by a wide audience. Following publication of data in scientific papers we will make use of social media platforms to further publicise our work, including contacting daily newspapers and magazines (which have run stories on our work in the past). Alongside this, participants undertaking work on this project will be supported to discuss the work widely, presenting seminars and giving talks both locally and globally.

Collaborations: We already have in place a global network of academic and clinical collaborators that we will engage with as we develop this work programme. Outputs with collaborators will be maximised by regular meetings and data exchanges.

Publication of Negative Data: Although not common we have a strong track-record of publishing negative results. We will continue this whilst undertaking this project, ensuring publication in the most appropriate journals possible.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

The studies outlined will utilise juvenile and adult mice, which may be genetically modified. These life stages are employed to examine mice with teeth and/or mice just proir to tooth eruption. Mice are the most appropriate species for these studies as the systems which we

are studying here (the immune system at the oral and distal mucosal barriers such as the gastrointestinal tract and lung) are well reproduced between mice and humans.

Typically, what will be done to an animal used in your project?

Approximately 70% of the animals utilised on the project will undergo a procedure to investigate oral inflammation and the impacts oral inflammation has on immune health at distal mucosal barriers. To achieve this the following approaches will be used:

Oral inflammation will be induced in mice. This will be via one of three methods, each representing a key tenant of the pathology of oral inflammation. Either (1) periodontitis will be induced by the placement of a silk ligature around the second molar tooth. (2) The oral barrier will be damaged by abrasion with a sterile cotton applicator. Or (3) periodontitis and oral barrier damage will both be induced. For all these procedures mice will be anaesthetised and oral inflammation will result.

Altering the immune response at distal mucosal barriers. Here we will assess the impact of oral inflammation of immune function at distal mucosal barriers, such as the lung and gastrointestinal (GI) tract. We will initially explore impacts of periodontitis on gastrointestinal immunity. To investigate alterations in gastrointestinal immune responses one of three approaches will be used, each will allow us to examine the impact of oral inflammation on a distinct aspect of GI immune responsiveness.

Prior to, and/or, during these procedures the immune system may be manipulated, through application of reagents to target specific cell types (e.g. through use of antibodies or tracking agents) or through transfer of cell populations.

In addition to these procedures, mice will be used in this project for breeding, and for provision of cells and tissues for ex vivo studies

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may experience mild adverse effects such as temporary stress or brief pain and discomfort. Temporary stress may be induced by a brief period of restraint, for example in order to administer an injection. Mice may experience a brief period of pain and discomfort following induction of oral inflammation, through any of the three methods outlined, as well as following blood sampling. In these instances the stress and discomfort will be transient, specifically ranging from a few minutes to less than 12 hours.

Weight loss will occur after the following procedures (1) ligature-induced periodontitis, (2) administration of antibiotics, (3) generation of chimeras and (4) gastrointestinal bacterial challenge. In all cases this will typically be in the range of around 10%, with this weight loss being transient, for example ranging from a) following ligature placement weight is usually recovered within 48hours to b) following chimera generation weight is usually regained by 3 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The studies outlined in this project will result in the following proportions of animals actually experiencing the following severity ratings:

Sub-threshold – approximately 20% Mild – approximately 30% Moderate – approximately 50%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are no good in vitro or in silico models able to reconstitute the complex interactions occurring between oral tissue, host immune cells and microbiota and extra-oral mucosal barriers. The aim of my research is understand how immune responses are appropriately controlled at the oral barrier, and how immune dysregulation at the oral barrier can impact immune responses at distal sites; in vivo models provide a unique window to probe this.

The mouse is a good model to understand the human oral barrier, as the immunological network and tissue structure is similar in mice and man and the pathophysiology of oral inflammation similar in mouse and man.

Inbred mouse strains will be used, allowing uniformity between animals and experimental repeats.

There is considerable use of knockout and transgenic animals, which are not available for other species. Transgenic mice are already generated, are well characterized and available for use to assess gene and cellular functions.

Which non-animal alternatives did you consider for use in this project?

In vitro: Approached that include cell-lines or co-culture systems (where multiple cell types are cultured together). We utilise such approaches as these to i) inform the animal studies to be undertaken and ii) further validate targets and pathways identified in animal models.

Human samples: we have an active research program obtaining and examining gingival samples from human dental clinical cohorts. With detailed clinical information and patient meta-data such samples can be used to correlate immune phenotype with disease characteristics.

Neither of these approaches can replicate the complex environment of the oral barrier or model the distal interactions with the gastrointestinal tract and therefore cannot replace the use of animals.

Why were they not suitable?

Although the above approaches are valid platforms for research investigation neither fully replace animal models for the following reasons: i) Our studies in human can only be correlative and will not mechanistically link cause and effect, which can only be achieved in animal models. ii) our research questions require complex in vivo systems to precisely define the complex interactions between heterogeneous cell populations in their tissue microenvironment and also how they may impact responses at sites distal to the initial challenge. To date these cannot be accurately modelled in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our group has extensive experience with the methodologies and approaches outlined here and of running projects of a similar scope. Consequently, estimates of animal numbers are based firstly on previous experience with the models to be utilised and the types of data generated, and secondly with careful consideration of the experimental design.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Throughout the duration of this licence, we will continue to consider the design of each experiment (as is required as a PPL holder). As we generate new data sets these will be used to further refine our experimental design.

For this application we have utilised data sets already generated from experiments which have led us to undertake this project. These data sets, along with our research objectives, have been discussed with the institute statistician, allowing us to get specialist advice on the types of experiments that will be undertaken and the nature of the datasets that will be collected. This has supported development of appropriately designed experiments which will yield biologically relevant and interpretable data with the fewest numbers of animals possible. We will continue to liase with this expert as our project develops and new data is generated.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout this project, optimal animal usage will be achieved by the following means:

Utilising the most effective and efficient means to breed transgenic mouse lines. This will be achieved by consulting local and commercial experts In addition we employ an electronic stock management tool to monitor our colonies allowing real-time checking and maintenance. In this way we will minimise numbers of animals bred whilst still achieving allowing us to undertake experiments from which we can generate relaible data.

Pilot studies will be employed to optimise experimental conditions when we are developing new approaches.

We will maximise the amount of data that can be gathered from a single animal by using the latest technologies and most efficient tissue processing methodologies.
We will archive all tissue possible from each experiment. We also make our banked tissue available to our collaborators.

We will discuss our findings and share data generated with collaborators and the scientific community (for example through depositing large datasets in online data repositories). In this way we will maximise the scientific knowledge than can be obtained from our animal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project involves the use of models of mucosal barrier inflammation. In both cases we will employ the most refined models available to address our experimental objectives. For example;

For the establishment of periodontitis in mice we will use the ligature-induced model of disease. This model results in 100% disease incidence and the disease is also temporally identically in each mouse; meaning treatments and experimental manipulations can occur concurrently. This model is also widely employed with others in the research community and has the additional advantage that disease development can be halted – by simply removing the ligature. Finally this disease occurs over an acute time frame, meaning period of time for which the mouse is showing signs of inflammation will be kept to the minimum possible to address the research question.

For the gastrointestinal (GI) challenges, the models to be used have been selected to drive well- defined immune responses in the gastrointestinal tract, leading to acute inflammation which will resolve, i.e. none of the methods employed lead to the establishment of chronic inflammatory reactions and as such, mouse suffering is kept to a minimum. All GI challenges employed have been well optimised in terms of doing route, dosage and time post-administration in order to induce a robust and consistent response whilst causing the least harm and suffering to experimental animals.
Where we seek to administer reagents to experimental animals we utilise the most refined route of administration possible. Furthermore we always seek to minimise the numbers of doses of a treatment in order to achieve our objective, this may involve pilot studies to identify an optimal dosing regimen.

Why can’t you use animals that are less sentient?

We cannot replace these studies in mice with studies in less sentient species, such as insects or fish, to achieve our objectives. Such species lack a defined oral barrier which is

comparable to humans. Moreover, they lack the complex immune found in higher order species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Appropriate animal handling techniques will be employed and updates, which further reduce stress and discomfort, employed as they are developed.

After procedures animals will be closely monitored in line with the refinement controls listed with each experimental step, for example this will involve detailed monitoring of weight and condition. Where transient weight loss is expected following some procedures, soft food/mash will be provided on the cage floor.

All animals will have environmental enrichment in cages and whenever possible, not singly housed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will base our approaches on the best published practises, for example those endorsed by the NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Myself, as well as those employed by me and working under this license, will stay informed on recent advances in 3R approaches by staying up to date with NC3Rs recommendations and developments. This information from the NC3Rs is obtained through interaction with their website, local seminars, reading their updates and published bulletins and also through liaising with their local representative. We also continue to discuss further refinement opportunities with the NVS and NACWO and through interaction with collaborators and the wider scientific community at conferences, workshops and seminars.

189. Investigating the role of Seminal Fluid proteins in male fertility in poultry

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

Seminal Fluid, Reproductive ageing, Proteomics, Strategic ejaculate allocation, Poultry

Animal types	Life stages
Domestic fowl (Gallus gallus domesticus)	adult
Red junglefowl (Gallus gallus)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify proteins in the male seminal fluid that are associated with high fertility in populations of poultry.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Identifying proteins in the male semen that convey high fertility is important to understand how reproductive traits evolve, and can drastically increase the productivity of commercial flocks and enable more effective husbandry.

What outputs do you think you will see at the end of this project?

The project will generate a better understanding of fertility in poultry by identifying how the seminal fluid protein composition changes within and across individual male fowl, and how such changes are associated with male fertility.

Specifically, expected outputs will include new information on the following:

Compositional changes in the junglefowl Seminal Fluid (SF) proteome associated with sperm fertilising efficiency, caused by rapid responses to socio-sexual conditions (female availability, female sexual novelty, male social status).

Compositional changes in the junglefowl SF proteome associated with sperm fertilising efficiency, caused by reproductive ageing.

The causal effect of junglefowl SF variation on sperm fertilising efficiency.

Characterisation of the SF proteome of Domestic fowl (commercial broiler breeder) males and patterns of variation across and within individual males.

This new information will be disseminated through scientific publications and communication to stakeholders and the lay public.

Who or what will benefit from these outputs, and how?

Understanding how seminal fluid proteins affect male fertility in poultry will benefit directly the Poultry Industry. The outputs of this project will inform strategies to better manage fertility and productivity of commercial flocks. These outputs will also be relevant to the management of animal welfare because Increased fertility will reduce the frequency of matings and hen exposure to males.

More broadly, the outputs expected of this project will collectively inform the following fields:

Andrology, assisted conception, sperm cryopreservation. Advances in the study of fertility and reproductive physiology in a vertebrate model may have relevance for the study of human fertility and especially research into declining sperm quality.

Biosecurity and Food security. Many SF Proteins in fowl and other taxa have antimicrobial properties. The reproductive tract hosts a diverse microbial community, including potentially zoonotic or pathogenic species. While little is known about sexual transmission in poultry, male semen has a diverse microbiota. The analysis of the SF proteome and seminal microbiome can therefore have major implications for the monitoring and management of livestock biosecurity and health.

Reproductive Physiology. The project represents one the most comprehensive studies of SF Proteins in birds, providing novel information on fundamental reproductive processes such as sperm maturation and metabolism, and the biological roles of seminal fluid.

Behavioural Ecology and Evolutionary Biology. Pioneering work on fruit fly accessory gland proteins have generated burgeoning interest in the role that SF Proteins play in postcopulatory sexual selection, sexual conflict and intersexual coevolution and reproductive barriers. The present project will establish an avian model system, informing

new avenues of theoretical and empirical investigations (male strategies of ejaculate allocation and phylogenetic analyses of SFP evolution rates).

Conservation Biology: The identification of avian candidate SF Proteins in fertilising efficiency will potentially benefit research into captive reproduction of endangered species, e.g. by informing more effective protocols of artificial insemination, the screening of individuals for selection in breeding stocks and sperm banks.

Understanding and exploiting Functional Genomics. The project will generate a wealth of new information on whole genome proteomics of a vertebrate model system. This will play a significant role in furthering our understanding of functional genomics and genome evolution, by contributing to genome annotation, identifying candidate genes and informing gene networks underpinning fundamental biological functions. These advances may in turn aid in the development of new genomic tools.

Ageing and Lifelong health. The project will directly benefit research into senescence, ageing and lifelong health, by providing a systematic characterisation of age-dependent compositional changes in the SF proteome and associated consequences for age-related changes in fertilising efficiency.

Cell, Cancer Biology. The study of cells secreting SF Proteins helps understand cell-cell communication, signalling pathways, and important infections and diseases: Drosophila accessory glands are used to study human prostate cancer. Nanotechnologies: SF often contains nanovesicles involved in molecular trafficking. We have found evidence that vesicles in junglefowl SF may be involved in delivering scaffolding molecules to maturing sperm. The study of these vesicles can inspire nanotechnologies, e.g. nanomedicine.

Bioinformatics. We will generate bioinformatic resources and help develop novel analytical tools of these data.

How will you look to maximise the outputs of this work?

Through the publication of scientific results, sharing of datasets, presentation of key findings at conferences, collaborations with other researchers and with industrial partners (e.g. commercial poultry breeders), stakeholder workshops and through a dedicated website.

Species and numbers of animals expected to be used

- Domestic fowl (Gallus gallus domesticus): 220
- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This research project seeks to establish the role of seminal fluid proteins in fertility in poultry flocks with a view to inform future strategies to improve fertility in commercial flocks. The project therefore necessarily focuses on two animal system: (a) a population of

red junglefowl, and (b) broiler breeder flocks of a widely used commercial line. The red junglefowl is the wild ancestor of the domestic chicken and as such represents a fundamental reference point against which to compare domestic chickens (e.g. to identify genes that may have been lost through domestication and artificial selection). Broiler breeders represent that parental stocks of broiler meat chickens. Broiler lines, which have been artificially selected for meat production tend to display suboptimal fertility rates and are therefore the most salient focus of this research project. Because the project focuses on seminal fluid proteins transferred during mating, it could not be conducted without studying sentient, sexually mature individual red junglefowl and broiler breeder that display their natural reproductive behaviours.

Typically, what will be done to an animal used in your project?

Individual males will be exposed to up to 40 semen sampling sessions per year, but typically 15 sessions per year, with at least 48 hours rest between each collection.

Females will be used to in staged mating to obtain semen samples from males, each female will be exposed to typically 15 and up to a maximum of 30 trials/year interspersed by a minimum interval of 2 days. Some females will be artificially inseminated (AI) with standardized amounts of semen, each female will be exposed to typically 4, and up to a maximum of 7 AI trials every year typically interspersed by a minimum of2 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect this work to have adverse effects or negative impacts on the welfare of the birds involved in this study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Red junglefowl - 100% Mild. Domestic fowl - 100% Mild.

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project studies the seminal fluid proteins that male fowl release during mating. Thus, the project requires live, sentient, sexually mature birds.

Which non-animal alternatives did you consider for use in this project?

We have considered *in vitro* approaches, and we have implemented these whenever possible. These approaches involve studying the interactions between sperm cells and seminal fluid in the lab.

Why were they not suitable?

in vitro approaches are suitable to experimentally investigate the causal role of seminal fluid proteins on sperm fertilising efficiency (e.g. swimming velocity). However, their use is limited. First, *in vitro* approaches still require obtaining semen samples from sentient birds. Second, *in vitro* approaches cannot replace sentient animals for aspects of the project, which focus on mating behaviour and related behavioural responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals needed for this project have been estimated based on effect sizes from previous experiments and our 20-year experience. Patterns of red junglefowl sperm and seminal fluid allocation behaviours have been well characterised by our research group in the recent past. In contrast, almost nothing is known about sperm and seminal fluid allocation in natural matings in commercial domestic chicken populations, including broiler breeders. The project will use a well- characterised study population of red junglefowl to study patterns of variation in seminal fluid proteins across matings under a range of socio-sexual conditions, following well-established experimental protocols used by our research group on this population. This part of the work will generate exhaustive information on how sperm fertilising efficiency is affected by changes (including age-dependent changes) in certain seminal fluid proteins. We will then screen a smaller number of broiler breeder males to compare and contrast the data from red junglefowl with seminal fluid compositional patterns and their relationship with sperm fertilising efficiency in this commercial line. Specifically, the junglefowl work will identify seminal fluid proteins related to fertility and we will investigate patterns of variation in these proteins in the broiler breeders. Because of this design, the project will seek to use more junglefowl than broiler breeders.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will take advantage of professional statisticians as well using our own experience. The number of animals used has been reduced by refining experimental design to follow ARRIVE criteria as closely as possible, e.g. through blinding, randomisation, and use of adequate controls including paired designs. Specifically, the experimental approach will utilise individual males as their own control through within- male comparisons following exposure of a bird to different experimental conditions in a randomised order. This design is powerful in that it minimises the noise caused by inter-individual variation. The species of animals investigated through mild experiments can be used on numerous occasions without any increase in harms to them. Estimates of the number of animals needed for

these experiments reflect an effort to minimise the number of animals while ensuring sufficient statistical power.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will make extensive use of the information gathered from substantial pilot studies and preliminary work. Detailed information on individual birds will enable us to select the most appropriate birds for each experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project will study red junglefowl and domestic chickens (broiler breeders), these two organisms represent the most salient comparison to investigate variation in male fertility in poultry. The project investigates the seminal fluid proteins that males release during mating, and thus the project cannot be conducted without the use of live, sentient, sexually mature animals. We will use the most refined procedures available to minimise pain, suffering, distress or lasting harm. Semen will be collected through non-invasive techniques, which our research group has refined over the past 20 years. These techniques represent the method for collecting natural semen samples that is most refined and causing the least amount of pain, suffering distress or lasting harm in these animals. The project will also use artificial insemination, a routine poultry husbandry practice, to study the fertilising performance of individual semen samples. This technique has also been used by our research group with no observed adverse effects, and represents the method to study fertilising performance in vivo that is most refined and minimises pain, suffering distress or lasting harm.

Why can’t you use animals that are less sentient?

The project investigates the role of seminal fluid proteins in released by males during mating, and as such it must study sentient sexually mature individuals. Given that its goal is ultimately to improve the management of fertility in poultry flocks, the project can only use galliform species (e.g. Gallus sp.). The use of less sentient animals such as insects (e.g. Drosophila) or even passerine birds would not generate relevant results because of fundamental differences in the reproductive biology across these taxa (e.g. male accessory glands, sperm physiology, ejaculate size, female sperm storage organs, seminal fluid proteome...).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures utilised have been refined by our group over the last 20 years, and we will incorporate any new additional refinement as and when it becomes available. All birds

utilised in this project will be acclimatised to being comfortable in the presence of humans and being handled. We will increase post- procedure monitoring compared to pre-procedure monitoring in both protocols. As per standard policy of the Establishment for the integration of new species, housing and husbandry of the Broiler breeders will be subjected to increased surveillance by the NVS in the initial stage of the project.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For experimental design we will follow ARRIVE guidelines. https://arriveguidelines.org

Specifically, for poultry we will consult the following resources:

https://www.gov.uk/government/publications/poultry-on-farm-welfare/broiler-meat-chickens-welfare- recommendations

https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/3192 92/Farm_Animal_Welfare_in_Great_Britain_-_Past_Present_and_Future.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Mostly through the University 3Rs Newsletter. In addition, the PI has been Chair of the Departmental Animal Welfare Ethical Review Board (AWERB) and member of the University Animal Care and Ethical Review Committee (ACER) for several years. Both AWERB and ACER review developments in the 3Rs at different scales (from within the University to international) at termly meetings. As such, the PI is kept abreast of advances in the 3Rs on a termly basis, and attends 3Rs day events regularly organised by the University.

190. Preservation of Pig Liver and Kidney for Transplantation, Using a Novel Solution

Project duration

3 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Transplantation, Preservation, Kidney, Liver, Novel Solution

Animal types	Life stages
Pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine whether LS-A preserves abdominal organs better than in use UW solution, in static cold storage preservation, using a large animal model (the pig).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Organ transplantation not only saves lives but enhances the quality of the life of recipients allowing them to live long healthy and fulfilled lives. This costs society and in particular the NHS far less than having a critically ill person who takes up hospital time, treatment (such as dialysis prior to kidney transplant) and money; indeed many patients return to full time

careers after successful transplantation so pay tax and put money back into the country. Children who have organ transplants return to school and many go on to further education, have lifelong careers, get married and have children of their own. One thing that is clear is that the better the organ preservation solution the higher the chances of the organ working and the patient surviving.

There are currently around 6,500 people on the UK transplant waiting list and for the last year that there is data for, nearly 500 people died whilst waiting for a transplant (NHS Blood and Transplant data 2017), and in the USA about 20% of people will die waiting for a transplant. Transplants often do not go ahead due to the organ being not suitable and decisions about their use having to be taken quickly, largely due to limitations related to the length of time that organs can be safely stored before transplantation. This is because the length of time an organ can be out of the body prior to being transplanted is dependent on the effectiveness of solution which has been used to perfuse and preserve the organ. For example, at present the maximum storage time for liver using the current "gold standard", UW solution, is less than about 12 hours and for kidney only up to about 24 hours, even when the organs are considered to be in ideal condition before retrieval.

LS-A has been developed by a group of researchers for use in abdominal organ preservation and experimental data has shown that LS-A can extend the static cold storage period successfully for organs for liver and kidney transplantation.

Older, or less fit donors who are referred to as extended criteria or marginal donors are being used much more frequently now, as due to better medical and surgical care, people are surviving longer and not dying after such things as road accidents and brain haemorrhages. It is believed that using machine perfusion is one way to enable organs from these types of donors to be checked in a more effective way to see if they are suitable for transplantation and gives time to manipulate the organ and or the recipient if needed.

In order to combat the general shortage of organs available for life-saving transplants, older, or less fit donors who are referred to as extended criteria or marginal donors are being used more, including organs retrieved from DCD (donation after cardiac death) donors, and donors with fatty liver disease for example. These "extended criteria donors" are being used much more frequently now and it is clear that they need improved methods of organ storage to ensure function after transplantation. One method is machine perfusion after initial static cold storage, in particular a method known as Hypothermic Oxygenated PErfusion (HOPE). It is believed that using machine perfusion is one way to enable organs from these types of donors to be checked in a more effective way to see if they are suitable for transplantation and gives time to manipulate the organ and or the recipient if needed. Currently UW- MP (UW for machine perfusion), or an identical formulation sold under different trade names, is the only clinically available solution for HOPE. Paradoxically, one major failing of both UW and UW-MP is that they contain a high concentration of hydroxy ethyl starch (HES), which is known to be highly toxic. LS- A does not contain any HES.

Currently there is a need to optimise not only the solution used for static cold storage but also for HOPE as in clinical practice UW needs to be used for the initial flush and cold storage period and then exchanged for UW-MP for HOPE. A single improved formulation able to work effectively in both situations is needed. LS-A may be this solution so it needs to be tested for HOPE after static cold storage using both ideal and marginal organs.

What outputs do you think you will see at the end of this project?

At the end of this work, we should be in a position to do a clinical trial, using LS-A for the preservation of kidneys and livers to keep them in a better condition than the preservation

solutions on the market at the moment can do. It will also allow organs to be kept for longer periods than is possible at present, and this in turn will give time for the manipulation of factors in both the organ and the recipient, which will mean that the organs will have a better chance of lasting in the recipient for longer. Organs from extended criteria donors will be kept in a better condition and will be able to be manipulated so that the recipient will recover quicker and have a better quality of life for a longer period.

Who or what will benefit from these outputs, and how?

Long term the patients who will benefit will be patients in chronic organ failure waiting for a kidney and/or liver transplant. By being able to preserve organs for longer and having time to manipulate the organ or the patient will mean there are more organs of better quality for transplantation, so hopefully more patients will get transplants which will last longer. This in turn will be better for the health service, as the patient will require less care, and society in general as many of the recipients will be able to return to work, have less time off work so help the economy of the country.

Medics and scientists will also benefit as it will allow time for the organs or patients to be treated in different ways so that the transplants will be successful. Many of these treatments have yet to be discovered but it is believed that stimulation of certain cells and suppression of others may help in this process.

How will you look to maximise the outputs of this work?

It is intended that all the data from this work will be published in peer reviewed journals and presented at conference both nationally and internationally to disseminate the results.

Once clinical trials start, it is expected that other groups around the country and abroad will also be involved in these trials so as the largest cohort of patients and organs will be clinically tested.

Species and numbers of animals expected to be used

- Pigs: 12

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult female Landrace-Great White Hybrids Pig are used as these are the type which are used at our University, so no new breeds will need to be introduced. Adult pigs are used as they are the nearest in size to those found in human organ donors and will weigh about 30 – 40 kg.
Pigs are used in this experiment because the anatomy of the internal organs of the pig is similar to that of a human, making the surgery and procedure as near to what would be seen in human transplantation as is possible.

Typically, what will be done to an animal used in your project?

This process will kill the pig while still under anaesthesia. We plan to harvest kidneys and liver. Organs will be kept cool and will be flushed with a appropriate solution to keep them in optimum condition for storage and later in vitro studies. Each pig will be sedated All surgical procedures on pigs under this project license will be carried out while animal will be terminally anaesthetised. Each pig will be sedated and subsequently anaesthetised by a competent personal licence holder with expertise in pig anaesthesia. A human surgeon with a personal licence to carry out regulated procedures on pigs will then perform surgical procedures that include laparotomy, cannulation of peripheral and deep blood vessels, perfusion of organs with preservatives collection of large blood sample for later use, and removal of organs for subsequent in vitro studies on harvested organs.

What are the expected impacts and/or adverse effects for the animals during your project?

The pig will be brought to from the establishment approximately 18 -24 hours before the induction of anaesthesia to enable it to acclimatise to new surroundings. It will be sedated prior to surgery and anaesthetised so should suffer no abnormal behaviour or tension.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals will be killed during the operation. The pigs will be sedated and all procedures will be carried out under anaesthesia from which the pigs will not recover.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To show that any organ preservation has been successful whole organs need to be used as when an organ transplant takes place the majority of the time it is a full organ which is used, the only exception being when lobes of liver or lung are used on tiny children. The only way that this can be done is by using whole animals. Looking and testing the effect of the solution on the whole organ rather than just certain cells is required.

Earlier work was done on rats but pigs are to be used in this research as pig kidney is multilobular and multipapillar, with a complex network of blood vessels, also found in humans but not in mouse or rats, so they are the closest there is to the human model.

Which non-animal alternatives did you consider for use in this project?

Some of the elements of the solutions have been tested initially on cell lines prior to their addition to the solution. If there were adverse events seen with the cell lines then these

were not added to the solution and were replaced without testing on whole organs or animals. We have now come to the stage when we need to use whole organs.

Why were they not suitable?

After preservation of the organs they will be reperfused with blood to mimic what happens following organ transplantation. Blood used in the reperfusion so that different biochemical perimeters specific to the organ transplanted can be tested after different lengths of time to ascertain how well the organs are functioning, for which we require the full organ. For liver we will be also collecting bile and for the kidney we will be collecting urine both of which require the full organ as more than one cell type is involved in their production.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These are preliminary studies to test viability and/or difference between two preservative solution being widely used in the preservation of organ before transplantation. We think 12 animals will give us statically viable information to see the differences in two solutions.

Many different types of tests on the organs, tissue and blood means plenty of results can be obtained despite the low number of animals used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals used several strategies have been used. Firstly, as much as possible of each animal will be used, so both the liver and kidneys will be retrieved. Secondly blood will be taken for use in reperfusion parts of the experiments rather than being bought in which would entail more animals being killed. Thirdly each time when a pig is going to be used, other researchers who can use other parts and tissues will be informed so that they can take what they can use.

If a pig dies unexpectedly, the organs will still be taken and used, as this situation mimics another way in which organs are retrieved for transplantation in humans, called extended criteria donors. This means that if other researchers are euthanizing a pig for any reason, we may be able to retrieve and use the organs, again soon after death.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Rather than transplant the organs into other animals, to reduce the number of animals used it is intended that we use an isolated perfusion rig, to mimic transplantation. This equipment allows us to reperfuse both kidneys and livers at the same time, outside of the pig, so each pig will have the liver, both kidneys and blood removed from it. The rest of the

pig will be offered to other groups to see if further use can be made of it.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The type of animal used will be Landrace-Great White Hybrids as these were used in earlier in the development of the solution and are the breed of pig which is kept at the University farm; therefore no new species will be introduced and there will be the minimal of movement of the animals which will cause them less stress.

Pigs are social animals and should not be kept alone for prolonged periods of time, therefore the pigs will be brought from the establishment where they are kept to where the surgery will take place, only 24 hours prior to it being required for surgery. This gives it time to acclimatize after the move but not long enough for itto get lonely.

All work on the pig will be done under anaesthetic so it will not feel any pain and will be euthanized whilst still under anaesthetic. All work on the pig will be done under anaesthetic so it will not feel any pain and will be euthanized whilst still under anaesthetic. Anaesthesia on the pig will be carried out by a competent personal licence holder with expertise in pig anaesthesia. Surgical procedures will be carried out under aseptic conditions by a competent transplant surgeon with a personal licence to work on pigs. No animal will recover from anaesthesia. This will mean that the pig will be caused the least pain and suffering possible for these procedures.

Why can’t you use animals that are less sentient?

Earlier work was done on rats but pigs are to be used in this research as pig kidney is anatomically more complex, with a lobular structure and a complex network of blood vessels, which are similar to those found in humans but not in mouse or rats, so they are the closest there is to the human model.

The pig liver is closer to human liver anatomy than rat or mouse liver and it is widely accepted that the porcine hepatocyte is the best non-human model to use as an alternative to human hepatocytes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Each pig will be brought to the University only 24 hours in advance of their use. Where the pigs are reared they are in a group as they are not solitary animals. They will only be at the site for a short period and will be sedated prior to anaesthetic so that it will not suffer many adverse effects. The pigs will be monitored by the University Veterinary Surgeon at all time from the point of sedation, through the general anaesthetic and surgery until the point

where it is killed. The monitoring will be the same as would be done during a routine operation on an animal, and if at anytime the pig is thought to be suffering initially we will try to alleviate it but if this is not possible it will be killed by a humane method so that it does not suffer any longer.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animals (Scientific Procedures) Act 1986 (ASPA)

EU Directive 2010/663/EU

UK Research Integrity Office Code of Practice guidelines. ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

A computer search will be carried out prior to each period of work with the pigs to see if there are any changes or advances in the 3Rs which need to be accounted for with the work. This will include checking on the Home Office site, NC3Rs site and also the Royal Veterinary site We will also check with the University Veterinary Surgeon to see if they have any knowledge of any changes which would impact on this work.

I already receive updates from NC3R and any changes regarding the use of the animals will be done in accordance to their advice.

191. Isolated tissues for the study of cardiac ischemia and cardiovascular function

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cardiovascular disease, myocardial infarction, ischaemic heart disease, arrhythmias, heart failure

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	neonate, adult
Guinea pigs	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of these studies is to understand how the heart works and, more importantly, how it goes wrong. Our ultimate aim is to improve the diagnosis and treatment of heart disease. We will examine the influence of pharmacological, dietary or physical treatments on the cellular processes involved in cardiac injury.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease remains the number one cause of death in Western countries accounting for over 30% of all deaths (Virani et al., 2021). It is predicted that cardiovascular disease is also set to become the leading cause of death in developing countries. This rise in cardiovascular disease reflects a significant change in dietary habits, physical activity levels, and tobacco consumption worldwide as a result of industrialisation, urbanisation, economic development and food market globalisation. High blood pressure, high blood cholesterol, obesity and chronic type 2 diabetes are among the major biological risk factors.

Virani SS et al (2021) Heart disease and stroke statistics - 2021 Update. *Circulation* 143 (8): doi.org/10.1161/CIR.0000000000000950

What outputs do you think you will see at the end of this project?

The principle outputs will be publications and conference presentations.

Who or what will benefit from these outputs, and how?

In the short term we expect the scientific community to be the primary beneficiary. However, it is the longer term aim of this work that either directly, or through the work of others, new products, drugs or life-style changes will be developed to substantially prevent, or improve the treatment of, cardiovascular disease.

How will you look to maximise the outputs of this work?

At all times work in our laboratories aims to be open and collaborative. We have many active collaborations around the UK and the world (i.e. USA, Israel, Germany, Canada etc). We will maximise our outputs be ensuring publication in international high-profile journals.

While positive data is sadly always easier to publish, we believe that scientifically reliable negative data is as important. A recent example of this relates to the mechanism of action of the SGLT2 inhibitor class of drugs in the heart. Based on a small number of flawed studies, the idea that SGLT2i's exert their effects by inhibiting the cardiac Na/H exchanger has gained traction. We have recently published negative data showing that this is not the case. See doi: 10.1093/cvr/cvaa323 and doi: 10.1093/cvr/cvab184.

Species and numbers of animals expected to be used

- Mice: 4500
- Rats: 1500
- Guinea pigs: 450
- Rabbits: 450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

All studies will be confined to either mice, rats, rabbits or guinea pigs. No experiments are proposed that involve *in vivo* ischaemia and reperfusion and/or the recovery from

anaesthesia. Over the past 30 years we have continually refined our in vitro techniques such that we (i) limit all studies within our laboratory to small animals (mice, rats, rabbits and guinea pigs), (ii) all of our studies ultimately involve terminal anaesthesia and/or *in vitro* experimentation, with the exception of the mild pre-treatment protocol (Protocol 2) and the breeding and re-derivation of transgenic mice, and (iii) collect tissue for molecular/biochemical studies from the same animals or hearts as those used for the assessment of *in vitro* function, where possible.

A significant proportion of these studies will be carried out using adult mice. The mouse has become a pivotal experimental system for animal-based cardiovascular research, due to the rapidly increasing availability of genetically modified models of various cardiovascular diseases. The availability of such mice has undoubtedly had an enormous impact on the understanding of cardiovascular disease. Transgenic or mutagenic mice will be created, either on other Project Licences or in other laboratories elsewhere in the world, and maintained under authority for use on this Project Licence. Provision is therefore made for the breeding of transgenic or mutagenic animals on this project licence. Specific provision is also made for re-deriving mouse lines (Protocols 5-7) if necessary and for cryopreservation of fertilised eggs.

In addition, studies will be carried out using the adult rat. This animal has been well characterised and its heart and tissues are robust and suitable for isolated studies. However, a number of important physiological differences exist between mice and rats and other species including man, such as altered action potential characteristics, subtle changes in calcium handling, the extent of myocardial collateral blood flow, etc. These differences are useful in some experiments as they allow specific cellular systems and characteristics to be investigated, however, it is essential that specific studies are also performed in species in which particular cellular systems are more closely analogous to the human heart. Such species include the guinea pig and rabbit (where cellular physiology and calcium handling are more similar to humans). Some studies will therefore be conducted in these species.

In a very limited number of studies, tissues will be isolated from neonatal animals after a terminal procedure. Such studies are necessary to (a) provide data on the neonatal heart and its maturation relevant, for example, to neonatal cardiac surgery, and/or (b) to provide isolated cardiomyocytes that can be readily cultured and transfected (Note: adult cardiomyocytes dedifferentiate in culture).

Typically, what will be done to an animal used in your project?

Most of our studies under this license will be performed i*n vitro.* The licensed procedures described here will mostly be limited to the terminal anaesthesia of healthy animals for the excision of tissues (usually the heart) which will be subsequently studied *in vitro.* For a typical experiment, animals will be anaesthetised and, after thoracotomy, the hearts and associated major vessels will be excised [Protocol 1]. This terminal anaesthesia would involve a single procedure of an anaesthetic agent delivered via an appropriate route according to species. Typically the duration of such procedures would be less than 5 mins.

In some experiments, animals may be pre-treated prior to terminal anaesthesia with drugs or dietary manipulations. The duration of such pharmacological pre-treatments will not exceed 28 days while dietary manipulation may be initiated from weaning.

What are the expected impacts and/or adverse effects for the animals during your project?

Terminal anaesthesia and heart excision: The vast majority of experiments will only involve terminal anaesthesia and therefore there are no chronic adverse effects to consider.

A small number of studies, *in vivo* pharmacological pre-treatment up to a maximum duration of 28 days will be conducted to examine the effects on heart function after excision from the animal. Some pharmacological interventions capable of modifying the myocardial response to ischaemia or reperfusion in vitro require administration prior to the excision of the heart. It is therefore proposed that a number of animals will be pre-treated with such agents,administered via appropriate intravenous, intraperitoneal, intramuscular, subcutaneous or oral routes at appropriate concentrations according to manufacturers instruction and/or known data. As some of our work involves the development and characterisation of novel therapeutic approaches, it is impossible to anticipate specific details of the exact substances, concentrations or routes of administration.

However, it is essential to stress that in ALL CASES, animals pre-treated in this manner will be monitored to ensure that, in itself, such treatment DOES NOT EXCEED THE MILD SEVERITY LIMIT designated in each protocol. Hence, administration will initially involve low doses that will only be increased to the required dose once detailed monitoring has been conducted to ensure no adverse effects are induced. In some studies, drug pre-treatment may be combined with dietary manipulation as described. A small number of animals pre-treated with either drugs, dietary manipulation or both may be subjected tocardiovascular monitoring by non-invasive imaging (e.g. echocardiography) or implantation of telemetry probes.

Dietary manipulation: Prior to tissue excision, some animals may be fed a modified diet. Such diets will be formulated to modulate the levels of existing nutrients (without causing imbalance that will result in overt and immediate adverse health effects). Examples of such dietary manipulation may include adding dietary achievable levels of fish-oils, fat-feeding, cholesterol enriched diets, lowering the amount of iron, etc. Such diets will only modify the levels of nutrients that occur naturally in a Western human diet. This modification will not limit calorie intake, or render the animals malnourished, induce excessive weight loss or any of the classical signs of listlessness or overt ill health.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All species - Mild (95%)

All species - Moderate (5%) (Telemetry)

What will happen to animals at the end of this project?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ischaemia is a complex multifactorial pathology that cannot be replicated in cell culture models. Although it can useful to study individual signalling pathways in *in vitro* cell cultures, the contribution of these pathways to ischaemia/reperfusion injury can only be usefully assessed in whole hearts or freshly isolated tissues. Isolated cardiac cells are required for the detailed investigation of cellular mechanisms. There are no immortalised ventricular myocyte cell lines available, which makes it necessary to isolate cells from neonatal or adult animal hearts. We have attempted to replace animals (i) by the increased use, where appropriate, of cell culture systems (such as human iPSC-derived cardiomyocytes, HEK293 and A10 vascular smooth muscle cells) to probe specific cellular mechanisms, and (ii) by the use of human tissue derived from routine operations to replace some animal experiments. However, human ventricular tissue is not readily available, and is almost invariably from diseased explanted hearts and cannot typically be vascularly perfused.

Which non-animal alternatives did you consider for use in this project?

Cell culture

Human Cardiac Induced Pluripotent Stem Cells (hIPSC) Computer modelling

Why were they not suitable?

Cell culture: Ischaemia is a complex multifactorial pathology that cannot be replicated in cell culture models. Although it can useful to study individual signalling pathways in in vitro cell cultures, the contribution of these pathways to ischaemia/reperfusion injury can only be usefully assessed in whole hearts or freshly isolated tissues. While hypoxia (with added potassium elevation and acidosis) recapitulates some features of ischaemia, it falls far short of being a suitable model of the multi-cell- type, 3-dimensional paracrine organ that is cardiac tissue. The 3-dimensional structure is also a prerequisite to study complex cardiac arrhythmias which cannot be mimicked in a dish.

hIPSCs: Recently experiments on cardiac hIPSC cells (Human Induced Pluripotent Stem Cells) have become popular. While these cells recapitulate some features of adult cardiomyocyte they are notoriously variable in phenotype, immature and a poor model for may physiological and pharmacological studies (Funakoshi and Yoshida, 2021).

Computer models: While computer models are useful in confirming and validating our understanding of physiological processes, they can only be parameterised and used in parallel with in vivo and in vitro models. They are an addition to, but not a replacement for, the use of real biological tissues.

Funakoshi S, Yoshida Y (2021) Recent progress of iPSC technology in cardiac diseases. Arch Toxicol. 95(12):3633-3650. doi: 10.1007/s00204-021-03172-3.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The large number of animals required (in particular the large number of adult mice) reflects the large number of licensees (~10) working on this project and our experience over many years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, all experiments are blinded and randomised. In biology, measurements made are often complex and variable. Therefore, in order to be able to compare between protocols, all experiments need to be repeated a number of times, averages taken and appropriate statistics applied. By rigorously controlling the conditions of our experiments, this variability can be minimised. However, for most measurements we need to repeat experiments at least 6 times. For some less predictable variables (such as arrhythmias) this number may increase to 10 or more. Each experiment may also require a number of different groups (different drug concentrations, control groups, different genetic backgrounds etc). This gives typically approximately 30-60 animals per experiment (this includes some that fail to meet the experimental inclusion criteria standard, for whatever reason). Each experiment may take 3-4 months to conduct; hence, each licencee may require 2-300 animals per annum. Most licencees will use predominantly mice or rats in their experiments. Animals will also be required for the production of myocytes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers of breeding pairs will be minimised to the number required to just meet our requirements. Unfortunately, due to variations in ischaemic tolerance across the oestrus cycle in rats and mice, most experiments will be conducted on male animals. This therefore requires culling of female mice before weaning.

Where possible tissue will be shared. Heart homogenates are frozen and a tissue bank managed locally to provide tissue across a number of investigators. On a routine basis, myocyte isolations are shared across a number of investigators. Typically, one adult rat heart can provide sufficient myocytes for up to eight 6 well tissue culture plates, or around 50 samples for biochemical analysis. Similarly mouse myocytes can be shared across projects. The number of animals used will be kept to a minimum by distributing cells from each preparation between several users.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority (90%) of the studies described in this license involve terminal anaesthesia only. Pain, suffering and distress will therefore be minimal. There is clearly always some stress in the induction phase of any anaesthesia but all PIL holders working under this license will be appropriately trained to minimise this distress.

In the small number of animals where drug pre-treatment is involved prior to terminal anesthesia (10%), all PIL holders working under this license will be appropriately trained and supervised. In this case there will be regular interaction and guidance from BSU staff and the NVS. Again, in the majority of cases, in this small cohort of animals, pre-treatment with drugs will be achieved using the least stressful route of administration - this is often by inclusion of a palatable drug in drinking water or diet.

In an even smaller small cohort of animals (<5%), drug pre-treated animals (and placebo controls) may be non-invasively scanned while under sedation or anaesthesia to measure cardiovascular function using modalities including ultrasound (echocardiography) or MR Imaging; OR, some animals may be monitored using implanted telemetry devices to measure physiological variables such as blood pressure, heart rate, ECG etc. These invasive measures will be used rarely and, when used, appropriate analgesia will be given.

Why can’t you use animals that are less sentient?

The majority (90%) of studies involve the isolation of tissues from insentient unconscious animals under terminal anaesthesia. All experiments where animals are pre-treated with drugs or dietary manipulation will be performed only on animals post-weaning. While less sentient animals such a zebra fish etc have a huge contribution to make to the understanding the cardiovascular system, they are better suited to developmental studies. Ischaemic heart disease, heart failure and arrhythmias are largely diseases of the adult human heart. It is unclear whether less sentient animals either suffer from heart disease or indeed make appropriate models for the human in this regard. Hence, the mammalian heart is used for the majority of such studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As the majority (90%) of the studies described here only involve terminal anaesthesia and tissue isolation, there are no issues about post-operative care. In the small number of pre-treatment or pre- termination monitoring (echo, telemetry etc) we will liaise with the NVS to ensure all procedures meet with evolving best practice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office and institutional protocols for induction of anaesthesia, sedation, and animal care. These include the LASA guidelines on aseptic surgery. ARRIVE guidelines will be followed in study design and in all publications depending on editorial constraints.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All researchers involved are constantly reading the scientific literature and continually refining our experimental approach. We also have regular updates from BSU staff and the NVS and institution-led training on animal welfare and the 3Rs.

192. Development of Therapeutic Agents to Treat CNS Disorders

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neurodegeneration, Psychiatry, Treatment, Therapeutic Efficacy, CNS disorders

Animal types	Life stages
Mice	adult
Rats	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to provide a service to support discovery and development programmes for therapeutic agents for Central Nervous System (CNS) disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is currently a huge unmet medical need for effective therapeutic agents to treat psychiatric disorders as well as for the symptomatic and disease modifying treatment of neurodegenerative disorders, such as Alzheimer's disease and Parkinson's disease.

What outputs do you think you will see at the end of this project?

Compounds, drug candidates or drugs that have efficacy in animal models of CNS disorders that could progress to clinical development.

Publications in peer-reviewed journals.

Who or what will benefit from these outputs, and how?

The ultimate benefit will be patients living with psychiatric diseases (for example depression and schizophrenia) or neurodegenerative disorders (for example Alzheimer's disease and Parkinson's disease) for which there is no medicine to slow or halt disease progression. In the short-term scientific knowledge may highlight disease related mechanisms relevant to their aetiology that would then direct research and testing new therapies in disease relevant models.

How will you look to maximise the outputs of this work?

Where possible - and if needed, with agreement of clients - data will be published in peer reviewed journals and presented at appropriate scientific meetings.

Species and numbers of animals expected to be used

- Mice: 1600
- Rats: 2550
- Guinea pigs: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rats and mice are the predominant species used in preclinical research into CNS disorders as they have a fully developed central nervous system, are the most common species type used in preclinical CNS research for which there is a wealth of scientific literature and experimental expertise. Moreover, the CNS circuitry and systemic physiology that determines the pharmacokinetic profile within the CNS and the associated pharmacodynamic response that underpin therapeutic efficacy is comparable to humans.

Typically, what will be done to an animal used in your project?

Animals used in the project may be naïve, genetically modified (e.g. expressing a disease relevant phenotype), undergone surgical procedures to lesion specific neuronal processes or been subject to pharmacological manipulation.
Naïve or genetically modified animals may undergo surgical procedures to implant devices to allow assessment of cellular or neuronal function in the CNS or for determining levels of test compound following acute or chronic treatment. Separately, animals which express pathologies or symptoms associated with a CNS disorder (e.g. using genetically modified animals, or animals with discrete lesions to particular neuronal systems) may be tested to

measure CNS relevant behaviours (e.g. related to cognition, anxiety, motor function). In these studies, test compounds will be dosed acutely by systemic or direct injection, but on occasions animals may be dosed chronically to assess the effect of more prolonged treatment to determine if pharmacodynamic effects are maintained, or if a test agent has neuroprotective properties.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals undergoing surgical procedures for implantation of cannulae, microdialysis probes, sensors or catheters recover within a few hours from anaesthesia and a full recovery from the procedure within one to two days. Following stereotaxic delivery of a neurotoxin adverse effects may include neurological impairment (e.g. motor dysfunction following a dopaminergic lesions) that may last for the duration of the experiment (typically no more than 60 days).

Most of the animals are not expected to show signs of adverse effects that impact materially on their general well-being following test compound administration. No more than 5% of animals are expected to show clinical signs of a mild or moderate severity because of unpredicted side-effects of administered compounds (typical effects may include reduced appetite, weight loss, reduced activity, and diarrhoea).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We anticipate that most animals will experience moderate severity due to the necessity to undergo surgical procedures and/or chronic administration

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are no current *in vitro* alternatives which would model the complex *in vivo* processes involved in absorption, distribution, metabolism and excretion or safety of candidate drug molecules. Similarly, there are no *in vitro* models for CNS conditions that usually involve integrated responses not only from the already extremely complex neuronal tissue, but also from the immune or the vascular system.
There are currently no alternatives to *in vivo* testing able to replicate the complexity of a whole organism accurately enough. As such *in vivo* studies remain essential in the search of novel therapeutic agents for CNS disorders.

Which non-animal alternatives did you consider for use in this project?

There are alternative strategies we can use, particularly for studies investigating a specific cellular response to target manipulation, where *in vitro* studies can be carried out on cultured or primary cells. We will also propose and use *ex vivo* experiments where possible, for instance, using synaptosome preparations to measure neurotransmitter release or use brain slices to measure electrophysiological responses of test compounds. We will also seek alternatives to *in vivo* testing by exploring the use 3D *in vitro* models, with particular interest on those able to replicate Blood Brain Barrier (BBB) properties.

Several *in vitro* and *in silico* assays have been developed to replace the use of animals for the initial steps of CNS drug discovery. These assays are designed to ensure that only compounds predicted to cross the BBB and with acceptable profile for efficacy, selectivity and suitable ADME (adsorption, distribution, metabolism & excretion), will be tested on live organisms. Although these experiments are usually performed by the client, we have in house capability to carry out such studies.

Why were they not suitable?

In all cases the scientific question to be answered in a proposed experiment will be carefully studied and *in vitro* and *ex vivo* alternatives will be considered. However, using animals *in vivo* offer more predictive methods to assess the complex integrated processes controlling the absorption, distribution and interaction of a test substance with a molecular target, and its functional effect on neuronal processes relevant to CNS disorders.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on typical study design and number of projects predicted over the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals to be used is influenced by previous extensive experience in designing and running studies of this type.

The minimum number of animals used is also underpinned by an understanding of the variation between animals, the sensitivity and reproducibility of the methods being used, and with statistician advice being sought when needed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies are frequently used when developing models and sharing of model information with collaborators to reduce the overall number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The overall premise of the license is that the most refined, most relevant, and less invasive method will be used at each stage. We will expect the greatest number of compounds to be tested in models with minimum burden on the animals (duration of study, stimulus required for experimental window and endpoint). When the experimental question justifies additional burden to the animal (i.e. surgery, lesioning, chronic dosing) we will aim to keep such burden to minimum levels.

Surgical techniques and post op-recovery standards will be continuously monitored and revised. Surgical procedures, including preparation, surgery, and recovery care, will be performed in keeping with current best practice guidelines (LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery).

With chronic studies, the dose route will be carefully discussed with the client and alternatives to repeated injections such as implantation of mini pumps or subcutaneous pellets will be contemplated.

We will continuously monitor the literature and involve the Named Animal Care and Welfare Officer (NACWO) as much as possible to help us to implement the latest animal husbandry and environmental enrichment practices.

Substances administered to animals by injection or gavage will be in the smallest volume commensurate with the aims of the procedure. The administration of substances to animals by infusion will also be at the lowest flow rates and for the minimum period practicable. Substances will be delivered in non-toxic biocompatible vehicles. The route of administration will be carefully determined by a number of factors such as the solubility of the substance, PK properties, number of administrations over time, volume, vehicle used or projected dosing route in humans. We will determine the route of administration in compliance with LASA guidelines (Good Practice Guidelines - Administration of Substances) and relevant literature with regards to substance administration (i.e. Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider, Turner et al (2011)).

Why can’t you use animals that are less sentient?

Species of choice will be primarily rat or mouse, depending on the pharmacological properties of the therapeutic agent, endpoint employed and the knowledge of the target. Adult animals will be preferred as they have a more developed nervous system and less sentient species do not allow application of the same methodological approaches, or translational aspects for inferring a drug's therapeutic potential.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continually review our peri- and post- operative care procedures and each of the PPLs learn from each other with respect to procedures and refinements. Our NACWO/NVS/NIO attends regular national meetings and provides us with feedback on learnings.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experiments will be planned so they can be reported in accordance with the NC3Rs' ARRIVE guidelines and we will conduct regular literature reviews to ensure that our work aligns with current best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By regular discussion with the Named Information Officer (NIO), NACWO and the Named Veterinary Surgeon (NVS) in addition to receiving regular updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Scientific Research (NC3Rs). The 3Rs are also an item agenda during our quarterly Animal Welfare and Ethical Review Body (AWERB) meeting.

193. Mechanisms controlling anti-tumour responses in primary and metastatic disease

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Cancer, Immune checkpoints, T cells, Therapies, Metastases

Animal types	Life stages
Mice	juvenile, neonate, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine how different cellular interactions control the anti-tumour immune response in primary and metastatic disease and how targeting certain mechanisms, termed immune checkpoints, alters this. Armed with this information we aim to determine how best to combine new treatments with the clinically approved immune checkpoint blockade therapies to further enhance the immune response in cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One in two people will suffer from cancer during their lifetime. Successful treatment of cancer is hugely dependent upon the type of cancer and also how quickly it is diagnosed. Late diagnosis for many cancers results in at best a prognosis of only a few more years of life. Considering Cancer Research UK statistics (from 2010-2011) of the 21 most common cancers, 12 have ten-year survival of 50% or more, and four types – testicular cancer, malignant melanoma, prostate cancer and Hodgkin lymphoma – have survival in excess of 80%. Some cancer types, however, remain difficult to diagnose and/or treat, and ten-year

survival is less than 20% for stomach, brain, oesophageal, lung and pancreatic cancers, which actually has a ten-year survival of just 1%. In short cancer remains the single biggest health concern of humans, particularly in Developed countries where infectious diseases have been controlled through vaccination.
In the last 10 years, there has been enormous advances in exploiting immune responses to kill cancers. Striking successes include targeting immune checkpoints, which have revealed that even with late stage diagnosis, common cancers such as melanoma can be cured in some patients. CAR T cells have proven to be stunningly effective in curing some types of lymphoma. However, it remains the case that therapies that manipulate immune responses work for only some types of cancer and typically in less than 50% of patients with 'responsive' cancers. Furthermore, manipulation of the anti-cancer response through targeting immune checkpoints can come at severe costs in terms of adverse events and toxicity. The lack of a universal effect reflects an incomplete knowledge of how immune responses to cancer are generated and sustained in the face of multiple signals that limit these responses. In particular, metastatic disease remains far more resistant to immune therapies. Discovery research investigating the mechanisms that still limit the anti-tumour response, particularly in the context of immune checkpoint blockade can help establish combination therapies so that more cancer patients can benefit.

In this Project we will investigate how different immune cells interact to support the anti-tumour response in both primary cancer and in metastatic disease. We will focus on T cells as we know that these are the cells best equipped to kill cancer cells and able to respond to therapies such as immune checkpoint blockade. Using novel mouse models developed in our lab we are able to track cellular changes in real time. We can distinguish cells based upon how long they have been within the tumour and this provides critical new insight into understanding how mechanisms act to control the T cell response. We will model the effect of the licenced immune checkpoint therapies and determine exactly how these impact the T cell response to both primary and metastatic tumours. We will then investigate the mechanisms that restrain the response in the face of this therapy to identify potential ways to further enhance it. Finally we will then test these combinations of therapies seeking to identify those that significantly improve control of tumour growth, in both primary and metastatic disease. This research strategy can rationalise and inform how best to refine treatments designed to enhance anti- tumour responses.

What outputs do you think you will see at the end of this project?

The key outputs of this project will be:

a detailed understanding of what happens to the T cell response within primary and metastatic cancers and how targeting immune checkpoints changes this. This information will be published in scientific journals and potentially influence the design of therapies in cancer patients.

detailed characterisation of the how the other cells within tumours support the anti-tumour T cell response and how this cellular 'infrastructure' is altered by targeting immune checkpoints. This information will again be published in scientific journals and will support efforts to optimise therapy combinations.

testing of new therapeutic combinations, informed by our dynamic analyses. These will provide initial evidence supporting the combined targeting of specific mechanisms.
We have consistently published all our findings in high impact immunological journals and we will continue to do so as the best way of advancing understanding from our research.

In addition we will continue to present our research findings at scientific conferences, invited seminars, interactions with industrial partners and public engagement events.

Who or what will benefit from these outputs, and how?

Short-term benefits: Our detailed in vivo research will directly benefit researchers, particularly cancer immunologists, seeking to better understand the anti-tumour response and how this can be best enhanced. In addition to academic research, research teams within industry, e.g. pharmaceutical companies, can exploit our research findings to refine their efforts to manipulate key pathways operating in the cancer.

Medium and long-term benefits: Our research outputs and observations will feed through into both academic and industrial efforts to develop better combinations of therapies to enhance anti-tumour immunity. It will also benefit clinical oncologists considering treatment options for cancer patients and how different therapies might be combined for optimal effect. This will feed through into better therapeutic options for patients with cancers that show limited responses to current treatments and for which new treatment combinations need to be tried.

How will you look to maximise the outputs of this work?

Throughout my research career I have actively collaborated with many researcher in my field and shared expertise, research tools and models widely and prior to publication. I think this is an essential part of maximising the outputs from basic research. I will continue to do this and further continue to instil this philosophy in the researchers of my lab. Publishing our work in high impact journals with broad readerships provides an effective means of disseminating experimental data and findings. I am also very active in presenting research findings from my lab nationally and internationally through invited seminars and conferences. Finally, I have established collaborative interactions with pharmaceutical companies and will continue to develop these to maximise the influence of our research activity.

Species and numbers of animals expected to be used

- Mice: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will use mice to further our understanding of what happens to certain immune cells (called T cells) within cancers and why this happens. The environment within cancers has an enormous effect on the cells within these tissues. Furthermore, immune cells traffic between lymphoid tissues and the cancer. Collectively this is far too complex to accurately model through non-animal methods currently available (e.g. in vitro cultures). This really means that the only way to control for all these parameters is to study what T cells do within the cancers within a living animal. This ensures that the data we acquire is of maximum relevance to understanding the mechanisms that control the response in human cancer patients.

We have chosen mice as our animal study for the following three key reasons:
The main components of the mouse immune system shared by humans, making the mouse an excellent model of the human immune system.

The mouse immune system has been extensively studied already, meaning that there are an extensive range of reagents available to help careful study of what mouse immune cells do and why. This is important because it means we can use pre-existing data, we don't have to validate evidence in a new species and our research is not restricted by a lack of experimental tools.

There are many genetically modified mice available which enable detailed information about what cells do or how they behave. This is hugely important, particularly in this Project as it means we can understand how cells change over time and in specific environments, which cannot be captured by other approaches.

The immune system alters over the course of development, and our research is focussed on functionality in the adult. For this reason we will use adult mice.

Typically, what will be done to an animal used in your project?

In a typical experiment on this licence, tumour cells will be injected into a specific location in mice and these will grow into a cancer over the following weeks. These tumours will grow in sites where they cause very little, if any, discomfort to the mice. Most mice will additionally be injected (typically by intraperitoneal injection as a route that causes limited and transient discomfort) with reagents on multiple occasions over about 2 weeks. Typically this will be less than 6 injections.

In some experiments we will assess how cells are changing over time and in response to the injected reagents through labelling the tumour with light (using ‘photoconvertible’ genetically modified mice).The vast majority of experiments would last for approximately one month or less and at the end all animals will be humanely killed and tissues taken post-mortem for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

All mice on the project will experience temporary discomfort and stress from the anaesthetic event used for injection of tumour cells. In most cases one or two tumours will then develop at superficial locations (for example on the flank under the skin) where they cause very limited if any, adverse effects. Some mice will be given tumours in their colon, but this is done via an endoscopy and under anaesthetic and again these tumours cause very limited discomfort to the mice in most cases. In all these mice, the greatest impact will be the transient discomfort and intermittent stress of handling and injections. We will keep the number of injections to the minimum required and the typically the injection route will be intraperitoneally (an injection through the skin into the body cavity). Light exposure to temporally label tissue will be done under anaesthesia, thus limiting distress to the mice. The process of light exposure to tumours under the skin causes no adverse effects to the animal. Light exposure to colonic tumours is performed via a modified endoscope, again under anaethesia. In some experiments we will model lung metastases by injecting tumour cells intravenously which then accumulate in the lungs as a collection of very small tumours. These tumours, if left unchecked, can impair respiratory functions, but we will

ensure that mice with these lung tumours are killed at the earliest opportunity to study the tumours and certainly before respiratory function is noticeably impaired.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum expected severity on any protocol is moderate. This is because almost all mice on the licence will be given tumour cells that result in a local cancer or cancers growing in the mouse. These developing tumours cause minimal adverse effects to the mouse when carefully monitored and not allowed to grow very large. The greatest adverse effects experienced by the mice will be through multiple injections. The combination of tumours and multiple injections and photoconversion means that we cumulatively expect a moderate severity for approximately 80% of the mice on this licence. We expect that the remaining 20% will experience a mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To investigate what happens to the immune response within cancers and following treatment, it is impossible to properly assess this without studying a living animal and the different tissues and conditions that exist. The tumour environment is a hugely complex mixture of many cell types and these cells constantly interact and regulate what happens to each cell type. Furthermore, the majority of these cells are not static and both move between areas of the cancer and between the cancer and other tissues. In addition other parameters change regularly over time (e.g. nutrients). It is not possible to effectively model this environment nor the cells within it in a way that captures any of the normal cellular behaviours and interactions. Findings from only non-animal experiments would still then require extensive validation in an animal model before there relevance to human patients could be assessed and confirmed.

Which non-animal alternatives did you consider for use in this project?

We do exploit computer-based approaches to capture existing information from previous studies. With the advent of sophisticated cell sequencing and bioinformatics approaches, which we will continue to use throughout this project, computer-based studies form the major non-animal approach we use. These experiments can provide clear direction in which molecules to try to manipulate to control what happens to different immune cells.

We also considered organoids (cultures of certains cell types), which can enable the study of single cell types in a more 3D environment and even multiple cell types for example

intestinal epithelium organoids. We further investigated 3D culture approaches using a 'framework' approach where cellular interactions are enhanced.

Why were they not suitable?

We concluded that neither organoids nor 3D culture models would be appropriate as they cannot accurately model the cancer environment and this is key to controlling the immune response. Organoids cannot recapitulate the interactions of multiple cell types, which we know have huge influences on the immune response. Currently, no in vitro model (3D culture nor organoid) can recreate the complexity or dynamism of the tumour microenvironment nor appropriately model the entry and exit of immune cells.

We will look to develop patient tumour fragment analyses where by small pieces of human tumours are cultured for a few days and the effects of treatments can be tested. These experiments can help direct the in vivo research and ensure appropriate mechanisms are investigated.

Computer models are excellent at capturing descriptive data and we will continue to inform our in vivo projects where possible, but they do not provide the means to test 'cause and effect' nor determine functional outcomes. We will screen initial candidates using cell cultures in the lab and this will enable us to rule out some pathways/approaches that do not function as predicted.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In calculating the number of mice we will use, I have reviewed data over the last 10 years of my animal returns on my existing and previous PPLs. The number here reflects the need to maintain an extensive breeding colony to generate sufficient experimental mice across multiple genetically modified strains.
Furthermore, efforts to reduce experimental variability, for example through using age and sex- matched animals within an experiment, or the correct use of littermate controls in conditional knockout mice experiments, means that a large colony of mice for each strain is required to ensure that sufficient numbers of the desired mice are available. For individual experiments, the number of animals required is calculated based on data obtained from previous experiments, pilot studies, and information in the literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In designing this experimental body of work, we considered our previous experience of experimental models to investigate T cell responses and have also utilised the NC3R's Experimental Design Assistant. It is our extensive experience in using the approaches described here that really enables us to keep the number of mice used in this project to a minimum. We have selected only those experimental models that gave the most robust

and quantitative analysis of the intestinal T cell response and eliminated other experimental approaches where there was greater experimental variability or less clear means of definitively testing T cell function.

Through extensive research in the lab we have further optimised our understanding of the tumour models underpinning this project and identified the key time points that need to be assessed. This reduces the number of analysis points when mice might be killed. Through establishing and sustaining a productive collaboration with industrial partners, we are able to acquire reagents that have been extensively validated in vivo and generated to extremely high standards. This massively reduces the numbers of mice needed to test new compounds that we want to use in our studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continue to monitor mouse usage on our projects by constant and careful consideration of the data and its appropriateness in addressing our experimental objectives. In developing our models we reassess group sizes as our experience develops and we will continuously look to use the minimal number of mice that provide robust experimental data adhering to standards of experimental reporting laid out in the Arrive 2.0 guidelines. In our publications we endeavour to fully report our data adhering to these guidelines to ensure experimental transparency and ensure that experiments do not need to be further repeated due to any ambiguities in their interpretation.

While our experimental models are all established and optimised, we will likely test new reagents in targeting pathways that might regulate T cell function. When this occurs, we will use small scale pilot experiments (n=3) to first test the novel reagent. Furthermore, through many years of active collaboration with industry, we typically acquire reagents from these collaborators (e.g. blocking antibodies for in vivo). This ensures numbers of mice used can be kept to a minimum as these items have been extensively validated previously and we adhere to the recommended dosing regimen in our pilot study, ensuring less animals need to be used in establishing the experimental setup in our models. Furthermore, the purity of these reagents is often substantially higher than what is provided through commercial sources ensuring less experimental variability and smaller group sizes.

Over many years of supervising my own mouse colonies, I have developed extensive experience in efficient breeding strategies. A key approach in our experimental models is that through tracking endogenous antigen-specific responses, the data is highly consistent between experiments (rather than in models where TCR transgenic T cells are transferred for example). This means that data from different experiments can be pooled to reach the desired number of mice per experimental group. Therefore we use mice as they become available, rather than trying to generate large cohorts and this is a considerably more efficient means of breeding the mice with less mice generated and not used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In all of our experiments we use mice to study the immune response to cancer and in most experiments we only use genetically modified mice. We have selected genetically modified mouse models that enable either dynamic labelling of tissues, to better inform of immune cell behaviour or models that provide further insight into specific mechanisms.

For example:

We use Photoconvertible mice as host for tumours and then violet light to label specific tissue (e.g. the tumour, the draining lymph node) to track cell migration in vivo and changes in cell phenotype and function in a given site. We have refined these approaches such that the adverse effects are kept to an absolute minimum (e.g. subcutaneous labelling rather than surgical exposure of the tissue to be labelled).

We utilise primary tumour models where the cancer grows either under the skin on the flank, in the mammary fat pad or in the wall of the colon. Here the tumour causes minimal adverse effects to the host and its growth can be easily monitored. This ensures that the tumours do not grow too large, which can potentially cause further adverse effects.

The tumour models used (mostly cell lines) express molecules that help refine our analysis and reduce experimental variation, thus maximising the detailed information generated.

We will use in vivo imaging (IVIS) of mice with tumours to ensure that we can monitor tumour growth. This is a non-invasive approach that can carefully monitor the size of cancers even when within tissues (e.g. lung, colon).

Why can’t you use animals that are less sentient?

Mice are the least sentient animal species we can use to study the anti-tumour response and inform human treatment as the cellular components of the immune system known to be key to the response to cancer, alongside tissues that control the response (lymph nodes) are present only in mammals (i.e. not, for example, fish). Our experiments further exploit the genetic modifications available in mice to maximise the detailed functional questions we can ask to provide critical new insight of relevance to human patients with cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have extensively refined our experimental approaches over the last PPL and continue to review our methodology. We have consistently worked with staff in the animal facility to refine experiments and will continue to seek their advice on this project. We have reduced the need for surgical interventions through developing ways that label cells without the need to expose the target tissue. Model refinement is an active and continual process that requires careful consideration of all stages of the experiments. This ethos is instilled within researchers in my lab.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All the researchers in my group are aware of the revised Arrive 2.0 Guidelines developed by the NC3Rs and recently published. We have consistently endeavoured to publish our research to the original ARRIVE standards and will continue to maintain this publication standard to ensure experimental transparency and reproducibility. In planning our experiments, we work to the PREPARE and LASA guidelines. This is taught to members of the lab when they arrive and actively discussed as researcher learn how to plan and then conduct in vivo experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Within our lab we continuously scrutinise the literature for experimental advances that might enable further refinement of our models, reduction in the number of mice used or ways to entirely replace in vivo experimentation. All members of the lab are actively encouraged to engage with this. We also engage with presentations and symposia organised by the animal facility and the NC3Rs and receive their emailed news updates. Both I and members of my lab have presented in 3Rs themed sessions, highlighting experimental refinements we have developed to try to benefit other research groups.

194. Understanding brain circuits in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neurodegeneration, Brain circuits, Epilepsy, Dementia, Drugs

Animal types	Life stages
Mice	adult, aged, juvenile, neonate, pregnant
Rats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to advance our understanding of how brain cells function normally and how their properties are changed in different neurological diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.
Why is it important to undertake this work?

Diseases of the brain including abnormalities in development (causing schizophrenia and autism) and also changes related to ageing (causing dementia) are still poorly understood. The research outlined in this proposal aims to further our understanding of both brain function during normal ageing, but also changes in brain activity in disease models. In particular diseases such as epilepsy, schizophrenia and different forms of dementia, are all related to changes in specific brain regions or brain cells. In order to find novel therapeutic treatments that could slow down, or even halt changes or loss of brain cells linked to these

conditions, we need a better understanding of the brain circuits involved.

What outputs do you think you will see at the end of this project?

The outputs of this work will include new information to share with the scientific community. The results from this work will be presented at meetings and also in peer reviewed journals.

Who or what will benefit from these outputs, and how?

Our results could inform the work of other scientists involved in research in the field and other related fields. Work published during the project could, therefore, have immediate benefit to the scientific community during the course of the project.

The results will also be of interest to pharmaceutical companies who are continuously developing novel approaches to treat different neurological conditions. In the group we work closely with pharmaceutical companies who will be interested in our results and data may inform the development of new projects which could be started during the course of this current licence.

In the longer term the results of this work will contribute to our growing understanding of the changes occurring in the brain in a range of diseases and will aid in the development of novel treatment approaches that could be moved into human clinical trials.

How will you look to maximise the outputs of this work?

I will publish the work conducted during this project in high impact journals; I engage with many collaborators both internally and in other Universities around the UK, Europe, USA, and Australia and have several joint publications with these collaborators; I have industrial links with large international pharmaceutical companies and have received funding both in the past and currently for our research. Some work may involve testing novel treatments that could ultimately move into clinical trials. Work from the lab will also be presented regularly at key scientific conferences both nationally and internationally.

I also have a long and successful track record in public engagement projects funded by Wellcome including art and theatre projects informing the public about schizophrenia and epilepsy which have reached large public audiences and resulted in appearances on BBC Radio 3 and Radio 4.

Species and numbers of animals expected to be used

- Mice: 6760
- Rats: 3760

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Adult rats and mice will be used in this project as these animals have been widely studied

and there is a large body of information concerning their anatomy and physiology that is already very well established. The brains of rats and mice contain all the same types of brain cells that are present in the human brain, and both rodent species generate patterns of brain activity in vivo that are similar to those observed in humans. The molecular mechanisms that contribute to brain communication are also very similar in all mammals.

The project will use rats and mice of all ages and both sexes. We are interested in studying changes in the brain in relation to both normal ageing, and also disease models of dementia such as Alzheimer's disease and Lewy body disease. We will therefore use rats and mice across the lifespan of the animals so we can follow both healthy ageing and disease progression.

Typically, what will be done to an animal used in your project?

The vast majority of the work on the project involves taking brain tissue for studies of brain cell activity in slices of brain tissue or for anatomical studies. For these experiments the animals are killed by terminal anaesthesia and the brain is then removed. It is possible to keep small sections of this brain tissue alive for a few hours and record activity of brain cells. In many cases no interventions will have occurred in the animals prior to tissue harvesting. Some animals may have undergone an intervention, e.g. a pharmacological treatment, given either by injection, or where possible in the drinking water or the animal may have undergone cognitive testing.

Some of the rodents used will have surgery for the implantation of brain recording devices. This is now a well-established technique and animals are then free to move freely in the home cages and eat and sleep while recordings of brain activity are conducted in awake animals. Such data gives us a true insight into normal brain activity and can be directly related to human EEG recordings. Implantation is done under general anaesthesia and there is close and careful monitoring (using score sheets) of the animals post-operatively to ensure there are no complications.

Some animals on this project will be used to study a neurological disease such as epilepsy and may, therefore, have had a drug injected into the brain to generate the abnormal activity associated with epilepsy. The injection is again done under general anaesthesia with close and careful monitoring of animals post-operatively. The techniques used have been developed so that animals typically have only very mild seizure activity, for example, twitching or freezing behaviour. We can then assess how epilepsy affects cognition and brain circuits and function and test novel therapies aimed at stopping seizure activity.

What are the expected impacts and/or adverse effects for the animals during your project?

Discomfort from the surgical implantation of the electrodes is expected immediately post-operatively but animals are administered pain relief for 1-2 days or as deemed necessary by veterinary advice.
Thereafter animals continue to thrive for months with the electrodes in place, just as in humans with deep brain stimulating electrodes implanted in the brain, who are able to continue with their lives.

Some animals in which seizures have been induced will have a change in behaviour during the seizures which can include facial twitching or freezing but in most cases these are transient (a few seconds) and not severe. Animals are monitored daily to ensure that

the seizures do not become too severe using a prepared score sheet. If seizures do become severe animals will be used immediately in other protocols or killed by Schedule 1.

Some of the transgenic mouse models of neurodegeneration that are used on the study develop Parkinson-like symptoms when very old e.g. tremor and rigidity, but animals in this project are usually used at an age before these symptoms occur. Again daily monitoring ensures the animals do not develop severe motor dysfunction symptoms.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

A lot of work is non-recovery ~50-60%.

Drug treatment protocols are moderate (~15%).

Surgical electrode implantation studies are moderate (~25%). Epilepsy models are moderate (10%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We cannot model the impact of novel treatments, for example, treatments to stop brain seizures in epilepsy without using animals. We need to assess the impact of interventions on cognitive function and network activity in the intact brain and this is only possible in either the whole animal of slices of living brain tissue. Some background studies can be performed in vitro in networks of living brain cells so reducing the number of animals needed for in vivo research.

Which non-animal alternatives did you consider for use in this project?

We work closely with computer modelling experts and modelling can help reduce the number of experiments but they cannot replace the use of live brain tissue.

In the lab we also use human tissue, taken from patients undergoing neurosurgical removal of brain tissue, for example, to gain access to a deep brain tumour. This data is highly valuable and allows us to validate our key findings from the rodents in human cortical tissue but it cannot replace all animal work.

Why were they not suitable?

Computer models rely on real data to generate the model so results from experiments are needed to input to the model. Computers do not work like the human brain as, obviously, they do not have brain cells nor any of the chemicals and molecules in the brain that effect function. We will not be able to understand how brain circuits function, for example, to consolidate memories using just a computer. However, we can test some predictions in a model and so reduce the number of experiments performed in animals.

The human samples we have access to are limited in number and come from patients who have severe disease (brain tumour) and who may have been on a range of medications. Furthermore, while very important this tissue is not normal control tissue.

Some manipulations such as controlling brain cells to stop epilepsy are in the early stages of development and need to be proven to work in animal models before any clinical trials in humans can be considered or would be approved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on previous experience and those used on the current licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant. We perform pilot studies to test potential efficacy of a treatment or to obtain numbers for power calculations prior to a larger study.

Animals are used in a manner that maximises the data from one animal. For example, cognitive testing can be performed in an animal, then studies of brain cell activity and morphology can all be conducted using the same animal. Tissue can be obtained from multiple brain regions, and many different morphological studies can be conducted in a single animal, thus reducing the number of animals needed for any study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All transgenic animals from models of neurodegeneration bred in house are used for studies. We do not waste any animals. We use all male and female mice as comparing data from both sexes is important. In addition, heterozygous and homozygous animals are used for our main transgenic lines.

We collaborate and have published for over 20 years with network modelling researchers and we share our data with them. We will provide data to open access online resources which can then be shared by many other scientists in the field thus reducing the need for

others to conduct experiments.

We share other organs of the body (e.g. liver and heart) with collaborators both in internally and elsewhere in the UK and provide them with fresh or fixed tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We obtain the maximum information from tissue that has been obtained from an animal killed with terminal anaesthesia. In addition, other experiments can be conducted under terminal anaesthesia where we can record brain activity for several hours. This greatly reduces the number of animals that are used for other awake behaving in vivo procedures. All the procedures in this project are classified as non-recovery, mild or moderate.

We have spent some considerable time working with the vets to develop surgical procedures that ensure minimal adverse effects. All surgeries are performed in the operating theatres under sterile conditions thus reducing the risk of post-operative infections. The surgery performed has been refined so that it can be performed quickly, reducing the time the animal spends under anaesthesia and thus speeding post-operative recovery. Design of the implants has meant minimal post-operative complications, such as failure for the wound to heal or the implant becoming detached.

The model of epilepsy chosen to use normally causes very modest seizure activity and most animals experience only mild symptoms of freezing or starring behaviour.

Why can’t you use animals that are less sentient?

We are studying brain activity in normal health and disease and, therefore, need to use an animal model that contains all the same brain cells as are present in humans. Rats and mice have the same types of brain regions, the same brain cells, and the chemistry and molecular properties of these brain cells are similar to humans. As outlined above we do as much of the research as possible using animals that have been terminally anaesthetised but if we want to understand, for example, how a treatment may stop an animal from having an epileptic seizure, we need to have an awake-behaving animal to assess this.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have, as outlined above, refined our surgery by developing small head implants that are fitted easily. Surgeries are all performed in the sterile operating theatres and we have check lists for daily monitoring of animal welfare post-operatively. We are in continuous discussion with the veterinary staff to consider ongoing refinements to the techniques

used.

For mouse breeding we try to use all mice, including heterozygous and wild type of both sexes so no animals are unnecessarily culled if possible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow ARRIVE guidelines and continually look for ways to improve experiment reliability and thus reduce the numbers of animals we need to use. For example, we are looking at ways to randomise animal group selection and for experimenters to be blinded to the animal group. As discussed below it is not always practical for the experimenter to be blinded but where possible this will be implemented.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continuously develop and refine our approaches throughout the duration of a study in discussion with the veterinary staff. There are seminars, regular leaflets etc. from our animal facility that also help inform us of new developments and the NC3Rs website.

195. Translational pharmacology for drug discovery

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Neurological, Central Nervous System, Pain, Inflammation, Translational

Animal types	Life stages
Mice	adult, neonate, embryo, juvenile, pregnant
Rats	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project are to continue our efforts to facilitate and optimise the advancement of potential new medicines being developed by other drug discovery scientists (e.g. pharmaceutical & biotechnology companies, academic institutes) for neurological disorders, pain and inflammation. This project will provide evidence from pre-clinical rodent models of the likely therapeutic benefit in the clinic, including determination of the dosage required to produce such benefits and potentially the type of patient and clinical outcomes most suited to the new treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could

be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The societal burden of neurological disorders, chronic pain and inflammation are enormous. For example, the global opioid crisis resulted largely from the lack of appropriate treatments for chronic pain, schizophrenia is a lifelong condition with an onset in adolescence, and in the UK in 2018, dementia (including Alzheimer's disease) was the leading cause of death in women.

Pre-clinical data produced by this project will help identify the best new drugs/therapies for progression into human clinical trials, and potentially reduce the failure rate currently observed in the clinic.

What outputs do you think you will see at the end of this project?

The studies performed under this licence will contribute to the understanding of disease areas previously mentioned that have a clinical unmet need.

We aim to have a better understanding of the science in these disease areas, to develop new disease models/technologies that are highly translational to the human conditions. This will facilitate the development of new medicines/therapies that progress into human clinical trials, and benefit the patient population.

Where significant results are not subject to confidentially agreements they will be communicated more widely at scientific meetings or published (Publications/abstracts).

Who or what will benefit from these outputs, and how?

Throughout the duration of the licence, Short term - Pharmaceutical, Biotechnology companies and academic institutes will receive data allowing them to make decisions on progression of potential drug candidates/treatments to enhance the likelihood of success in the clinic.

Medium term - Will help Pharmaceutical, Biotechnology companies and academic institutes expand their knowledge around programs of work and potential candidates, including the effectiveness of potential medicines in disease area of interest, the mechanisms by which these treatments work, and potential adverse side-effects. This knowledge can be used focus research on the chemical structures most likely to benefit patients, and to halt animal testing of compounds which are unfit for progression. By halting the progression of compounds early will potentially lead to a reduction in the number of animals being used.

Long term - We aim to broaden the understanding of the mechanism of the disease modifying targets and aid the development of treatments that will improve the quality of life for the patients and carers.

How will you look to maximise the outputs of this work?
We will work both independently and with clients/collaborators to publish our findings/knowledge gain throughout the duration of the licence. We will disseminate findings by publications at industry conferences, via publications in the literature and via publication of online posters.

Species and numbers of animals expected to be used

- Mice: 36000
- Rats: 38000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Most of the animals used under this licence will be adult rats and mice (Including genetically altered animals), some animals may be juvenile, where they are required to be around 5-6 weeks of age, lower in weight range to animals over 7 weeks of age, where this will impact the study readout.

Genetically modified animals will be used because of human specific targets and disease specific mechanisms. Some genetically modified mice will be humanely killed as new-borns where tissues are required for cell culture, in order to be used for testing in non animal models and thus reducing the number of live animals used down the line.

Aged animals may also be used where we are investigating diseases strongly associated with the older patient population, such as cognitive/memory disorders.

Rats are widely used to provide data in drug discovery because there is a large body of data describing some of the similarities and differences between rat and human physiology.

Mice are used sometimes in situations where antibodies optimised for use in human, work via the target in the mouse but not in the rat. Also, because genetically altered animal models of human disease mechanisms are most commonly produced in mice.

Typically, what will be done to an animal used in your project?

Experiments/studies requiring surgery

Animals will be anesthetised and surgically prepared (area of incision cleaned/made sterile to reduce chances of infection) for the appropriate model such as by implanting electrodes/transmitters/transmitters onto specific brain regions to enable recordings of brain patterns or implanting a cannula into specific regions of the brain for administration of test substances, or a disturbance/trauma to a nerve for induced models for pain. Animals will be allowed sufficient time for recovery dependent on the surgical procedure performed. Animals will typically be treated with test treatments, either under the skin, into the abdomen or directly into the stomach and subjected to behavioural testing in response to a stimulus (such as mechanical or thermal), or to more natural behaviours (such as Burrowing or nest building).

Non surgical models/assays (Pain)

Animals will be assessed for behavioural response to a stimulus (such as mechanical or thermal), or to more naturalistic natural behaviours (such as Burrowing or nest building). Animals will typically receive some form of pain insult (either by an injection into the paw or sometimes the abdomen) causing a swollen or sensitive paw, they will then be treated with test treatments which maybe a single or repeated dose either under the skin, into the abdomen or directly into the stomach and re assessed for the behavioural measures.

Non surgical models/assays (Epilepsy)

Animals will typically be treated with test treatments which maybe a single or repeated dose either under the skin, into the abdomen or directly into the stomach. Animals will then be subject to either some form of electrical or chemical stimulus to cause seizure activity that is measured. Electrical stimulus is typically very brief (0.3-3 seconds) and the response/end point is very quick (10-20 seconds). Chemical stimulus is typically via single or repeated dose either under the skin, in to the abdomen and animals observed for a period of time, typically between 30 mins and 2 hours.

Non surgical models/assays (PK/PD or cognition)

Animals will typically be treated with test treatments which maybe a single or repeated dose either under the skin, into the abdomen or directly into the stomach. Animals will then be assessed for behavioural measures, either in a home cage or observation box for visual observations, or using an automated system designed to measure and record many behaviours such as general movement, grooming, rearing, circling, eating and drinking, behaviours may also be assessed using a rotating wheel, to look at effects of balance or sedation.

What are the expected impacts and/or adverse effects for the animals during your project?

Some level of pain is inevitable for evaluating test treatments in models of inflammatory and Neuropathic pain, but these are kept to a minimum and typically do not cause other changes in the welfare of the animals. For example food and water intake are normal, animals grow at the normal rate and the general health and behaviour of the animal is unaffected. Some animals show slight initial weight loss, but are provided with addition food sources and are monitored carefully.

Some animals may show changes in behaviour, following treatment with pharmacological agents to induce disease characteristics such as amphetamine induced activity, continuous stimulated movement.

Streptozotocin (STZ) induced neuropathy/nerve pain causes typical symptoms of diabetes, including increased thirst, increased urination, excessive sugar in the urine and high blood sugar levels. Therefore, animals will drink more than usual and this will be taken into consideration during the husbandry care. Post STZ injections, 2 % sucrose is added to the drinking water to avoid the initial drop in blood sugar levels, and animals will stay group housed to help maintain body temperatures.

With electroshock induced seizures, animals receive a single electrical current to the eyes or ears, to produce a clear seizure endpoint. After application of the current, animals may or may not achieve a generalised seizure, but are all killed within 10 seconds to minimise any suffering.

With chemical induced seizures, animals typically receive a single injection to induce seizure activity, depending on the disease model that it is mimicking, this may last for a short period of two minutes or for longer periods on 2-3 hours dependent on the model. Animals will be monitored at all times post dosing and are humanely killed when reaching the specified endpoints (seizure level) or at the end of the observation period.

With animals that have had electrodes surgically implanted into areas of the brain (EEG), some animals may have small swellings in the abdominal area post surgery, which typically show no sign of infection, discomfort or pain and normally resolves without intervention within 1 week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 10% Sub threshold/non recovery
20% Mild
70% Moderate

Rat: 10% Sub threshold/non recovery
20% Mild
70% Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tissue or cell-based assays cannot replicate the impact of potential therapies in whole organisms, especially for the neurological conditions. For example, drugs destined for human treatment are usually given systemically (oral or by injection) rather than by direct application to the brain, and therefore they must survive digestive or metabolic processes and cross the blood brain barrier before having the desired effect.

The complexity of the mammalian brain cannot be overstated, and there are no computer simulations which even come close to mimicking that complexity, though they are useful for generating novel ways of thinking about problems in neuroscience. Human or animal tissue preparations can provide useful information at a molecular level (e.g. drug binding to a receptor of interest), and cell cultures can also be useful, but are also highly artificial, as the cells are grown outside their normal environment and without any connectivity with other parts of the brain. Whilst this information helps understand what a drug might do in an isolated preparation, research in a whole animal is still required.

No cell-based systems are in existence that can replicate the whole functioning organism.

A range of chronic diseases/disorders are covered by this licence, including cognitive deficits associated with Alzheimer's Disease, a range of pain and inflammatory conditions (Osteoarthritis/Rheumatoid arthritis), Neuropathic conditions (nerve damage, diabetes and chemotherapy induced neuropathy) and various forms of epilepsy. These are all conditions where the whole organism (i.e. intact nervous system) is required in order to measure a cognitive/painful/seizure response.

Which non-animal alternatives did you consider for use in this project?

The overarching aim of this project is, specifically, to provide animal research services for studies where this is most appropriate. For this reason, consideration of non-animal alternatives is beyond our remit. The particular scientific questions we seek to answer are driven by our client needs, and before any work is undertaken we confirm that a minimal level of non-animal research has already been conducted to establish that the compounds are safe for use and should, in principal, have the desired effect. Beyond this, our work addresses questions which, by their very nature, cannot be answered using non-animal alternatives. In short, we are providing services which tackle the next stage of the development of medicines, after non-animal research has provided as much information as possible.

Why were they not suitable?

There are no non animal alternatives that can currently replicate the complexity of the mammalian body. Whilst all the non animal experiments provide information that helps understand what a drug might do in an isolated preparation, research in a whole animal is still required. For example, even if a potential treatment for schizophrenia can be shown to activate the correct cell-type grown in culture, the effects in a whole-animal where those cells interact with the rest of the brain can be very different and unpredictable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Because this project is used to provide a service to clients, and the models/data that we are able to provide are extensively used the total numbers are reasonably high. I have estimated the number based of the total usage of animals in the previous project licence.

We have a large number of historical datasets which will guide our decisions about the number of animals required. Where we lack internal data we will refer to external datasets, published data and best practice and following on from initial small scale pilot studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For both rat and mouse studies, historical datasets and power-analysis will be used to ensure all studies maximise the chances of detecting the effects of the treatment, if those effects are present. In this way results, whether positive or negative, should be conclusive, minimising the necessity of repeating studies. We have access to a statistician when required and will continuously monitor group sizes and modify as appropriate.

Where possible, we will use a "Latin-square" crossover study design in which all animals receive all treatments, so that each animal can serve as its own control. This can dramatically reduce the number of animals required for confidence in the statistical analyses, but may not be possible for some protocols. Where possible, animals will be used for multiple studies (such as surgically prepared animals), within the defined limits specified in the licence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be used when designing new studies to ensure the minimum number are used with the minimal amount of suffering.

Best practice and good experimental design will always be used to ensure quality data and reduce the risk of studies needing to be repeated.

Where possible tissues will be collected from animals at the end of life and used for additional assays.

Animals will be bred for use in the project, to ensure that animals are available at the required age for use, this will potentially reduce the overall number of animals bred.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.
The models used in the project have been extensively used to identify candidate drug molecules and are the lowest severity that will allow decision making data to be obtained. These models are also selected based on their translational potential – for example, their face validity for human conditions.

Where pain models are used, the insult is kept to the minimum required to show a pain response, with suffering, distress and lasting harm kept to a minimum. For example, animals receiving nerve injury are placed onto an environmental enrichment protocol, where the enrichment is changed on a regular basis (approximately 2-3 days) with different objects/enrichment to help reduce the incidence of autotomy (toe chewing).

For all pain studies we will continue to encourage the use of spontaneous, non-evoked behaviours and non-invasive (natural) endpoints to reduce the pain and suffering

experienced by the animal such as weight bearing, burrowing and paw volume and any other naturalistic behaviours.

Various models of epilepsy will be used in the project to cover the various types and complex mechanisms in this disease area. Application of electrical current can be used to detect either pro- or anti-convulsant activity, and is therefore useful in detecting an increase in seizure susceptibility, a potential liability associated with several mechanistic approaches of therapeutic interest in this area.

Other models of epilepsy will also be used, such as chemical induced seizures. These models are well validated and doses will be kept to the lowest level required to induce the desired behaviours and to mimic the seizures and biochemical changes seen in human patients. All epilepsy models to be used also have humane endpoints to ensure minimal suffering.

Most models of schizophrenia, Neurodegeneration and cognition used for this project will be mild with minimal pain and suffering to the animal. Some models require administration of chemicals to induce a behavioural deficit similar to that of the condition of the patient such as effects on memory for Alzheimer's and social interaction for schizophrenia, with a non invasive endpoint, assessment of natural behaviours.

Why can’t you use animals that are less sentient?

In drug discovery, in order for an animal model of human disease to be considered valid, it must replicate key aspects of the disease. For neurological conditions this requires a certain degree of genetic and structural similarity. For example it would be pointless to measure hippocampal degeneration - a signpost of Alzheimer's disease - in a species that has no hippocampus. Decades of research have shown that, unlike birds, insects, fish and amphibians, the most ancient cortical structures in rats and mice bear a close anatomical similarity to humans and generate similar patterns of electrical activity. Moreover, almost every gene associated with human disease has an equivalent in rats and mice, making them ideal species for study.

All of our models typically involve a natural response/behaviour such as withdrawal to stimulus or assessment of exploratory behaviours which cannot be detected in an anaesthetised animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All surgical procedures will use aseptic techniques and allow full recovery after surgical procedures. All animals will be provided with sufficient pain relief and post operative care.

Where appropriate, animals will be habituated to environments, equipment and procedures to minimise stress and any lasting harm.

All animals will be provided with environmental enrichment where possible and will be socially housed where possible for the benefit to the animal provided that it does not interfere with the results/data from the studies.

Where possible non evoked/ natural behavioural endpoints will be used, such as burrowing, weight bearing, and behavioural observational scoring systems.

When new models/studies are being developed a small number of pilot studies will be performed to ensure the model delivers the expected results/responses. These will also be used to ensure that the animals experience minimum severity required to give the desired effects needed for the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to the Home Office and EU guidelines, relevant best practice guidance will be gained from NC3R's (Enrichment and handling techniques, experimental design), LASA (blood sampling volumes, dosing administration volumes, surgical techniques) and GOV.UK (ASRU). We can also use www.bps.org.uk/news-and-policy/new-bps-research-and-ethics-guidance

examples:
https://nc3rs.org.uk/rat-tail-vein-non-surgical, https://www.lasa.co.uk/wp-content/uploads/2018/05/LASA_BAP_BNA_ESSWAP_GP_Behavioural_LAS_Nov13.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to keep abreast of developments in animal welfare by attending scientific meetings, keeping up to date with current literature, attendance to AWERB meetings and maintaining an active member on the AWERB committee.

We will continue to work closely with the NACWO and NVS and seek advice on potential improvements that could be implemented.

We will continue to have an ongoing working relationship with the UK's NC3Rs and will continue to maintain those contacts in an effort to evolve our best practice.

196. Molecular and Cellular Mechanisms of Chronic Pain

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Pain and therapy, Somatosensation, Ion channels and receptors, Signalling, Metabolism

Animal types	Life stages
Mice	adult, neonate, juvenile, aged, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project are to understand how chronic pain is generated, transduced and maintained and reveal the molecules and cells crucial to these processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will significantly enhance our understanding of the fundamental events and processes underpinning different types of chronic pain. These mechanistic understanding will provide the rationale and foundations for developing more efficacious therapies for transforming the treatment of chronic pain, an unmet clinical need.

What outputs do you think you will see at the end of this project?

We will have a better understanding on how different types of chronic pain are generated and then be maintained for a longer period. We will uncover novel molecules and players

involved in these processes and clarify how they work together to bring about the outcome of chronic pain. This new information and knowledge will be published and made available to the general public, and have great potential to open up new therapeutic opportunities for a better treatment of debilitating chronic pain.

Who or what will benefit from these outputs, and how?

The general public and patients with chronic pain will benefit from the outputs. The research will enhance their understanding of chronic pain and the factors essential to the development of chronic pain. It will impact on pain management of the patients. For example, pain management through diet.

Pharmaceutical companies interested in analgesics development will also benefit from the outputs. We will reveal molecules that could be targeted for developing novel analgesics. We will also test and validate compounds that are effective for chronic pain. These compounds could be further explored for developing efficacious drugs for transforming pain therapy. We will show genetic manipulation of chronic pain which is feasible to be used for gene therapy. If an effective drug and/or a new way of gene therapy were developed based on our outputs, it will benefit millions of patients suffering form chronic pain.

How will you look to maximise the outputs of this work?

We will disseminate our outputs to the general public through science festival, public forum, contributions to magazine, our establishment webpage, press release and other social media. We will directly engage with the patients with chronic pain through one-to-one meeting and online meeting. We will also invite patients to attend our research meeting. Collaboration with our research partners will be another route to publicise our outputs. One of collaborator is a consultant at hospital. His direct link to the patients will facilitate our output dissemination.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult mouse, because: (1) mouse is the lowest organism that models complex diseases in humans and findings from mice are translatable to humans; (2) different types of chronic pain have been successfully reproduced and well-established in mice and pain behaviours in mouse are well characterized; (3) Mice are amenable to genetic manipulations and many gene knocks have been generated in mice and ready for use; (4) Mice are cost-effective and easier to breed and maintain; (4) Pain model and behaviours are more stable in adult mice.

Typically, what will be done to an animal used in your project?

We will generate different types of chronic pain models (e.g. neuropathic pain and inflammatory pain) in normal or genetically altered mice through injection of chemical compounds or surgical operations. A drug or genetic materials will then be delivered to the mice to intervene in the molecules and events crucial to the development of chronic pain. We will monitor pain behaviours of mice and compare pain behaviours before and after interventions. The experiments typically last for 4 weeks, but some will take up to 18 weeks, for example, for diabetic neuropathy.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will mostly experience a moderate level of pain and discomfort typically lasting for 4 weeks and may have reduced mobility and swelling in the paws or joints. Ob/ob mice will likely develop hypercalcaemia and chronic pain. Animals with surgical operations may develop wound infection and bleeding, though these are uncommon. Some animals may also have body weight loss but this should not reach over 20%.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity are mild or moderate. Animals used solely for breeding and control group will be subthreshold or mild severity accounting for about 30%. The remaining animals will be in moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The formation of pain involves collective actions of multiple body systems and numerous cells, many of which even remain unclear. Therefore, neither is it possible to synthesise pain *in vitro* nor possible to directly study pain on humans. Animals are the most practicable platform to achieve our research aims.

Which non-animal alternatives did you consider for use in this project?

We do combine use of immortalised cell lines expressing the molecules of interest to mimic conditions in animals and humans. We use these cultured cells *in vitro* to understand and predict the events and processes that occur in the animals. We will also use tissues from human patients after surgery on condition that ethical consent is approved.

Why were they not suitable?

Cultured cells and human tissues are instrumental in understanding the effects of a molecule or a process or event relevant to pain. However, they do not recapitulate the systemic or global effects of pain that results from pooled actions of millions of cells and numerous molecules and events, most of whom are even unknown, involved in chronic pain. Therefore, cultured cell models are not suitable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate animal numbers based on our current use and the ongoing and future projects that require to maintain 5-7 transgenic mouse lines. These mouse lines need to be crossed to generate novel tissues-specific deletion mutant mice which will then need to be expanded to produce numbers required for both behavioural and tissue research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use power analysis based on published data and previous experience to predict the minimal required number of animals. By using strict statistical prediction in experimental design, we have established optimal numbers of mice needed to reach the 5% significance level, thereby reducing the numbers of subjects used. To reduce experimental variability, littermates of transgenic animals will be used as controls. We will use unbiased experimental design (e.g. randomized block design, blinding) considering animal sex factor difference (we will use either sex of mice). Furthermore, we will use tissues from human patients rather than from animals, serving to further reduce use of animals to a minimal level.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use heterozygous mice to breed wild-type and gene knockout animals that will be further used for experiments. This breeding scheme makes the most of every genotype of animals, reducing unnecessary waste of animals. We will also carry out pilot experiments to determine the optimal operations, procedures and dug dose schemes before formal experiments. Good practise from the published resources will also be regularly sought to improve the consistence and reliability of our experiments, which should also help to reduce the number of animals to be used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime

of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use models of different types of chronic pain including inflammatory pain, chronic rheumatoid and osteoarthritis pain, nerve injury-induced neuropathic pain and peripheral neuropathy. These models are well-established in mice and in common use amongst other experimenters, which has the advantage that they have been well validated and are reliable, that pain is well-defined regarding the onset, progression and duration of pain, that they are known to cause minimum discomfort, and that the results we obtain will be readily comparable with the work of other labs. These advantage will maximise our research outputs meanwhile minimising suffering and distress to the animals.

Why can’t you use animals that are less sentient?

Pain is an alerting behaviour warning animals of dangers and threats in the environment. Therefore, pain requires alert actions of well-developed systems and consciousness. During immature life stage, the involved pain systems and the links between systems are not well developed and established. Pain behaviours therefore do not reflect and represent the actual processes in human pain and not useful for our research purpose, though animals may experience less pain at immature life stage. Indeed, there are reports showing that juvenile pain and adult pain utilise different mechanisms. Our research focusses on chronic pain which is more prevalent in adult and older people. Therefore, less sentient animals do not suit our research purpose. For the similar reason, terminally anaesthetised animals are not useful for our research, as pain does not manifest under anaesthetised condition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will closely monitor the general heath conditions of mice including body weight, feeding, drinking, walking and grooming after a procedure such as surgical operation and drug administration at a daily basis for the first 3 days. In the event of an animals displaying abnormal behaviour such as failure to move freely, feed, groom or socialise normally the affected animals will be closely observed and the NVS or NACWO will be consulted. We will further refine and improve the procedures based on our observations and advice of NVS or NACWO.

To recover anaesthetised animals in a procedure, animals will be put in a warm cage and closely monitored during recovery from anaesthesia and daily thereafter. Appropriate analgesics (e.g. NSAID) will be administered to the mice soon after surgery for the first 24 hours of post-surgery. All the pain behaviour tests will be carried out after sufficient habituation of animals aiming to reduce stress to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will observe the guidance on the operation of the Animals (Scientific Procedures) Act 1986 and the ARRIVE guidelines, and follow the LASA guidelines on dosing and surgery. We will also follow the principles of reducing harms and optimising benefit (Harm-Benefit analysis) throughout the conduct of animal research, making sure that our experiments

and procedures are well refined to the best of our knowledge.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To keep abreast of advances in the 3Rs, we will regularly discuss with our animal technicians and manager on potential improvements on our experimental procedures and practice and new development in this area. We will also learn new 3Rs approaches, tools and technologies through attending and watching related webinars and keeping an eye on the NC3Rs website and activities.

197. Immunobiology of leishmaniasis

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Leishmaniasis, Immune system, Myeloid cells, Vaccines, Immunotherapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

A key feature of leishmaniasis is the ability of the Leishmania parasite to spread within and between different tissues. This ability to disseminate underpins the pattern of clinical disease, but the mechanisms controlling dissemination are poorly understood. The aims of this project are to understand how Leishmania exploits the immune system to aid its dissemination (including in the presence of co-infections such as malaria), to identify pathways for intervention that limit clinical disease (immuno-therapy) and to further develop vaccine candidates for the treatment and prevention of leishmaniasis (including the conduct of pre-clinical studies supporting clinical trial authorisation).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Leishmaniasis is a globally important parasitic disease with approximately one billion people at risk of infection and over 1 million new cases and ~20,000 deaths reported each year. We currently have no vaccines licenced for use in humans to prevent or treat leishmaniasis. Current drugs have significant side effects and / or are poorly effective against many forms of leishmaniasis. Understanding how Leishmania parasites

disseminate in the body and finding ways to prevent this, using drugs and / or vaccines will lead to dramatic improvements in health and economic development in countries affected by leishmaniasis.

What outputs do you think you will see at the end of this project?

We expect the following outcomes:

publications in scientific journals and in publicly accessible reports that enhance the collective understanding of leishmaniasis by academics, clinicians and the public.

identification of mechanisms of parasite dissemination and interventions (drugs, vaccines) that inhibit this process, leading to reduction in disease prevalence and / or severity of clinical disease.

data supporting the further development of new vaccine candidates, vaccination strategies or immunotherapies into early phase clinical trials.

Who or what will benefit from these outputs, and how?

The benefits and beneficiaries include:

people living in countries with endemic leishmaniasis will have direct health and economic benefits if a preventative or therapeutic vaccine or other immuno-therapy is developed. Our work aims for registration of a new therapeutic vaccine within a 5 year time frame and a prophylactic vaccine within a 5-10 year time frame.

countries with endemic leishmaniasis will have increased prosperity due to improved health of the work force, with benefits seen over the 10-20 year time frame post implementation of a vaccine or new treatment. The scientific community will gain additional understanding of this disease and of immune mechanisms that may also operate in other infectious diseases. The benefits from new knowledge will be both short (12-24 months to first publication) and long (5 years +) term.

How will you look to maximise the outputs of this work?

The project is highly multidisciplinary and international. Animal studies are conducted in parallel with clinical research and clinical trials, allowing an iterative approach. Research collaborations exist in many countries where leishmaniasis is endemic. We have built infrastructure for efficient data sharing. We publish in open access journals and deposit manuscripts prior to publication in pre-print servers to facilitate rapid data exchange. Social media is used to rapidly disseminate key information. Patient and Public Involvement and Engagement is central to our work and will be extended.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents provide the best pre-clinical models to study parasite dissemination and the immune response during leishmaniasis. Mice are the preferred species due to the greater availability of immunological tools. Adult mice of either sex are used, with or without genetic modification or environmental conditioning (e.g. UV exposure; co-infection). Occasionally, young or old mice may be required to address specific questions related to immune system development and / or to assess vaccine or drug efficacy across the life-course.

Our work with mice is complemented by collaborative research on animals conducted outside the UK and with leishmaniasis patients, reflecting a "one health" approach to addressing the problem of leishmaniasis.

Typically, what will be done to an animal used in your project?

Typically animals in this project are used to understand more about the disease process caused by Leishmania parasites and to evaluate new vaccines and therapies. A typical animal (>70% of animals in the Project) might therefore receive five or six injections (of vaccines, drugs or cells) to manipulate its immune system and receive a single injection to establish a Leishmania infection. Alternatively, infection may be established through the bite of Leishmania-infected sand flies. The infection and immune response would be monitored for four – eight weeks by taking a small blood sample every week or by using a special camera to quantify the number of parasites present. No overt signs of disease or changes in behaviour are expected over this time period. After four to eight weeks, the animal would be killed to recover parasites and immune cells for further study. Allowing uninfected sand flies to take a blood meal (one millionth of a litre each) from some animals (<5% of those in the Project) whilst they are anaesthetised is an important way to find out if drugs and vaccines can stop transmission of parasites.

Other procedures or combinations of procedures may be used on some animals. In complex experiments, animals may have a small microchip inserted under the skin to aid identification. <5% of animals in the Project may be co-infected with different parasites or bacteria that also co-infect humans with leishmaniasis and affect immune response. Other animals (<5% of those in the Project) may be exposed to irradiation and have their immune system replaced by a bone marrow transplant. This procedure lasts a few minutes and is usually performed 8-10 weeks prior to infection. Some animals (<10% of those in the Project) will be used to maintain infective stocks of the parasites under study. These experiments last several months, but again without overt clinical signs or impact on the animal behaviour. Some animals (<10% of those in the Project) are used to provide normal blood or tissue (e.g. for in vitro work) and are used without manipulation or within days of an injection.

Experiments are terminated by a humane method of killing. This may be preceded by imaging of tissues exposed by surgery of by using a simple technique called “microdialysis” that allows sampling of body fluids over a few hours.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals used in this project show no outward signs of distress or suffering. Injections produce mild discomfort and some stress associated with handling. Sand fly

bites may cause a minor transient inflammation at the bite site that resolves over a few days. Anaesthesia is used for restraint where needed and recovery from anaesthesia occurs within minutes. Irradiation and bone marrow transplantation produces no overt clinical signs. Infections are always terminated before any severe symptoms occur and in most cases before any clinical symptoms occur. Weight loss can occur over a period of several weeks but will not exceed 20% body weight and in most cases is negligible. Animals show no abnormal behaviour because of the infections, drugs, cells or other substances administered. Cutaneous leishmaniasis causes skin lesions at the site of injection (or sand fly bite) that develop over several weeks, but these do not impede normal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Infections with Leishmania and other pathogens is "moderate" (40%) All other procedures are “mild” (60%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our research on parasite dissemination requires studies to be performed in the context of complex tissues linked by a circulatory system of lymphatics and blood vessels. This complexity cannot be recapitulated in organ culture or other in vitro systems.

Pre-clinical data supporting immunogenicity and / or efficacy of vaccines and immunotherapies using animal models of disease is required by regulatory authorities prior to clinical trial authorisation. There are no substitutes to conducting vaccination / therapy studies in intact sentient animals due to the complexity of the host pathogen interaction and the dynamic nature of the host immune response. In vitro culture models and mathematical models are not sufficiently advanced to provide data sufficient to support regulatory submissions.

Which non-animal alternatives did you consider for use in this project?

We have an active research program exploiting using mathematical and computational models and these inform some aspects of our work.

We continue to explore new types of organ and in vitro models as they are developed.

We use existing high dimensional data sets in the public domain to supplement, compare with and add value to our data, minimising repetition of experiments conducted by others.

Why were they not suitable?

These approaches fail to provide the appropriate context for understanding parasite dissemination and / or for supporting requests for clinical trial authorisation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimates of animal usage are based on consideration of the scope and duration of funded work, staff workload, balance of experimental and analysis time and the need to ensure adequate training and research planning.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In vaccine studies, we normally only study candidate antigens or delivery systems well advanced in pre-clinical development, using antigen delivery platforms with established safety data in man and applicability to developing country use. Most drugs we study are clinically approved and available for re-purposing.

We use the NC3Rs EDA, coupled with statistical analysis using InVivoStat software and /or additional packages in R. to ensure appropriate and minimal numbers of mice are used to generate statistically meaningful results. Local statistical advice is also available.

Tissues collected from animals used in in past experiments may be used in new experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We reduce breeding of genetically-altered and / or mutant strains by careful planning of experiments, tissue / cell banking (creating a curated tissue bank for cross reference and future analysis) and through high density data collection (e.g. through imaging and omics approaches). Material from our tissue banks may be made available to other investigators for independent studies on inflammation and immunity.
Whole body non-invasive imaging is used to generate longitudinal data from small cohorts of mice and other imaging techniques allow cells rather than mice to become the experimental unit (reducing animal numbers required for statistical analysis).

Data are used to develop mathematical models which can be used to inform on experimental design.

Experiments are often conducted in parallel to allow re-use of tissues / cells between experiments, reducing the number of mice needed only to supply tissues and cells.

Our active research into human disease allows us to restrict animal studies to those questions of direct translational relevance

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are most-commonly used as the lowest mammalian species in which the various infection models used in this Project can be studied. Mice also provide the opportunity to learn the mechanistic basis of host protection and pathology in a way unrivalled by other models.

Most studies will use standard strains of mice to understand parasite dissemination and the host immune response to infection. Leishmaniasis is not usually lethal in mice, reducing the possibility of severe outcomes compared to other rodent models.

A rigidly enforced health policy exists in the animal facility, including screening for additional bacterial pathogens beyond standard guidelines. Any changes in breeding success, animal behaviour or any unexpected deaths are rigorously investigated.

We minimise pain suffering and distress by early termination of most infection experiments, for example before significant hepatosplenomegaly or cutaneous lesions develop. Strict adherence to the use of appropriate humane endpoints and adverse event scoring will be observed. We restrict the total number of injections and anaesthesia sessions per animal as advised by the NVS.

Any animal showing behaviour that is unexpected will be killed by a schedule 1 method and examined post-mortem and the NACWO and NVS are informed.

Fluorochrome-expressing genetically-altered mice are used to minimise the need for additional animals to provide populations of cells for studying cell trafficking.

Any surgical techniques are practiced on dead animals until competency is achieved and then pilot studies are conducted under NVS supervision.

Based on previous experience we have developed new protocols to minimise animal use in maintain sand flies and conducting infectious challenge experiments

To ensure minimal UV damage to skin, we use advanced instruments to monitor redness and changes to skin structure.

Why can’t you use animals that are less sentient?

The mouse is the lowest sentient mammalian species for the study of Leishmania parasites. Leishmania can infected macrophages from zebrafish but this is not a realistic model of infection in vivo given differences in the circulatory systems, tissue organisation and immune response. Lower vertebrate species are not infected with species of Leishmania that infect humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We adhere to the rolling program of advances in husbandry introduced by the animal facility e.g. implementation of environmental enrichment, changes in handling methods and changes in the policy regarding re-use of needles.

Increased monitoring of animals under procedure is being introduced to minimise any adverse events e.g. during long term parasite passage in immunodeficient mice.
Body score conditioning sheets and grimace scoring will be used to monitor the condition of animals, where appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow ARRIVE2 guidelines for reporting of experimental results. The NC3Rs EDA and associated webinars and publications are used to ensure robust experimental design (in conjunction with "The Design and Statistical Analysis of Animal Experiments; Bate and Clark (2014)"

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly consider and follow new approaches in experimental design, new technical innovations that may reduce animal usage or increase data acquisition / robustness and ethical issues related to animal research. Where appropriate, amendments will be sought to introduce or pilot new techniques scoped from the NC3Rs website or elsewhere. Regular lab meetings and investigator meetings (e.g. Animal Facility Users' meetings) provide a forum for discussion and implementation.

198. Cell-cell adhesion signalling in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

retina, vasculature, aging, inflammation, diabetes

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Cells in endothelia and epithelia are joined by adhesion complexes that regulate how these tissues function and form barriers that separate different compartments such as the blood from the surrounding tissue. Our aims are to elucidate how adhesion complexes are deregulated in disease and to establish new therapeutic methods exploiting such knowledge.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?
Cells in epithelial and endothelial tissues are joined to each other by intercellular adhesion complexes. One of these complexes is called tight junction (TJ). TJ are essential for

epithelial and endothelial barrier formation. They also signal to the cells to guide cell behaviour and function.
Pathological processes affecting endothelial and epithelial cells in the retina are the major causes of blindness in the developed world. Visual impairment has major consequences for the quality of life of the affected individuals and represents a significant burden to society. Our research on TJ functions in ocular endothelial and epithelial cells in mouse models thus addresses a major clinical need.

Controlling inflammation and aging are a major emphasis of our research. Inflammatory and aging diseases affecting the eye are very common and mechanistically related inflammatory diseases affect other organs such as lung, liver and intestine. The socioeconomic costs of such diseases are considerable and there remains a real need for developing new therapies. Our programme to understand the role of TJ proteins, to identify specific ways to regulate TJ functions, and to test specific inhibitors for TJ associated proteins such GEF-H1 will directly address this need.

Therefore, the work to be undertaken is important as it will enable us to understand the functions of TJ components in health and disease, and it will support the development of new therapeutic approaches to treat wide-spread and debilitating diseases and, thereby, addressing a clinical need.

What outputs do you think you will see at the end of this project?

Outputs will include information about how cell-cell adhesion and tissue barrier formation is coordinated by TJ proteins during development, adult aging and pathological stress conditions. This is needed to understand the basic mechanisms of how aging and diseases such as diabetes impact on the retina. Such new information will be published in research papers. We will also test new therapeutic approaches. This will lead to outputs in the form of information on how to apply such new therapies and on the potential of particular therapeutics. Such information will also lead to publications but will also provide the basis of clinical trials to test such therapies and associated therapeutics in humans. Hence, the information expected will contribute to the development of new therapies and new products to be used in such therapies.

Who or what will benefit from these outputs, and how?

The generation of new knowledge and the development of new therapeutic approaches will benefit scientists and clinicians in academia and industry who work on the development of new therapies, as well as patients who need improved and more effective therapies.

The benefit on other scientists and clinicians will be more immediate as the expected output will directly impact on their work. The expected information will help them to design new therapeutic strategies to be tested first in the laboratory. Information about new therapeutics and the compounds themselves will help clinicians to design clinical trials to test them in humans.

In the longer term, the outcomes are expected to benefit patients and society as a whole. The new therapeutics by leading to better treatments will impact on patients health, which, in turn, will reduce socioeconomic costs.

How will you look to maximise the outputs of this work?

This project will investigate the physiological and pathological relevance of molecular mechanisms by which TJs regulate epithelial and endothelial tissue functions as well as their role in disease initiation and progression during inflammatory, aging and degenerative conditions. We will also develop new therapeutics.

To maximise the outputs we will

disseminate our results in publications, meetings and workshops to reach other scientists and clinicians;

build on and further extend collaborations with clinical colleagues to accelerate the development of clinical applications based on our research and expected products;

seek advice and support for Intellectual Property (IP) and commercial development, which will support funding of follow-up research;

and engage with the general public and patients to inform them about new research developments pointing to new therapies and for a consultation to support the design of new clinical approaches.

Our approach is built on extensive (in a test tube or elsewhere outside a living organism) in vitro work that we have performed during the last 20 years using different types of cultured cell models that have allowed us to identify the most promising molecular targets. However, it is possible that mechanisms identified in vitro are of lesser importance in vivo (in a living organism). It will thus be important to disseminate positive as well as negative results.

Species and numbers of animals expected to be used

- Mice: 6000
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project is built on extensive in vitro work on the structure and function of TJ in epithelial and endothelial cells that has been performed in the past and that will be continued to complement and support the in vivo experiments. The data and insights gained from those in vitro studies are providing the necessary knowledge base to design meaningful in vivo studies in order to establish the functional relevance of TJ-associated signalling mechanisms in normal development and clinically relevant animal disease models, as well as to determine the potential of therapeutics targeting such signalling protein.

We will make use of well-established and validated mouse and rat disease models for which we have experienced collaborators within UCL and elsewhere who can advise on experimental design and animal manipulations. This will allow us to base our studies on

years of experience that have led to refined protocols that enable the collection of meaningful results with as few animals as possible.
Moreover, we will be able to compare our results with the existing literature to support conclusions about the importance of our findings.

The mouse and rat disease models (neonatal, juvenile, adult) have been refined to understand human diseases. These will be used to determine the effectiveness of therapeutics that we have developed in in vitro experiments to attenuate tissue inflammation and degeneration due to conditions such as diabetes, or age-related and inherited forms of retinal degeneration. We will further employ genetic mouse models (embryonic, neonatal, juvenile, adult) deficient in specific junctional proteins to determine how far their associated signalling mechanisms are important for development and tissue maintenance, and how they interact with disease pathways. The use of animals at different life stages is important as analysis of developmental defects will require adult and neonatal animals, and the disease models are based on juvenile and adult animals.

Typically, what will be done to an animal used in your project?

Wild type and genetically altered animals that are deficient or conditionally deficient in specific genes encoding TJ components to be studied will be bred using protocol 1 and 8. These mice will then be studied using protocols 2 to 9. We will also purchase and maintain wild type rats and strains with naturally occurring mutations that lead to spontaneous retinal degeneration.

Protocol 1 is to maintain wild type, genetically modified and naturally occurring variants of mouse and rat strains and to cross-breed strains to generate novel combinations of genetic alterations. Offspring carrying desired alleles and their wild type littermates will be used for analysis at various developmental stages and at different ages after birth to study the role of TJ proteins in healthy and disease animal models.

Protocol 2 is to characterise and validate therapeutic approaches to rescue pathological responses during ocular surface inflammation; e.g., allergic conjunctivitis or dry eye. To induce ocular surface inflammation, we will use only one of the optional protocols. If we use an allergen (either ovalbumin (OVA) or short ragweed (SRW) pollen), mice will be sensitised by intraperitoneal injections. Disease induction, assessments and treatments will last up to 3 months.

Protocol 3 involves refined models for experimental-induced uveitis (infectious and autoimmune). To induce uveitis, we will use only one of the optional protocols, by intraperitoneal injections of retinal antigen or intraocular injection of LPS (Lipopolysaccharides are large molecules found in the outer membrane of bacteria). Only one of the methods to induce uveitis will be used for a specific animal. Depending on the method used, disease induction, assessments and treatments will last up to 4 months.

Protocol 4 is a model of neovascularisation during development and pathological conditions to characterise junctional signalling molecules and test therapeutics. Offspring mice carrying desired alleles will be used at various developmental stages and at different ages after birth. Neovascularization will be induced by exposure of animals to high oxygen levels prior to incubation under normal oxygen, or exposure to strong light sources. Disease induction, assessments and treatments will last up to 9 weeks, depending on the method used. Only one method will be used for a specific animal.
Protocol 5 is to model diseases affecting the retinal vasculature. Ischemia and increased permeability of the retina, as well as corneal or retinal wounding will be induced by laser

ablation. Diabetes will be induced in mice or rats by intraperitoneal injections of Streptozotocin (STZ is an antineoplastic agent that is toxic to the pancreas in mammals) or high fat diet. Diabetes development will be followed by taking blood samples to analyse glucose levels and eye assessments to determine the role of a given TJ protein or potency of therapeutics for up to 15 months.

Protocol 6 is the generation of specific monoclonal antibodies for junctional proteins. We will do intraperitoneal injections of an antigen every 30-45 days, 3-4 times, and collect blood samples until we detect the production of specific antibodies.

Protocol 7 is to assess whether novel therapeutics rescue permeability triggered by common disease mediators (e.g., LPS, VEGF, TNFalpha, etc) in an assay called Miles assays.

Protocol 8 is a breeding protocol to allow to assess those GA strains that show a moderate severity. The protocol will allow us to assess eye functions in these GA (genetically altered) strains to decide in which protocol a new GA strain will be analysed.

Protocol 9 is to test experimental gene therapy approaches to rescue retinal function. We will manipulate expression of TJ or associated signalling proteins by ocular injection of viral particles into wild type and GA mice, or rats and evaluate if and how retinal function is rescued by different types of eye assessments, e.g. acquiring electroretinograms (ERGs) and by ophthalmic examination through non-invasive fundoscopy or laser scanning ophthalmoscopy for up to 15 months.

What are the expected impacts and/or adverse effects for the animals during your project?

In Protocol 1, mild, we do not expect pain, weight loss, tumours, or abnormal behaviour. In the majority of animals covered by this protocol activation of conditional mutations will be harmless. However, occasionally it will not be known in advance whether the activated transgene will cause any harm to the animal.

In Protocol 2, moderate, intraperitoneal sensitisation is expected to induce low adverse effects. Ocular surface allergic conjunctivitis leads to mild to moderate adverse effects leading to eye swelling, tearing and mucus production.

In Protocol 3, moderate, uveitis is usually well tolerated (>99%) by the animals. Animals with uveitis exhibit transient mild inflammation of the eye with onset about 9 days after disease induction. Eyes will appear cloudy at this point, due to white blood cell infiltration into the eye. This usually completely resolves by 3-4 weeks after disease inoculation. This may result in sight loss due to photoreceptor damage. Vision is not the major sense by which small rodents perceive their environment and most animals will be killed after 14 days. The loss of sight does not affect their normal behaviour and feeding but animals with uveitis will have reachable food at all times on the cage base as well as in the hopper.

In Protocol 4 and 5, moderate, disturbed retinal development is anticipated to be pain free because the retina (like the brain) lacks pain receptors. Blindness may be a potential outcome, but mice kept in captivity make very limited use of their visual senses, which is illustrated by the fact that genetically blind mice thrive and breed as well as normal mice in captivity. Hyperoxia exposure can have toxic effects on adult mice and, therefore, mothers are only exposed for a maximum of 5 days to hyperoxia. In Protocol 5: mice do not become ill as quickly as diabetic humans. Adverse effects can be observed at sites of

administration of Streptozotocin; thus, a particular focus will be the monitoring for infections and wounds.

In Protocol 6, moderate, most antigens can be injected without causing adverse effects on the animals' wellbeing. However, immunizations may cause mild responses. As a consequence of Freund's complete adjuvant injection granulomas may be formed at the site of adjuvant injection. Injection in the flank reduces these adverse reactions and the animals show no untoward side effects as a result of this protocol.

In Protocol 7, moderate, the effects of hyperpermeability-inducing agents in the skin induce mild to moderate adverse effects leading to swelling and itching.

In Protocol 8, moderate, the adverse effects expected to result from the genetic alterations are unknown. Animals bred on moderate severity limit protocols are expected to develop a phenotype that is sufficient to cause a disease comparable with the moderate severity description (as Home Office document Advisory notes on recording and reporting the actual severity of regulated procedures). The disease is not expected to be fatal, and animals will be killed before any disease becomes life- threatening.

In Protocol 9, moderate, sequelae from intraocular injections are generally temporary and cause little discomfort. Local antibiotic/steroid ointment and aseptic injection techniques will prevent infections potentially associated with intraocular injections. Placement of ERG electrodes may occasionally result in infections which will be prevented through local antibiotic/steroid ointment and good aseptic technique.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1 is Mild severity (60%).

Protocol 2 to 9 are of Moderate severity (90%).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We have studied cellular functions of TJ proteins in cultured cells in great detail and will continue to do so in the future. Our strategy is to elucidate the molecular mechanisms and structure/function properties of TJ proteins in vitro so that in vivo experiments can be designed carefully and with sufficient insight to keep animal numbers to a minimum.

The mechanisms to be analysed are processes for which we have generated inhibitors as potential therapeutic tools. These inhibitors have been characterised in vitro extensively using cell lines as well as disease models based on primary cultures of endothelial and retinal pigment epithelium (RPE) cells, as well as patient-derived cells; however, before they can be tested in clinical trials, animal experiments are essential to establish that such therapeutics are as effective in vivo as they are in vitro.

We will also analyse the role of junctional signalling mechanisms during development and organ function as there are no alternative to animal models to model complex tissues and organs such as the eye, or to determine effects of retinal dysfunction on visual function.

We will focus on TJ components that we have analysed in great detail in vitro and have established the signalling mechanisms they control in cultured cells. However, an in vivo analysis is now needed to understand more complex in vivo roles such as how such junctional signalling mechanisms regulate complex morphodynamic processes of developing tissues, how different cell types cooperate in organ development and function, how junctional barrier defects lead to tissue and organ malfunction and disease, and how TJ-associated signalling mechanisms regulate neovascularization. Such processes cannot be analysed in vitro only.

Mice and rats are the species best suited for the planned studies because their cells and tissues are similar to the human ones, powerful genetic tools have been developed, and appropriate disease models have been established and well characterised.

Which non-animal alternatives did you consider for use in this project?

All our in vivo studies are based on extensive in vitro data and we will continue to refine our understanding of the junctional proteins using different cell lines and primary culture models. We are also employing models based on induced pluripotent stem cells derived from patients carrying retinal disease genes to model human ocular diseases. Additionally, we will include the analysis of primary cultures of cells from genetically modified mice to reduce pain and discomfort on live animals.

Why were they not suitable?

The in vitro models are limited to 1-2 cell types and cannot recapitulate complex eye diseases and effects of cellular defects in the retina on visual function. Animals are therefore necessary to determine the role of new mechanisms identified in cells in culture and validated in in vitro ocular disease models of eye diseases such as uveitis and diabetes. Unfortunately, whole eyes and retinas cannot yet be modelled in the laboratory without animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All estimations of animal numbers are based on results from similar studies in the past as well as pilots experiments that allow us to identify differences between conditions using appropriate statistics. The minimal magnitude of such differences (i.e., effect size) have been predefined so that the number of animals calculated is neither too small to detect such differences nor too large to avoid unnecessary use of animals. The total number of animals for specific protocols was then estimated by multiplying these numbers with the number of expected studies to be performed.

For protocols that include different assessments, the main readouts have first been determined to calculate required animal numbers. For example, in the analysis of vision in live animals, the ERG measurements are the most important assay as they allow conclusions about retinal function; hence, we calculated how many animals are required to detect expected effects in ERG measurements. We also considered the number of animals required to perform meaningful post-mortem tests to ensure that conclusive results will be obtained.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We based our calculation on previous experiments, pilot studies and published results that allow estimation of all analysis methods to be used. Additionally, we use the Experimental Design Assistant (EDA) online tool from the NC3Rs, designed to guide researchers through the design of their experiments, to ensure that we use the minimum number of animals consistent with our scientific objectives, methods to reduce subjective bias, and appropriate statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Prior to analysing newly developed therapeutics and the function of junctional proteins, we have and will continue to perform extensive in vitro experiments with cell lines and primary cultures originating from different cell types and tissues.

When we use animals, we will first carry out pilot experiments to test the best experimental settings. Depending on the type of question to be addressed, the pilot experiments will include control and experimental groups with up to 2 animals per group. These will then be translated into full scale studies if satisfactory results are gained and repeated in sufficient numbers, assessing both qualitative and quantitative outcomes to ensure reproducibility and statistical significance. A variety of approaches (in situ hybridization, antibody staining and genetic labelling) will be used to assay the effects on the specific cells. Experimental repeats are primarily aimed at ruling out random events, artefacts and errors. It is therefore generally possible to establish the effect of a given manipulation by comparing a small number of experimental animals (typically around three to five) with non-treated or wild-type controls, thus avoiding experiments with large cohorts of mice.

The serial retinal imaging of animals (e.g., by angiography) and measuring retinal function by ERG reduces the need of killing animals at every experimental time point and facilitates the selection of optimal timepoints to terminate the animals. The mouse numbers used at each age and/or experimental condition will thus be kept at a minimum by assaying different parameters in the same mice and by keeping the numbers to the minimum required for statistical significance,

For the maintenance and generation of genetically modified strains, the colonies will be kept at the minimum size required to generate sufficient animals of appropriate genotypes for statistically sound experimentation and to keep the colonies stable. The breeding scheme will minimise the generation of harmful mutants and involves breeding heterozygous animals that have no or only mild symptoms (e.g., p114RhoGEF deficient homozygotes are not viable). It is therefore unavoidable that mice are generated that do not carry the wanted alleles. They will be culled without having undergone any experimental procedures or used as controls in experiments to reduce the breeding of control animals. In any case, we will be conducting our experiments so that we will be able to publish according to the ARRIVE guidelines [https://www.nc3rs.org.uk/arrive-guidelines] and will use randomisation and blinding where appropriate to avoid bias.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will design breeding strategies that reduce animals with deleterious mutations. Postnatal animals will be health monitored on a daily basis or, if an unknown strain is analysed, more frequently. If animals show signs of suffering due to the genetic mutation or to an unexpected strong response in a disease model, they will be immediately humanely culled using a schedule one method.

A mammalian experimental model is important to bridge the gap between in vitro studies and humans. Considering the existing knowledge and available strains and experimental tools, mice provide the most refined model and allow us to make use of strains and experimental tools that have been generated as part of international efforts to generate genetic models of the entire mammalian genome (e.g., p114RhoGEF knockouts). Moreover, we can use conditional transgene technology that reduces the number of genetically altered mice actually suffering from their mutations as both the effector and the responder strain are symptom-free. When possible, inducible systems will be used as the offspring from responder-effector crosses from pairs that are symptom-free. Only administration of the activating substance (tamoxifen) will activate the mutation in such offspring from inducible cre recombinase mice. This means that the time window of transgene activation is much shorter and can be followed along a defined time window to identify the type and level of the phenotype, which reduces the impact on the mouse with regards to welfare. As specific cell types can be targeted at specific times, more precise questions can be asked and convolution of the results by the presence of different affected cell types can be reduced.

The junctional proteins and therapeutics to be analysed have all been extensively characterised in vitro (such analyses will be further extended); hence, experiments can be planned with disease models that involve these signalling pathways. As the disease models are validated and used widely, we will be able to use well established quantitative assays and can easily compare our results with the literature.

Refined Protocols are:

Protocols 1 and 8 are for breeding and maintenance (https://www.gov.uk/government/publications/animal-testing-and-research-improve-your-project- licence-application). The use of tamoxifen has been well-established (Feil S, et al Methods Mol Biol. 2009;530:343).

Protocol 2, eye allergy

We will use models to induce allergic eye disease that have been established by different laboratories over many years. Hence, refined protocols have been established that keep the number of animals required at a minimum.

Protocol 3, Models of experimental retinal inflammation

We will induce different approaches to induce retinal inflammation by injecting animals. These methods have been refined over many years. The retina lacks pain receptors and mice to do not require vision to live in captivity. Hence, uveitis is an ideal model to study inflammatory diseases as it keeps discomfort low.

Protocol 4, Characterization of vascular development and degeneration

Animals will be kept at different oxygen levels to manipulate blood vessel growth. This model used for many years; hence, precise times are known and will be adhered to induce the desired effects without causing harm to animals. The model is well accepted for the type of studies to be performed and closely reflects a human disease caused by the same conditions.

Protocol 5, Models of retinal vascular diseases

Protocols to induce diabetes and acute inflammation will be used that have been refined over many years by different laboratories. Hence, they are well accepted and sufficient knowledge is available to keep animal number as low as possible. Animals will be injected with reagents to induce diabetes or inflammation. Disease progression is well understood and measures will be in place to reduce suffering.

Protocol 6, Production of hybridoma cell lines

High-quality antibodies can reduce the number of animals required for experiments as they enable more specific and reproducible detection of relevant antigens. Mouse hybridoma generated from immunised animals is still the best way of generating such antibodies. Once such cell lines have been generated, unlimited amounts of antibodies can be produced without requiring further animals.

Protocol 7, Vascular leakage or permeability Miles assays are excellent to provide quantitative readouts for vessel permeability.

Protocol 9, Vector/stem cells/pharmacological agent eye administration
The protocol to be used to test therapeutics and the importance of mechanisms identified in vitro closely follows the methods used for human therapy. Hence, results obtained can be easily translated to clinical applications. The procedure has been pioneered at our Institute and, hence, we can build our studies on many years of experience and know-how.

Animals will be anaesthetized for retinal injections. Surgery will be done aseptically (following HO Minimum Standards for Aseptic Surgery and LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery http://www.lasa.co.uk/pdf/lasa_guiding_principles_aseptic_surgery_2010.2.pdf). Animals will then be followed up with live imaging methods to determine effects on the retina and visual functions. All these methods are used throughout the project and refined methods have been established to reduce the suffering of animals.

Why can't you use animals that are less sentient?

Unfortunately, eye diseases like diabetes and uveitis have to be studied in animals that have retinas that closely resemble those of humans to be able to make conclusions relevant for humans. Consequently, novel therapeutics have to be tested in mammalian models like mice and rats to ensure their relevance for human disease and to fulfil regulatory requirements for clinical trials.

Many of the experiments require disease models that require weeks or even months to develop. Such experiments cannot be performed in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Newly generated genetically modified strains are routinely monitored more frequently to identify early whether mutations lead to unexpected suffering and, if yes, appropriate measures are taken. Similarly, we carefully monitor animals after procedures with the aim to reduce pain. For example, in procedures that require full anaesthesia, animals are monitored until they completely recovered and are then provided with soft wet food. Animals are also monitored the subsequent morning. If they do show the lasting impact of the anaesthetic, they are terminated using a Schedule 1 method.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow:

RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

PDF document available for download from www.rspca.org.uk/ethicalreview and www.lasa.co.uk/publications.html

The ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines are intended to improve the reporting of research using animals – maximising information published and minimising unnecessary studies (https://www.nc3rs.org.uk/arrive-animal-research-reporting-vivo-experiments).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly visit the relevant websites of such as https://nc3rs.org.uk/the-3rs#replacement to implement advances during the project that can be more effective to

obtain useful results and reduce animal suffering. There are also regular e-mails and meetings to disseminate the principles of the 3Rs that inform us about new developments.

199. Imaging and radiation treatment of cancer

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Radiotherapy, Cancer, Radionuclide, hypoxia, Antibody

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overarching aim of this project is to improve the outcome of cancer patients by enhancing the effectiveness of radiotherapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Radiotherapy is a highly effective therapy used in the treatment of 50% of patients with cancer. There are several different types of radiotherapy. External beam radiotherapy is applied in a radiotherapy department using an external radiation source which is rotated around the patient producing a series of radiation beams that intersect in the cancer. This means that the cancer receives a large dose but the surrounding normal tissue - organs

etc - receive a smaller dose. The greater the dose that the cancer receives, the greater the chances that it will be destroyed. However the dose of radiation that can be given is limited by damage to normal tissue.
Targeted radiotherapy (TR) which is used to treat lymphoma and prostate cancer and is being rolled out to other cancer types due to its proven effectiveness. Cancer cells have on their surface, markers that are not found or are found in far less amounts in normal cells. These markers can be targeted by highly specific drugs. These drugs only bind to their selected marker. TR involves drugs attached to radioactive atoms (radionuclides) that specifically target these markers and irradiate them at close range. This type of radiotherapy is very specific and will also destroy the secondary cancers (where the main cancer releases cells that set up many new cancers throughout the patient). However cancers contain many cells which vary in the number of markers that they have on their surface - this is called heterogeneity and diminishes the effectiveness of TR as not all parts of a cancer will receive the radiation from a TR radioactive drug.

The project will address tumour heterogeneity by altering the drug so it targets several markers and by using several different radioactive atoms that irradiate cells nearby and at a distance.

As cancers grow their blood supply does not grow with them in a well co-ordinated way so they have regions within them that do not receive much oxygen - these areas are called hypoxic. Radiotherapy is much less effective at killing cancers that have large hypoxic regions. By identifying markers on hypoxic cells we can target these with TR to boost the radiation dose to these cells.

The effectiveness of targeted radiotherapy in a patient can be measured by giving the patient a version of the TR agent with an imaging beacon (another type of radioactive atom that is far less damaging to tissues) that distributes in the patient before a therapy version. The patient is imaged and the amount of RT agent measured. This project will also design and test imaging and therapy versions of targeted radiotherapy agents.

What outputs do you think you will see at the end of this project?

The work from these projects will be published in high quality cancer and radiobiology journals.

Optimisation of radioactive cancer marker-targeted drugs for cancer patients receiving targeted radiotherapy (TR).

To demonstrate that imaging can be used to predict if a TR compound will localise in cancer tissue and be effective in a patient before a therapeutic version of the compound is administered.

Who or what will benefit from these outputs, and how?

Short term - increased knowledge in developing radiotherapy-based drugs which will be published Long term potential benefits:
Improved response of cancer patients treated with targeted radiotherapy by optimising the radioactive drugs administered to patients that seek out and destroy their cancers: Current TR compounds have one type of radioactive atom attached and targets one type of cancer marker. Cancers are heterogenous in the expression of cancer markers between different areas in a single cancer. There are also blood flow issues affecting where the TR molecules go to within the cancer. To overcome this we are developing TR compounds

that have two types of radioactive atom that will emit lethal particles both nearby and at a distance from where the TR molecules localises within the cancer. We are also targeting two cancer cell markers. Our hypothesis is that this will enable a better distribution of lethal radiation within the cancer so that all the cancer receives lethal radiation and no part of the cancer is left to regrow.

Reducing morbidity from radiation damage to normal tissues: TR molecules are damaging to normal tissue if they do not preferentially go to the cancers in the patient. However it is possible to determine where the TR compounds go by labelling them with an imaging radioactive atom (which is far less damaging) and imaging the patient and calculating how much goes to each tissue. From the image the radiation dose delivered to each organ and the tumour can be determined (this is known as dosimetry). If the dosimetry indicates that a patient the benefit/harm ratio is high the patient can be given the TR compound this time with the lethal radioactive atom attached. It is also possible to tailor the amount of TR molecule that is given to the patient to reduce normal tissue damage.

How will you look to maximise the outputs of this work?

Targeted radiotherapy (TR) uses a range of radioactive atoms which produce different forms of radiation. One of the challenges with researching and clinical delivery of TR is obtaining the radioactive atoms. This work will involve collaboration with the a nuclear institute which will optimise the delivery of several clinically useful radionuclides. Collaboration with a Government nuclear laboratory will ensure a source of 212Pb which is a very effective cancer killing radioactive atom. Ensuring a broad stakeholder audience for the developments from this project will be assured through interaction with the CRUK steering group on targeted radiotherapy.

It is envisaged that the project work described here will provide useful methodology for advancing radiotherapy. However it is possible that not all approaches will prove to be effective. These less positive outcomes will still be published.

Species and numbers of animals expected to be used

- Mice: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The cancer models that are required for this work are cancers growing in nude adult mice or rats. These animals are the least sentient organism in which cancers can be grown that can receive radioactive drugs and be monitorable with medical imaging modalities such as PET. The cancers (xenografts) need to be of a large enough size to contain emissions of radioactive atom which can be 1cm in distance so a 1.2cm3 (1.0cm diameter) is required.
Typically, what will be done to an animal used in your project?

Cancers will be generated in nude mice by injected cancer cells or pieces of cancer into one of the flanks of anaesthetised animals. Animals are anaesthetised which is carried out by placing them in a tank filled with an anaesthetic gas. The animals are kept

anaesthetised via delivery of anaesthetic gas through a face mask. Insertion of cancer cells via a needle by insertion of a piece of tumour into a flank via a tube with an outer diameter of about 3mm. In both cases the needle is inserted just under the skin (sub-cutaneous) and only in one flank. The animal will not be aware of the procedure until regaining consciousness - generally mice do not demonstrate any awareness that the procedure has taken place - rapidly returning to feeding.

Cancer growth will be monitored by regular inspection of the cancer site. The cancer will not be allowed to get any larger than 1.2 cm^3 volume (about the size of a standard marrowfat pea). This size will not interfere with the animals movement or cause it distress. This volume is to accommodate radiation from high-energy radiation-emitting radioactive atoms which travel up to 1.0 cm distant from the radioactive atoms. It is envisaged that for most of the studies using lower energy emitting radioactive atoms (where the radiation range is low) outlined in this PPL the maximum volume will be <1cm^3 volume (about the size of a garden pea). Mice do not demonstrate any awareness of the growing cancer. During cancer growth dimension measurements are taken using calipers. When handled during these measurements the mice are curious and do not demonstrate any signs of stress. The animal is also weighed by placing on a top-tray balance. When the cancer is a suitable size for experiments the animal might be injected with a radioactive drug that seeks out and binds to the cancer. It is unlikely that the mice will be aware that they have been injected as these drugs do not irritate and are suspended in a a non-irritating medium that has a neutral pH. Apart from decreasing the growth rate of the cancer the substances are unlikely to have any effect on the mice. The animal may then be killed by schedule 1 under anaesthesia between 5 minutes and several days after injection. Alternatively the effect of the radioactive drug on the growth of the cancer may be monitored over a period of several weeks.

For some experiments the animals may be imaged after injection of a radioactive substance. Imaging involves anaesthetising the animal as described above. The mouse in then placed in an animal PET scanner. During imaging under anaesthesia the animal will be placed on a heating pad to ensure the animals is kept warm. It is likely that mouse core temperature will be monitored by a rectal thermometer. At the end of the imaging session the animal is either euthanised by a schedule 1 method or allowed to recover. Some animals are scanned on two occasions with at least a 4h gap between during which time the animal will have fully recovered and be exhibiting normal behaviour.

If animals do not recover consciousness within 1h they are euthanised by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

The mice develop tumours which are unlikely to spread beyond the site of injection. Mice will be closely monitored and scoring system developed and humane end points identified and updated as required.

For some of the studies we will require a large blood sample which can most humanely be acquired by cardiac puncture under terminal anaesthesia.

If any of the procedures result in pain as evidenced by apparent facial expression (Facial expressions of pain) analgesia may be given as a first line but if this is insufficient to alleviate pain the animal would be euthanised by a schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The level of severity is expected to be moderate or more commonly mild for any of the procedures detailed in this project.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Targeted radiotherapy uses radioactive atoms which emit radiation of different energies. Radioactive atoms that produce low energy radiation kill nearby cells. Radioactive atoms producing high energy radiation travels further and kills cells at a distance. One part of this project is to overcome the problem of heterogeneity in the distribution of cell kill within the tumour by combining different energy atoms to kill cells close by and at a distance. The distance that we need to observe cell binding and cell kill is several mm. We can only demonstrate the benefit of these systems in 3D using cancers growing in living organisms.

This project will produce optimised targeted radiotherapy drugs which will be aimed at clinical translation. Before any radiolabelled drug is administered to a patient it must be tested in animals and organ dosimetry determined - (where the TR compounds go and how much radiation they carry into organs) by labelling them with an imaging radioactive atom (which is far less damaging) and imaging the patient and calculating how much goes to each tissue.

Which non-animal alternatives did you consider for use in this project?

The only alternatives are tumour spheroids which are 3D models of cancer grown in vitro.

Why were they not suitable?

Tumour spheroids lack a vascular system so only grow to a few hundred micro-metres in size which are far too small for cancer heterogeneity studies.

Exploring imaging methods to characterise tumours requires an in vivo tumour model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise

numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Radiation-sensitive cancer cells will be used to derive the xenografts to achieve the greatest effect of radiation on tumour growth. Inbred animals of similar age will be used for each study to reduce variation. The basis of most of the work in this PPL is developing radiopharmaceuticals that can be used in man. To achieve clinical translation these compounds must be preclinically testing in animal tumour models and bio-distribution determined. The uptake and tumour distribution of radiopharmaceuticals is also dependent on a blood supply.

Similar work in the literature (human cancer cell derived xenografts grown in nude/SCID mice, receiving targeted radiotherapy) in the literature typically use 5-7 mice in each treatment group in order to achieve mean differences at 5% significance levels. However we will be comparing the efficacy of tumour growth inhibition by different radionuclides so the differences in growth rate are likely to be smaller so we may require larger treatment groups. We have sought advice from a statistician who has recommended a pilot study to assess the magnitude of cancer growth inhibition is achieved by the radioactive drugs to determine treatment group size.

PET is very sensitive and its quantitative accuracy is highly dependent on minimal subject motion which is best achieved through anaesthesia. Image degradation through movement would inevitably lead to the requirement of more animals per time point negating the benefit of reduction in animal numbers through serial imaging.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Pilot experiments will be used to check that the transplanted cells produce regular sized cancers suitable for autoradiography and that the radiation dose administered during treatment, determined from in vitro experiments and the literature, is sufficient to produce appreciable cancer growth inhibition compared with untreated tumours. We will seek advice from the University's biostatisticians regarding actual sample sizes required informed from pilot data.

Cell lines are authenticated and regularly tested for mycoplasma contamination by the University's core facilities.

(Reference: Workman et al Guidelines for the welfare and use of animals in cancer research. Br. J. cancer 2010 102:1555-1577)

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mice used in these studies are inbred which will reduce genetic variability between the mice.
As described above we will use pilot studies to determine the growth inhibitory effect of targeted radiotherapy on xenografts to inform on the actual number of mice needed in the control and treatment groups.

Where possible experiments will be designed so that multiple treatment groups can be compared with a single control group.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The procedures carried out in this study are the induction of carcinogenesis by subcutaneous injection of cancer cells into the flanks of nude mice followed some days later by injection of a radioactive agent that targets the cancer cells. These tumours do not usually spread. Tumour growth of sub-cutaneous tumours does not result in constriction of blood vessels or organs.

Why can’t you use animals that are less sentient?

Rodents are the animal of lowest sentience that can support the growth of xenografts and that can receive radiotherapy, hyperthermia and radioactive drugs. Nude mice are genetically altered so that they can be hosts to tumour derived from human cancers.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The generation of cancers in nude mice under anaesthetic will be painless. Once recovered from anaesthesia (within 1h) the mice feed and behave normally and do not display signs of discomfort. As the cancers progress the mice will be carefully monitored for behaviour suggesting discomfort. Generally the cancer enlarges with no apparent evidence of discomfort. These types of cancers (xenografts) do not usually spread beyond where the cancer cells were inserted. Occasionally (<10%) animals bearing xenografts display weight loss. Animals are weighed 2 times per week from the time the cancer cells were implanted. Once palpable the cancers are measured twice per week. From 0.75cm3 in volume (size of a garden pea) the tumours are measured daily and the animal weighed. Weight will be monitored and the mice will undergo euthanasia if their weight loss exceeds 15% of body weight from start of treatment (after subtracting an estimate of cancer weight).

PET is very sensitive and its quantitative accuracy is highly dependent on minimal subject motion which is best achieved through anaesthesia. Image degradation through movement would inevitably lead to the requirement of more animals per time point negating the benefit of reduction in animal numbers through serial imaging.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Workman et al Guidelines for the welfare of animals in cancer research. Br. J. Cancer 2010 102 1555-1577

An updated version of this paper is in progress. Recommendations in the revised version on publication will be followed.

NC3Rs website

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs website to follow any developments in cancer models. If a suitable cancer model becomes available which enables 3D tumours to be generated that are several mm in diameter in vitro we will compare results from dose-distribution experiments with that from xenografts in a cell line to determine if some of the work can be carried out using the model.

200. Quantitative metabolomics for prediction of lameness and elucidation of related mechanistic pathways in dairy cattle

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
    - Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Dairy cattle, Lameness, Biomarkers, Metabolomics, Machine learning

Animal types	Life stages
Cattle	adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop methods to predict the risk of lameness (impaired mobility) and lesions causing lameness in dairy cattle using a combination of cutting-edge chemical analytical techniques and artificial intelligence.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lameness (impaired mobility) is one of the highest priority diseases for the UK dairy industry. This painful and debilitating condition affects cattle welfare as well as production and health. Current estimates suggest that at any one time ~30% of dairy cows in UK herds are suffering from lameness. Implications extend beyond the cow to the sustainability of dairy farming and environmental impacts from disease reducing efficiencies. As a complex disease with many factors contributing to its occurrence, lameness is inherently challenging to tackle and major gaps exist in our understanding of disease processes contributing to lameness because of these challenges. Additionally there is currently a lack of data relating to the interplay between the lesions that cause lameness and the cow displaying impaired mobility (clinical lameness) due to resource challenges in collecting this data from appropriate sample sizes of cattle. Detection of lameness is currently only possible at an advanced stage of disease when pain causes cows to walk with an altered gait. The ability to detect lameness early on, prior to this stage, would be a huge advancement on the current situation resulting in improved health, welfare and productivity.

This work will generate data that will provide a vital insight into the disease pathways contributing to lameness in dairy cows and the ability to predict disease risk. This in turn will inform disease management and provide the building blocks to develop tools for early prediction of lameness, offering a step change in the detection and management of lameness in dairy cows. Additionally, the methods developed will be applicable to many other complex disease in both livestock and humans and will be further utilised in future work.

What outputs do you think you will see at the end of this project?

This research will develop methods to predict lameness risk during first lactation and identify key information from chemical analytics that show whether a cow is more likely to experience lameness. In turn, this information will be used to understand the biological pathways that contribute to lameness and lesions causing lameness. This work will advance knowledge of the fundamental biology of the disease pathways leading to lameness, enabling improvements in management strategies to reduce lameness and therefore improve welfare through reduction of this painful condition. Additionally, the methods developed will provide the building blocks for future development of diagnostic and management tools for lameness in dairy cows. For example, in-line milking diagnostic tools will enable individual cows that are more likely to experience lameness to be identified during routine milking and management decisions to be made (including breeding decisions). Findings of this work will be published in a number of peer-review publications. Data generated under this project will be presented at multiple national and international conferences by the principal investigator, post-doctoral researchers and PhD students.

In addition this project will result in the establishment of a bank of samples (biofluids) from two large groups of dairy cows entering their first lactation that will provide a valuable resource for future research studies and aid in the generation of further data for subsequent grant applications. Through future work involving a range of different chemical analytical techniques, analyses of these samples, utilising a range of non-animal techniques using artificial intelligence the research approaches can be developed reducing further need for animal research.

Who or what will benefit from these outputs, and how?

The research outputs have the potential to be extremely valuable to the dairy industry; providing the knowledge and foundation to construct a robust monitoring and preventive strategy for lameness. There will be direct and substantial benefits to animal welfare. Key beneficiaries include, animals, dairy farmers and consumers through improved understanding of the pathogenesis of lameness and the ability to develop tools to prevent and manage lameness, ultimately reducing the prevalence of a condition with major health, welfare and economic impacts. Societal benefits will come from improved sustainability through reduction of lameness in the national dairy herd of approximately 1.8 million dairy cows.

Outputs from the research will be used by industry through the development of management and diagnostic tools to reduce lameness in dairy herds as well as the research community through the ongoing investigation and optimisation of lameness management and the application of the methods developed to other complex diseases of livestock and humans. The research is funded by BBSRC and aligns with the BBSRC research priority areas of: ‘Animal Health’ and ‘Sustainably enhancing agricultural production’ within the strategic priorities of ‘Agriculture and food security’ and ‘Bioscience for heath’, as well as ‘Data driven biology’ under the enabling theme ‘Exploring New Ways of Working’ and ‘Welfare of managed animals’.

Establishment of a biobank will provide a valuable resource with benefits to the research community for grant applications and research as well as the animals, farmers, advisors and consumers benefiting from outputs of this research. The biobank will be managed by the PI and research group with storage of samples at -80oC and comprehensive cataloguing of samples. Access to samples and accompanying data will be available to the research group as well as internal and external research groups where appropriate for collaboration.

Short-term benefits will be realised through timely communication of results directly to the industry (via AHDB Dairy (the dairy farmers levy board for Great Britain), BCVA and other industry organisations), the research community and policy makers (via national and international conferences and peer- reviewed publications). Short term benefits will improve cow welfare and health and improve farm sustainability (through reduced disease, improved long-term cow heath and productivity).

Longer-term benefits will be realised through future work to develop and commercialise tools to predict lameness. These decision-making support tools will benefit farmers, farm advisors and vets involved in the health management of dairy cows. The research will provide the building blocks to develop these tools and findings will be communicated and made available to other scientists and industry through publication in peer-reviewed journals and presentation at scientific conferences and meetings. In terms of financial benefits, reduction of lameness will provide farms with a substantial reduction in economic losses. Lameness has been demonstrated to impact on production parameters including culling rates, fertility and milk yield with indirect costs in addition to the direct costs associated with the treatment of lameness. Estimates of costs for the average lameness event are in the region of £330, which is likely to be conservative figure, based on calculations reported in 2009. For a 200-cow herd with an average of 25% the herd lame at any one time (current estimated average for UK herds is around 30%), the costs per year for lameness have been estimated at £40,000 per year.

Additional longer-term benefits will be realised through the application of the methods developed to other complex disease of livestock and humans. Dissemination of research

findings to the scientific community through conferences and peer-reviewed publication will enable this work to be used for application to a wide range of diseases.

How will you look to maximise the outputs of this work?

To maximise the output from this project data will be published in high-impact, open access journals. Data collected under this project will also be presented at international and national conferences, meetings and seminars. Additionally we will use established networks (e.g. AHDB Dairy, BCVA, Dairy Cattle Mobility Steering Group and other working groups) to disseminate research findings.

Where possible we will collaborate and share resources (samples, knowledge, technical skills) with other researchers within and outside of the University, to maximise the scope and impact of our research.

It is our anticipation that data generated under this project (both positive and negative) will be made available.

Species and numbers of animals expected to be used

- Cattle: 320

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will follow a standard population of dairy cows from one unit to monitor for naturally occurring lameness outcomes at the prevalence and severity experienced by the average UK dairy herd, with accompanying collection of samples for metabolomics analysis (chemical analytics). In order to identify biological markers (biomarkers) for lameness and lesions causing lameness in dairy cattle it is necessary to conduct the research in the same species managed for milk production. This project therefore uses this type of animal at this life stage (adult cows entering lactation). There are no other species appropriate for this research.

In addition the use of dairy cows maintains continuity with existing preliminary research enabling data to be generated to further understanding of the pathogenesis of lameness in dairy cattle and identify robust biological markers for accurate prediction of lameness risk.

Typically, what will be done to an animal used in your project?

Under this project we will be evaluating differences in the metabolic profile of lame and non-lame first lactation dairy cows to identify biological markers for lameness and lesions causing lameness prior to the onset of clinical lameness (impaired gait).

Two separate cohorts of 160 cows (320 in total) will be housed and managed (including feeding, milking, disease and health management) according to the normal farm management routines for the rest of the herd in high quality, spacious facilities. At enrolment (~2-3 weeks pre-calving) urine and blood samples will be collected under restraint (minimum 1 week between sampling). From ~2 weeks post-calving blood, urine

and milk samples will be collected typically every 2 weeks (minimum 1 week between sampling) for either one lactation (about 305 days) or until the first lameness event (whichever occurs first). At the onset of lameness an appropriate intervention according to best practice will be made to treat the cause of lameness and cows will be removed from the study to remain within the herd at the existing farm facility. The definition of lameness will be based on a published 6 point mobility score scale (0, 1, 2a, 2b, 3a, 3b). Score 2a represents uncertain lameness and therefore two consecutive weeks at 2a will be used to define lameness. Sample collection will include; blood via a superficial vein (tail or jugular), hand-stripping of one quarter for milk and collection of urine via free-flow or catheterisation. Samples will be stored for later analysis using mass- spectrometry (chemical analytics).

Data relating to lameness (mobility score and foot lesion score) and body condition score will be recorded by visual assessment of cows in their normal housed environment. Lesion scoring will be conducted by lifting the feet in a cattle crush to inspect the claw surfaces and surrounding skin.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect a majority of the samples to be collected whilst cows are housed in their normal environment using normal husbandry methods of restraint (locking head yokes or stalls). Where it is more refined from a welfare perspective (e.g. collection of blood samples from an alternative site such as the jugular instead of the tail vein) or for a safety reason cows may be restrained in a cattle crush. Collection of blood samples from a superficial vein (tail or jugular) for metabolomics analysis may result in inflammation and/or soreness at the site of sampling. However, the impact will be localised to the site of injection and the duration should typically be no more than 24 hours. Some cows may be catheterised for urine sample collection where it is not possible to collect urine via free-flow. This may result in minor discomfort and irritation at the site of sampling however the impact will be localised to the site of catheterisation and the duration should typically be no more than 12 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Over the duration of this programme of work, it is anticipated that 100% of animals will experience a procedure of a mild severity as blood samples will be collected from all cows on the study.

What will happen to animals at the end of this project?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Lameness is a complex condition commonly seen in dairy cows and aspects of the disease pathways of lesions causing lameness are specific to this species and risk factors relate to the way that dairy cows are managed. This project aims to identify biological markers for disease by investigating how differences in the metabolic profile (metabolome) relates to phenotypic state of lameness. It is therefore necessary to conduct this research in animals in order to achieve the aims of the project.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives are not possible for this study type.

Why were they not suitable?

Expression of disease outcomes (lameness) is required in order to evaluate differences in the metabolome.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in this project is based on pilot data which has demonstrated that for the sample size and methods being used (metabolomics and subsequent analysis of data generated using machine learning) the expected accuracy of prediction of lameness risk is >90%.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We conducted 2 separate pilot studies from 2 cohorts of dairy cows at the same unit to ensure the appropriate minimum sample size was identified. Robust analysis of these pilot data enabled the the accurate estimation of the minimum number of animals needed to maximise the likelihood of obtaining highly predictive algorithms; this number is used in the current study design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?
Pilot studies have been conducted prior to the design of this project. Additionally this study involves the establishment of a biobank of samples that will be stored and catalogued for future use to ensure the samples collected will be easily accessible for ongoing research. Samples will be made available for under-and post-graduate studies within the University, for the generation of preliminary data for further grants and will also be made available to collaborators where appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Dairy cows represent the most appropriate animal model for studying lameness in this species and will enable the underlying biological mechanisms that are relevant to cows producing milk in a commercial farm setting to be studied in detail. Holstein cows have been chosen as this breed makes up the majority of milk producing cows in the UK so the results of this study will be applicable to most animals in the UK. Throughout the work, animals will be group-housed to provide near-commercial environments and conditions to ensure findings are relevant to the UK dairy industry. As such, our choice of animals and approach is the most refined for the intended purpose and the only possible method to meet our research aims. Their use also maintains continuity with existing data collected as part of pilot studies, therefore expanding on the data available to achieve the aims of the study.

Why can’t you use animals that are less sentient?

Lameness is primarily a disease of adult cattle and the underlying mechanisms being studied are likely specific to dairy cattle, therefore this stage of the species needs to be used to achieve the study aims and to make the substantial improvements in lameness urgently needed for the global population of dairy cattle.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals on the study will be monitored daily by farm staff and weekly monitoring of lameness and body condition score will be conducted as part of the research protocol. This level of monitoring will ensure any changes to condition, demeanour or behaviour or significant deviations from normal will be recorded, and where appropriate, result in discussion with the staff within the facility, the NVS or their deputy and appropriate action taken. Health and production parameters are also measured with a high frequency via the robotic milking system which alerts farm staff to health and production deviations from normal. These alerts will also result in the appropriate discussions. All animals will be sampled within their normal environment to minimise any welfare costs due to separation from the herd.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Throughout the course of this project we will make reference to multiple sources for best practice guidance including:

NC3R’s website for details on experimental design: https://nc3rs.org.uk/experimental-design

NC3R's ARRIVE guidelines: https://www.nc3rs.org.uk/arrive-guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular liaison with local NACWO and NVS. Subscription to the NC3Rs monthly email alerts provide the most recent developments in NC3Rs publications, guidance and information. We also receive regular updates and latest animal welfare guidance information via bulletins disseminated from our Biomedical Research unit.

201. Mechanisms regulating gene expression in health and disease

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

gene expression, development, enhancer, transcription, RNA

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand how genes are switched on and off in the correct cells, at the right time and at appropriate levels during the development of embryos and organs, and why inheriting mutations that affect this process can cause developmental disorders in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important as it will allow us to:

test how cells switch genes on and off in cell types that are typically difficult to access in human patients

test if mutations that have been identified in patients with certain developmental disorders are responsible for that disease understand better how mutations in our DNA affect genes switching on and off so that we can better predict disease-causing mutations in patients and families

What outputs do you think you will see at the end of this project?

The primary outputs of this project will be research publications that improve our understanding of how genes work and how inherited mutations cause genetic disease.

Who or what will benefit from these outputs, and how?

Short-term impacts are likely to be primarily on scientific researchers working in these immediate research areas, and these impacts are likely to be continuous throughout the life of the project.

Medium-to-long term impacts beyond the timeframe of this project include better predictions of whether some types of inherited mutations will or will not cause developmental disorders, which has potential to impact on patients with these disorders and their families.

Longer term impacts might potentially extend to better understanding of how some developmental disorders arise, and the development of therapeutic approaches to treat or prevent these disorders.

How will you look to maximise the outputs of this work?

Outputs will be maximised through publication in high profile research journals, and publicity through conventional and social media channels. Work covered by previous versions of this project licence has been incorporated into popular science books and media.

Raw and processed data will be made available on public databases to allow other researchers to study and build on this work, and to identify any links that we might not have been able to find ourselves, potentially using approaches or techniques developed subsequently.

Genetically altered lines developed in this project will be made available to other researchers, and genetically altered lines that are likely to be in high demand will be deposited in appropriate repositories (e.g. MRC Harwell hub of the European Mouse Mutant Archive).

Dissemination of new knowledge that has potential to be translatable to the clinic will be achieved through collaboration with clinical colleagues.

Species and numbers of animals expected to be used

- Mice: 20000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mouse is a good model to study regulation of gene expression, its impact on normal development and how it can go wrong in human disease as there is a large volume of genetic and molecular knowledge in this area in this species. The work on exemplar disease loci such as *Sox9*, *Pax6* and *Shh* build on extensive detailed previous studies defining enhancer elements and gene regulatory mechanisms at these loci in mice. The availability of reagents such as antibodies, and existing genetically altered lines, that are used to study these processes also facilitate research using mouse models. The ease of genetic manipulation of this species, and the relatively short generation time are also advantageous.

This work will use mice containing genetic alterations in genes that affect regulation of gene expression. These animals will allow us to uncover and understand how gene expression is regulated during normal development, and how inherited genetic mutations can disrupt this process and cause developmental disorders. Non-genetically altered animals will also be used as controls, and to assess regulation of gene expression during normal development.

The choice of life-stages used is mainly determined by the gene expression patterns of the genes under study, the developmental timings of the organs in which these genes function, and the stages of development at which the associated developmental disorders arise. Most of the work in this project will be done on embryos, sometimes at developmental stages before the embryo becomes protected. Some work may be done in post-partum pups or in adults to assess longer term consequences of altered gene expression, or to study development of cells and organs where significant parts of their development occur during post-natal stages (e.g. neurons).

Typically, what will be done to an animal used in your project?

Most (>90%) of the animals used in this project will be used in breeding and maintenance procedures to generate mice with the desired genetic modification. Animals will typically be killed using a schedule 1 method, then post-mortem tissue dissected for subsequent analysis by molecular techniques.

Some mice (~5%) will experience an additional procedural intervention prior to killing and tissue collection e.g. intraperitoneal injection with the nucleotide analog BrdU to label proliferating cells.

A small number (~1%) of mice may experience ageing to 12 - 24 months to allow effects on age- dependent effects on regulation of gene expression to be studied (e.g. analysis of NMD reporter mice).

What are the expected impacts and/or adverse effects for the animals during your project?

The majority (>80%) of the mice used in this project are expected to experience sub-threshold levels of severity.
Some mice (~10%) used in this project are expected to experience mild levels of severity due to the nature of the genetic alteration used (e.g. mild growth restriction that does not impact on the ability of the animals to feed or drink, or detectably alter their movement or behaviour).

Some mice (~5%) used in this project are expected to experience mild levels of severity due to administration of agents (e.g. procedural intervention to intraperitoneally inject the nucleotide analog BrdU to label proliferating cells will result in transient mild threshold pain due to the injection itself).

A small number of animals (~1%) may also experience mild adverse effects associated with ageing to 12 - 24 months.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (>80%) of the mice used in this protocol are expected to experience sub-threshold levels of severity.

Some mice (~20%) used in this protocol are expected to experience mild levels of severity due to the nature of the genetic alteration used (e.g. mild growth restriction), or due to administration of agents (e.g. procedural intervention to intraperitoneally inject the nucleotide analog BrdU to label proliferating cells), or due to ageing to 12 - 24 months.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The genes and mutations that will be studied in this project are associated with regulation of gene expression and originate from either genetic changes associated with developmental disorders, or from studies in cell line, biochemical or other animal models.

For genes and mutations that are associated with clinical mutations and human populations, animals are needed to study how these genes and mutations cause these developmental disorders as this type of mutation as relevant human tissue at the appropriate stage in development is typically difficult to obtain from normally developing embryos, and extremely difficult to obtain from embryos affected with these disorders. Therefore, animal models allow the effects of candidate genetic mutations and

polymorphisms to be studied in the relevant tissue and at the correct developmental stage to help understand how these mutations and polymorphisms cause to these disorders.

For genes and mutations that are associated that have already been studied in cell line models, biochemical or other animal models, animal use is often needed to test whether key aspects of gene function that have been uncovered in these other models is relevant to cells and tissues during normal development, and how these relate to developmental disorders. Therefore animal models are needed to study mechanistic aspects of gene expression regulation in transient and dynamic developing tissues that are often not particularly well modelled in cell culture, or readily available from human embryos.

Which non-animal alternatives did you consider for use in this project?

Cell-free *in vitro* models, computational predictions and cell line models were, and will continue to be considered during the course of this project. Notably, some of the mechanisms that will be studied in this project build on information obtained from work from some of these alternative systems.

This project is part of a larger programme of work that incorporates biology across scales, spanning computational predictive models, cell line models, animal models and human population genetics and human clinical genetics. The animal use within this project is typically a component of a larger piece of work spanning at least two of these experimental approaches, and will model and validate key findings from *in vitro* experiments and clinical data.

Why were they not suitable?

Biochemical reconstitution of gene expression in its entirety is not currently possible, therefore could not be used to replace animal models in this project. Biochemical reconstitution of individual reactions within this process can provide some insight but likely still lack key components and are restricted in scope.

Cell line models are the main alternative to developing embryonic cells and tissues, however cell lines typically do not model these transient and dynamic developing tissues particularly well. Many of the genes that will be studied in this project have been studied in cell line models that approximate some aspects of development (e.g. embryonic stem cells, differentiating embryonic stem cells), but key findings need to be confirmed in the tissues in which these genes are normally expressed and developmental orders typically arise.

For studies involving regulatory elements such as enhancers: these modular regulatory elements are typically tissue-specific and active only transiently during development, with different cell types and developmental stages using distinct enhancers. Therefore some experiments relating to these elements need to be done in the developing tissues where these elements are normally active.

Computational predictions of the effects of non-coding mutations on gene expression are still developing, and are not at the same level of accuracy as those involved in predicting the effects of coding mutations on protein activity. Therefore these methods are currently not reliable to predict the impact of many non-coding mutations and genetic variation on disease. The work that will be undertaken in this project will improve our understanding of how non-coding mutations and genetic variation impact on gene expression.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based on similar projects currently undertaken on three expiring project licences held at MRC Human Genetics Unit that have this overlapping research theme (P93007F29, P2A477A62, and P76777883).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The majority of the animals used in this project are used in breeding and maintenance protocols to generate experimental animals of the desired sex and genotype.

I have consulted with a statistician to determine appropriate sample sizes and experimental design to associate genotype with phenotypic effects in these cohorts of experimental and control animals. Data from previous phenotypic analyses were used to generate estimates of data distributions and effect sizes to facilitate those sample size calculations.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cell line models, structural predictions, and biochemical assays will be used where possible to design and test specific types of genetic alteration, or to test functionality of fusion proteins, to identify the key genetic alterations to introduce into mice. This will reduce the number of mice used by limiting the genetic alterations studied to those that are likely to be most informative.

Efficient breeding strategies will be used to limit the number of animals used. Genetically altered lines will be cryopreserved to facilitate sharing and distribution of these lines, and to limit breeding and maintenance once all experimental cohorts have been collected.

Multiple phenotypic assays can typically be performed on tissue isolated from each animal, and some material frozen for use in multiple molecular assays over long time scales, reducing the number of animals needed to generate significant mechanistic insight.

For some aspects of this project, cell line models (e.g. neural stem cells) can be established from genetically altered lines that can allow extensive detailed molecular laboratory analysis that can continue for years.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the

mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most of the animals used in this project (>70%) will experience breeding and maintenance protocols, but will not experience any additional procedural intervention, and will therefore experience minimal distress or harm. The genetic alterations typically involve genes and pathways involved in regulation of gene expression, and the pain and suffering associated with these genetic alterations will be minimised by using humane end-points that precede the onset of clinical symptoms. The genetically altered tissue that will be obtained from these animals will be obtained post-mortem after killing by a schedule 1 method.

Some animals will experience additional procedural interventions (e.g. injection of agents to activate/inactivate transgenes) prior to killing by a schedule 1 method and tissue collection. This is expected to cause mild and transient discomfort, but is not expected to cause lasting harm to the animals. These additional procedural interventions are often refinements that restrict any potential harmful effects of a transgene to specific tissues and times in relation to the injection, reducing the
harmful effects and severity of a genetic alteration (injection of agents to activate/inactivate transgenes).

Why can’t you use animals that are less sentient?

The life stages used for these experiments are largely dictated by developmental disorders that are being studied, and the expression patterns of the associated genes. Experiments that model developmental disorders caused by altered expression of developmentally regulated genes must be carried out at the embryonic stages during which these genes are expressed and the developmental disorders arise. Experiments that model developmental events that occur post-natally (e.g. neurons, spermatogenesis) will need to use post-natal mice.

Animals that are less sentient (e.g. nematode worms, fruit flies) often do not use the same genes, developmental mechanisms or have the relevant developmental tissues as some of the processes under investigation in this project. Zebrafish will be used to model some aspects of eye development and developmental gene regulation where appropriate under this programme of work, but this will be undertaken under a separate project licence.

Most of the animals used in this project (>80%) will experience breeding and maintenance protocols, but will not experience any additional procedural intervention. The genetically altered tissue that will be obtained from these animals will be obtained post-mortem after killing by a schedule 1 method, therefore in most cases terminal anaesthesia does not provide significant benefits. However, on occasions, terminal anaesthesia may be used to allow exsanguination, when we require to limit blood contamination of tissue for downstream studies or for perfusion or perfusion fixation when we require to ensure compete tissue architecture is retained or for organ/tissue removal when we require to remove organs immediately to snap freeze to maintain RNA integrity at the point of culling.

Occasionally, when we need to limit blood contamination of tissue for downstream studies by exsanguination, or to limit subsequent blood or immune cell contamination of tissue by perfusion, or to retain tissue architecture by perfusion fixation, or to maintain RNA integrity

at the point of culling by immediately snap freeze organs, terminally anaesthetised animals will be used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The majority of the animals (>70%) will only experience breeding and maintenance protocols. Refinements associated with this protocol include environmental enrichment, and implementation of non-aversive mouse handling.

Any necessary injections will be refined by implementation of non-aversive mouse handling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs - Responsibility in the use of animals in bioscience research
https://nc3rs.org.uk/3rs-resources/responsibility-use-animals-bioscience-research

Medical Research Council - Guidance on research proposals involving animal use
https://www.ukri.org/councils/mrc/guidance-for-applicants/proposals-involving-animal-use/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Annual PIL refresher courses run by the University will help keep me, and other PIL holders implementing this project, informed about advances in 3Rs.

Experimental interventions will be authorised locally by the our Named Veterinary Surgeons through a time-limited Experimental Request Form (maximum duration 1 year), which will allow timely implementation of 3R advances in these regulated procedures.

202. Recognition memory in an animal model of Alzheimer's disease: Associative mechanisms

Project duration

5 years 0 months

Project purpose

- Basic research

Key words

Association, Recognition memory, Alzheimer's disease, Mouse

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to refine understanding of the psychological mechanism underlying a specific recognition memory deficit we have found in a young transgenic mouse model of Alzheimer's disease (AD), and which we think could serve as a cognitive marker of preclinical AD.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The brain changes that characterise Alzheimer's disease (AD) begin many years before symptoms become apparent, and once the condition is diagnosed the condition can be difficult to treat because the brain damage is advanced. Thus early diagnosis and treatment of AD is a research priority, and this requires development of effective screening tools to identify AD at an early stage, as well as evaluation of prospective treatments. Psychological tests are ideal for screening purposes as they are cheap, noninvasive and easy to administer, and if such tests are translational, they can also be used for drug evaluation in preclinical studies. The specific aim of this work is to refine a translational

psychological test that our previous work has shown is indicative of early cognitive deficits in a mouse model of AD.

Our previous work on a transgenic model of AD identified a subtle and early-emerging pattern of deficits in one particular, well characterised mouse model of AD, the APPswe/PS1DE9. We used an object recognition task, performance on which relies on a rodent's natural curiosity. If mice explore an object and are then permitted to explore it and a second, novel object, they preferentially explore the novel object - suggesting they recognise the previously experienced one. We interpret this behaviour in terms of associative theory, which explains recognition in terms of two processes, self-priming and retrieval-priming. Self-priming refers to the phenomenon in which a stimulus is processed less well if it has been repeated; for example, if someone bangs on the door twice, you would less startled the second time).In contrast, retrieval-priming refers to the processing of a stimulus being reduced when it is anticipated (for example a ring on the doorbell might make you jump, but less so if you heard the footsteps coming up the path. We found that although performance on the standard recognition task was normal in these young mice, specially designed task variants that measure self-priming and retrieval-priming separately revealed a selective deficit in retrieval-priming in the transgenic mice, compared to wild-type littermates. This subtle deficit emerged at 4-5-months of age, a point at which neuropathology is only beginning to develop in this strain, and so could be an important diagnostic sign of preclinical AD.

We interpreted this finding in terms of an established model of associative learning, according to which these impairments reflect a deficit in an associative learning process. If this hypothesis is correct, it implies that performance should also be impaired on a wider range of tasks that depend on such associative learning. It also raises the question as to whether it is association formation that is impaired, or whether the deficit stems from e.g. a failure to process certain types of stimuli involved in an association (e.g., spatial cues), or is only evident when the to-be-associated events are separated in time or space. The work in Objective 1 aims to establish the boundary conditions under which this associative learning deficit may be observed, refining our characterisation of the deficit seen in these animals. This will be achieved partly by studies using the recognition-type task; however, an integral part of our hypothesis is that association formation might be impaired in these animals, and as association formation is time-sensitive, some of the experiments will require use of a Skinner-box type task, motivated by mild food deprivation, as these afford a degree of temporal control over the delivery of the various stimuli that is impossible in the recognition tasks. Some of these Skinner-box tasks will require pilot work in non-transgenic, C57 mice, to refine the parameters before the transgenic animals are put through the procedures.

This work is key to improving our understanding of the cognitive processes impaired in prodromal AD, and will inform future development of diagnostic tests suitable as screening tools, and translational tasks for testing new drug treatments.

This work has a more general importance. Recognition memory is a theoretically important phenomenon that is impaired in dementia and also normal aging, and recognition memory tasks are routinely used across the field of neuroscience. Our theoretical interpretation of this effect in terms of an associative mechanism is an advance over previous accounts, as it seeks to explain recognition in terms of a more general theory of learning. Thus, the proposed work will have significance beyond its specific application to Alzheimer's disease.

What outputs do you think you will see at the end of this project?

First, this work will give us new theoretical information about the nature of recognition memory impairments in the early stages of the disease in this transgenic model. This will, more generally, increase our understanding of how cognitive impairments develop in AD, which is of clear theoretical interest to those with a specific interest in AD. In addition, these experiments are motivated by application of a new, associative theory of recognition memory. Thus it will also be of immediate interest to those concerned with the theoretical associative mechanisms underlying recognition memory.

The publication outputs of this project primarily comprise scientific articles that will be published in leading journals, and presentation at international conferences.

Who or what will benefit from these outputs, and how?

The behavioural results will be of immediate benefit to those studying the early cognitive correlates of AD and also to those interested in the study of associative learning, and how it may be applied to broader phenomena like recognition memory. Also, as the work develops a translational model of recognition memory, it will be of interest to the many neuroscience researchers using tasks of this type to evaluate memory performance.

In the medium term, as this work will provide information about the potential recognition memory deficits that may be present in human patients in the early stages of AD, it will be of benefit to more clinically oriented researchers who are interested in developing new diagnostic tests for AD.

In the longer term this work could potentially result in a new, diagnostic test for AD, that could be used by clinical practitioners to identify people in the early stages of the disease who could benefit from potential treatments.

How will you look to maximise the outputs of this work?

The outputs will be maximised by rapid publication of the key findings, including null results, presentation at both national and international scientific conferences (e.g. Associative Learning Symposium UK, Associative Learning Group, Australia, Alzheimer's Research UK, British Neuroscience Association), and also more general dissemination public engagement events (e.g. Pint of Science) and also interested user groups (e.g. IMH dementia groups).

Species and numbers of animals expected to be used

- Mice: 1840

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.
Explain why you are using these types of animals and your choice of life stages.

Broadly, the aim of this project is to conduct a theoretical analysis of the subtle recognition memory deficits seen in this model, at an age equivalent to human prodromal AD. The work on which this project is based was conducted in mice, specifically the APPswe/PS1DE9 mouse, and so we propose to continue using this strain. This strain is

highly characterised, and there is a considerable body of relevant previous work using this specific model which justifies its continued use in this project.

Specifically:

previous research allows us to pinpoint the age equivalent to the prodromal stage of AD: systematic evaluation of the development of the amyloid plaques characteristic of AD in these animals has revealed that they first appear at 4-5 months of age, but are only consistently observed from 6 months (Garcia-Alloza et al., 2006). Other signs of neuropathology appear much earlier, however; Zhang et al. (2012) first observed elevated levels of oligomeric Aβ at 4 months of age in these mice, and these were positively correlated with indices of cholinergic dysfunction and oxidative damage – which the authors interpreted as early pathological responses to oligomeric Aβ. These authors also found that cognitive deficits appeared at the same age. This work underpins a key assumption of this project, that 4-5 months of age may be regarded as equivalent to the preclinical stage of AD.

an unusually high number of studies in this strain have examined performance on the spontaneous object recognition (SOR) test of recognition memory, on which this work is based. From this research a clear picture emerges: recognition deficits are routinely observed in older mice (9-12 months) but only occasionally reported at 6-7 months (e.g. Donkin et al., 2010; Jardanhazi-Kurutz et al., 2010; Li et al., 2014; Yan et al., 2009; Yoshiike et al., 2009; but see Frye & Walf, 2008), but never at less than 6 months (Bonardi et al., 2011; Bonardi, Pardon & Armstrong, 2016; Pedros et al., 2014). These findings underlie the second key assumption underlying this project, that performance on the simple object recognition task is not impaired in the 4-5-month-old preclinical stage of the disease in this model, and only subtle deficits are evident at this point. Our own work has explored these postulated subtle recognition deficits in this strain. We argue that SOR recognition performance comprises the component processes of self-priming and retrieval-priming, and we have observed a selective deficit in the retrieval-priming process in 4-5-month old mice of this strain. This result underpins our main hypothesis, that components of object recognition ability are impaired at this specific, early stage.

Some of these studies will require preliminary pilot work to refine parameter choice, and these will be conducted on C57 mice of approximately the same age, as these are a base strain for APPswe/PS1DE9 animals.

Typically, what will be done to an animal used in your project?

The first type of behavioural study, a recognition-type task, might involve:

extensive habituation to the apparatus

a series of recognition-type tests to evaluate associative interpretation of recognition memory performance. All behavioural measures are taken by videoing the animals with cameras placed above the arenas.

Habituation involves a series of placements, typically six of 10-min duration, in which the animal is placed in the experimental arena (a white perspex box with high walls) and allowed to explore. After this period it is returned to the home cage.
This behavioural recognition-type test typically comprises a series of occasions (2-4) in which the mouse is placed in the arena for a short period of time (10-15 minutes). These placements may occur within a day or across days, with interplacement intervals ranging

from 5 minutes to 24 hours. During these placements a number (2-4) of small, domestic junk objects (e.g. salt cellars, ashtrays etc) are placed in the arena, which the animals are allowed to explore. The arenas may also be lined with various inert materials to make aspects of this surrounding 'context' more distinctive; these materials could include covering the walls with patterned linings, or the floors with distinctively textured materials.

Animals might experience 4-6 such behavioural tests in a typical study. The entire sequence of tests (including rest days) would normally be no more than 4 weeks.

A second type of behavioural study, a Skinner box task, would involve

mild food deprivation (gradual reduction to no less than 80% of free feeding weight – i.e. no more than 20% weight loss relative to free feeding weight – over the course of about a week), and then this weight level is maintained over the course of the study by controlled feeding. This level of deprivation is usually considered mild.

a series of testing sessions in a Skinner box, in which the animals are trained that various combinations of motivationally neutral stimuli (e.g. low intensity auditory or visual stimuli) are either paired or not paired with outcomes such as food or sucrose pellets. Testing sessions would be typically conducted once daily, and each session would last for about an hour. An animals would typically experience no more than one Skinner box-type task, and a typical experiment would last about 2-3 weeks.

An animal would experience either mild food deprivation and a Skinner box-type task, or one or more recognition-type tests, or both types of task.

If recognition testing follows a Skinner box-type study, it would be preceded by a period of at least three days of access to full food. The total duration of testing for an animal would normally not exceed 7 weeks

What are the expected impacts and/or adverse effects for the animals during your project?

The recognition-type task involves placing animals into an arena and allowing them to explore small, domestic junk objects (e.g. salt cellars, ashtrays etc) while they are video-recorded. The only adverse effect we have seen is mild stress on initial placements - evident as a tendency to freeze and defecate. Both are typically confined to the first time the mouse is in the arena. Thereafter the mice seem relaxed – which is critical to the success of these experiments, which rely on the mice being willing to freely explore the objects presented.

The Skinner-box type task involves mild food deprivation; no specific adverse effects associated with food deprivation have been reported with this strain, nor major differences in growth rate compared to control mice. Placing the animals into the Skinner box chambers will initially be mildly stressful, but this quickly dissipates, being typically confined to the first time the mouse is in the chamber. That the mice are relaxed during training is critical to the success of these experiments, which rely on them being able to learn efficiently.
Perhaps the main potential adverse effect of this project stems from the use of this strain of transgenic mouse. In common with other strains with these mutations, it has an elevated mortality rate (10.5% for the colony as a whole, approximately 4% in our experiments). These deaths are sudden, and we have never yet experienced any sign that the animal suffers beforehand; for instance, in one case we have video footage of an animal

exhibiting normal exploration behaviour about an hour before it was found dead. Evidence suggests that these deaths are the likely the result of brief (~30-s duration) seizures that occur in this strain, which in a few cases can be fatal (Minkiviciene et al., 2009). Consistent with this interpretation, none of the deaths we have observed are associated with any post-mortem pathology. We have no evidence that mortality is elevated by the behavioural task. At the end of the experiments the mice will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Transgenic mice: Moderate; Pilot work in normal mice: Mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Achieving the objectives requires observation of behaviour, and so we must use live animals. Performing the studies in patients at an equivalent stage of the disease is impossible, as early diagnosis is impossible (developing an early diagnostic test being the motivator for the work).

Which non-animal alternatives did you consider for use in this project?

None - achieving the objectives requires observation of behaviour.

Why were they not suitable?

Because achieving the objectives requires observation of behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For the behavioural work our initial estimate of sample size for these studies is guided by power analysis of our previous work (using Gpower Erdfelder, E., Faul, F., & Buchner, A., 1996), which yields approximately 16 animals per group, and hence 32 per experiment. Assuming 10 experiments per year over 5 years, this yields 1600 animals in total. An

additional 3 experiments per year will also be required to pilot the Skinner box tasks; these will be within-subject experiments, and so add 16 x 3 = 48 animals per year, and an additional 240 animals over the course of the project. This gives a total of 1840 animals, 1600 transgenic and 240 C57 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will minimise the number of animals by using within-animal comparisons for our key recognition measures and analysing behaviour over repeated time periods. We will also use statistical techniques to estimate the minimum number of mice consistent with obtaining a scientifically meaningful result. We will reduce variability by counterbalancing the stimuli, objects, arena linings etc, and ensuring the animals are well habituated to the apparatus and extensively handled before the start of testing.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Key effects will be routinely piloted in non-transgenic mice to perfect methodology, and hence optimise estimates of sample size.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Achieving the scientific objectives of this work, and so realising the benefit of this project, requires us to continue using the APPswe/PS1DE9 mouse model. This choice is driven by the fact that the assumptions underlying the proposed project stem from the considerable body of previous work using this specific model, and that the critical evidence on which this project is based comes from work with this strain. Although these animals develop a form of Alzheimer's disease, this does not affect their behaviour in any obvious way, aside from a slight tendency to be more active. This strain does, as is common with genetically manipulated animals, have a slightly elevated mortality rate (4% in our experiments), but these deaths are sudden and unpredictable, and not preceded by any sign of distress or accompanied by any obvious pathology**;** evidence suggests they are caused by brief (~30s) seizures that are characteristic in this strain (Minkeviciene et al., 2009).

The behavioural experiments we propose are very benign. The recognition-type tasks involve placing the mice in an arena where they are free to explore small domestic objects, such as ashtrays and salt cellars – which could be regarded as a form of environmental enrichment. The Skinner box-type tasks involve placement in a Skinner-box chamber and presentation of pairings of various combinations of benign stimuli (e.g. low intensity tones, lights etc) and food or sucrose pellets. It is important for the quality of the results obtained to ensure the mice are relaxed enough in this apparatus to explore the objects, and so

every effort is made to minimise stress in these tasks by extensive habituation to the apparatus and handling of the animals before the start of testing.

The mild food deprivation required for the Skinner-box type tasks will be at the minimum level compatible with obtaining reliable experimental results, and never less than 80% of growth-adjusted free-feeding weight. In fact restricted feeding can increase longevity in rodents: life expectancy of laboratory rats maintained at 80% ad lib weight is longer than that for rats maintained on ad lib feeding (e.g. Vitousek, Gray & Grubbs, 2004).

Why can’t you use animals that are less sentient?

Because the work relies on behavioural measures, which requires use of an awake and moving animal, and because the age at which the experiments are conducted is central to our experimental hypothesis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Optimal performance on these behavioural tasks requires the animals to be relaxed enough to explore the objects or learn the Skinner-box tasks, and this is an additional motivation to constantly keep an eye on refining our procedures. The extended habituation procedure is one example of this; another is the introduction of daily handling a number of days before the behavioural testing begins. Moreover, although as noted the elevated mortality in the transgenic mice does not have an obvious cause or trigger, in the eventuality that it is exacerbated by stress these refinements should be of benefit in this respect also. The food deprivation schedules will be the minimum required to obtain reliable performance, and this will be monitored throughout.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult resources such as N3CR and LASA websites and newsletters (see above) on an ongoing basis, as well as routinely using ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to the regular NC3Rs newsletter, ensuring we are kept informed about all advances in refinement, so that we can implement all relevant measures promptly.

203. Defining early entry mechanisms of Mycobacterium spp. into the host

Project duration

5 years 0 months

Project purpose

- Translational or applied research with one of the following aims:
  - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Mycobacteria, Pathogenesis, Diagnosis, Cattle

Animal types	Life stages
Cattle	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Johne's disease (JD) is a common and chronic disease of the gut of ruminants caused by infection with the pathogen Mycobacterium avium subspecies paratuberculosis (MAP). The aim of this project is to investigate pathogen-encoded factors which allow MAP to invade the gut. By better understanding the pathogen-host interactions at the early stages of infection, we hope to identify cellular pathways that could be targeted to facilitate the rational design of strategies to control and treat MAP infections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

JD has a significant impact on the health and welfare of cattle leading to reduced productivity, economic losses and, ultimately, death. At early stages following infection animals show little evidence of the disease, making it difficult to detect and easy for infection to spread unnoticed. Currently, reliable effective vaccines and treatments are not

available for JD so control programmes rely on detect and cull policies which are ineffective and expensive. A better understanding of the biology of JD, particularly of pathogenesis and the complex host-pathogen interactions in early MAP infection, is required to develop improved diagnostic tools and novel vaccines.

What outputs do you think you will see at the end of this project?

Outputs arising from this project include:

Determination of the cell types involved in transit of MAP across the gut lining to accurately identify the cellular portal of entry

Characterisation of the mechanisms by which MAP crosses the gut lining to identify critical cellular pathways and mechanisms of entry

Identification of critical MAP genes required for host tissue invasion by comparing e.g. naturally occurring field strains of MAP versus mutant strains

Who or what will benefit from these outputs, and how?

The principal beneficiaries of the studies conducted under this Project are:

Researchers studying JD, MAP and other intestinal diseases who will benefit from data on early events following MAP infection including key cellular responses and changes in bacterial function and gene expression

Students, research assistants, post-doctoral and early career scientists will benefit from training opportunities in diverse areas including molecular biology, cellular and molecular immunology, pathology and in vivo research with large animals

The pharmaceutical industry will benefit since we will pinpoint areas for the development of new diagnostics, treatments and vaccines

Policy makers, the farming industry and the dairy industry will benefit from data which has the potential to improve JD diagnosis and management strategies, and reduce economic losses associated with JD.

Animals affected by JD will benefit from improved JD diagnosis and management resulting in reduced disease occurrence and reduced suffering of individual animals.

Work arising from this Project will be of interest to the general public, not least because of the publicised but controversial link between MAP and Crohn's disease in humans, affecting approximately 1 in 1,000 people in the UK. Ultimately a reduction in JD will result in lower levels of human exposure to MAP in animal products.

How will you look to maximise the outputs of this work?

Subject to approval from academic partners, we will endeavour to publish as much information as possible from this Project:

We will engage with policy makers and academics through publications, presentations at conferences, invited lectures, via our website pages and through links with relevant professional societies.

We will identify, protect and exploit intellectual property and engage with industry as appropriate
We will exploit existing links to those delivering knowledge and tools to the farming industry and will engage with veterinary surgeons responsible for delivery of JD diagnosis and management strategies.

We will use short films, public presentations and lay articles to engage with the general public including promoting education in schools through a series of events organised through the host institutions.

Species and numbers of animals expected to be used

- Cattle: 45

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use calves <5 months of age since this is representative of the age at which calves are typically exposed to MAP on farms.

Typically, what will be done to an animal used in your project?

Typically the following will be done to animals in this project:

For 24 hours prior to surgery food will be withheld but animals allowed free access to water.

Animals will be anaesthetised and maintained under anaesthetic throughout the procedure which will be of 2-18 hours duration.

Surgical procedure - The peritoneal cavity will be opened and loops will be made in the small intestine by ligation. An inoculum of infectious agent will be injected into each loop, the loops replaced into the abdomen, and the abdomen closed. At various time-points post-challenge the abdomen will be re-opened and the intestinal loops will be excised and removed. Following removal of the loops between 2 and 18 hours post-challenge animals will be humanely killed by an approved method while still anaesthetised.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect to see any adverse effect in the procedures carried out under this Project.
Animals will be anaesthetised prior to any procedures being performed and will be maintained under anaesthetic throughout the surgery and should therefore not experience any adverse effects other than an intravenous injection to induce anaesthesia.

Animals will be killed by an approved method while still under anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

100% of calves will experience a Non-recovery severity limit

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of a gut-loop model of infection allows detailed investigation of the initial stages of Mycobacterium avium subsp. paratuberculosis (MAP) infection at the relevant areas of the gut, which could not be achieved using cell-based systems or standard oral challenge of animals.

Which non-animal alternatives did you consider for use in this project?

We considered a number of in vitro models including an M-cell like cell culture system, MAC-T epithelial cell lines, polarised epithelial cell lines, and intestinal organoids. However, none of these models are able to accurately recreate the complexity of pathogen-host interactions of MAP at the gut lining.

Why were they not suitable?

All of in vitro models we considered are unable to accurately recreate the complexity of the gut lining and MAP pathogen-host interactions to a degree that is biologically relevant.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated 9 animals per year includes up to 7 animals that will undergo the gut loop procedure as well as up to 2 additional animals to be made available in case of anaesthetic death or surgical complications.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals used in this Project has been scrutinised and approved by an internal Experiments and Ethical Review Committee in conjunction with statistical advice to ensure that as few animals as possible are used to generate statistically robust data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In each animal, multiple gut loops will be created in multiple regions of the gut. For each gut loop section, tissues collected will be subject to multiple different tests. By maximising the number of gut loops created in a single animal and the number of tests performed on samples from each gut section we will minimise the total number of animals required while still generating statistically robust data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Calves <5 weeks old will be use since this represents the age at which calves are exposed to MAP on farm. Calves will be group housed prior to entering the Project to minimise distress.

Procedures will be performed under general anaesthesia and animals' vital signs will be monitored closely throughout. Animals will be humanely killed by a Schedule 1 method while still under anaesthesia (non-recovery). Since animals are not conscious during the procedure they will not experience pain or distress.

Why can’t you use animals that are less sentient?

We strive to use the least sentient animal possible whilst still maintaining the objectives of the Project. Calves <5 weeks old will be use since this represents the age at which calves are exposed to MAP on farm. It is not biologically relevant to use a more immature life stage.

The procedure will be performed under terminal anaesthesia so that the animals are not conscious at any point during the procedure.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For the duration of anaesthesia animals' vital signs will be monitored. Additional supportive measures e.g. intravenous fluids, heating pads etc. will be available if required to keep the animals as comfortable as possible during the procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are no specific best practice guidelines for the specific procedure used in this Project. More general best practice guidelines including NC3Rs, ARRIVE, PREPARE and RSPCA resources will be consulted and followed.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of my institution's 3Rs Committee which meets on a monthly basis to discuss and advise on advances in this area. There are a number of 3Rs Committee members who are also on my institution's Animal Welfare and Ethics Review Board (AWERB), and who will be able to advise on effective implementation of any 3Rs advances that arise during the project.

204. Investigating mechanisms, novel therapeutics and diagnostics in thrombus formation and its resolution

Project duration

5 years 0 months

Project purpose

- Basic research
- Translational or applied research with one of the following aims:
    - Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
    - Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Thrombosis (clots), Inflammation, Stents, Atherosclerosis, Imaging

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, embryo, aged
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The objectives of this project are to address questions in 2 main interconnecting areas.

Molecular and cellular mechanisms - What are the molecular and cellular interactions that: (i) give rise to a blood clot (thrombus) in blood vessels; (ii) regulate the natural removal of a thrombus by the body (natural thrombus resolution); (iii) give rise to a thrombus that forms inside wire mesh devices (stents) deployed to restore blood flow in vessels with existing clots; and (iv) are responsible for the effects of thrombosis on the development of other inflammatory vascular conditions such as the build up of fatty deposits in the arteries (atherosclerosis)?

Treatments and diagnostics - Can we use information gleaned from our mechanistic studies to: (i) target novel pathways that prevent thrombus formation, enhance the resolution of an existing thrombus, or prevent the potentiating effect of thrombosis on the

development of atherosclerosis in arteries; (ii) identify biomarkers that can be quantified to provide accurate and specific measures of the presence and structure of a thrombus; (iii) further develop and refine imaging methods (e.g MRI) to provide objective information on thrombus size and structure and hence susceptability to being dissolved by thrombolytic agents (enzymes)?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Thrombosis in blood vessels (arteries and veins) that help move blood around the body (to and from major organs, such as the heart and brain), are a major cause of death and long-term conditions including paralysis (from strokes), leg ulceration and limb loss, which are debilitating and inflict a considerable economic burden on healthcare provision.

Current treatments include: the use of drugs (anticoagulants) that stop further thrombus development (allowing their natural removal by the body); enzymes (thrombolytics) that break up clots; or interventions that either surgically removes the thrombus, or deploy a wire mesh device (stent) to re- open a vessel by pushing the thrombus against the vessel wall. The problems with these treatments are that they can lead to a significant risk of fatal bleeding, or re-thrombosis in up to 30% of stented vessels that will then necessitate further intervention.

What outputs do you think you will see at the end of this project?

A better understanding of the mechanisms that regulate thrombus formation and its natural resolution, in particular the relationship between these processes and inflammation.

The development of novel therapeutics that prevent the formation of a thrombus or promote its dissolution without the risk of bleeding.

The development of novel therapeutics that enhance natural removal of already formed thrombus without the risk of bleeding.

The development of imaging methods (e.g. MRI) that facilitate better targeting of patients for treatment e.g. show which clots can be removed by dissolving agents (lytics) and those that will require placement of devices (stents) that push aside the existing clot to establish blood flow in the affected blood vessel.

High impact publications that will disseminate our findings to the greater scientific and medical community and stimulate further work and clinical trials in this area.

Who or what will benefit from these outputs, and how?

Several of our findings could be readily translated into patients in the short term. For example, detecting thrombi that are dissolvable could reduce the incidence of heart attack, stroke and the development of chronic ulceration in the limb affected by thrombosis (post-thrombotic syndrome). In the longer term, our understanding of mechanistic processes that lead to cardiovascular disease discoveries of drugs that prevent thrombosis, or enhance

its removal, without risk of excessive bleeding would lead to improved outcomes in the clinic.

How will you look to maximise the outputs of this work?

We will closely collaborate with clinical colleagues to ensure that any therapeutic strategy or imaging method derived from our work can be tested in clinical trials for safety and efficacy and ultimately find widespread clinical use.

We will also disseminate the results of this work at national and international conferences and workshops and publish in peer reviewed international scientific journals in line with the ARRIVE guidelines (https://arriveguidelines.org/).

Workshops will be organised within our institution where we will share our results and provide hands on training for internal and external academics interested in this work. Other means of dissemination will include talks: at patient and carer events organised by the Vascular Society of Great Britain and Ireland and The Circulation Foundation; the Pint of Science initiative; and active participation in the summer festival of the Royal Society.

Species and numbers of animals expected to be used

- Mice: 7800
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rodent models of thrombosis will be used in this project licence because their molecular and cellular responses to clotting and natural thrombus removal by the body are similar to those seen in patients with this condition.

Typically, what will be done to an animal used in your project?

Rodents used for the thrombosis models may undergo the following.

Bred to express certain gene defects that will allow us to interrogate the importance of those genes in thrombosis; or be given a diet that promotes a similar condition (fatty arteries) to that seen in patients who develop thrombosis in their arteries.

Undergo an operation to create a thrombosis in a vein or artery followed by treatment with agents, cells or bone marrow that might help prevent thrombosis or promote its resolution. These will be administered via direct injection into the thrombus; injection via a blood vessel, muscle, beneath the skin, or into the abdomen; or infused by a mini-pump placed inside the animal.

Imaging over time (by e.g. ultrasound or MRI) to determine the size and structure of the thrombus.

Have small blood samples taken at the time of imaging to evaluate the body's cellular and molecular responses to the thrombus.
Humanely killed and the vessel containing the thrombus, together with a blood sample, removed for analysis in the laboratory.

The duration of this experiment will typically be up to 28days. This will depend on whether the question be asked relates to processes involved in thrombus formation or its natural resolution.

Rodents used as a cell donors may undergo the following.

Bred to express specific gene defects so that cells obtained from these animals also express the same gene defect.

Administration of an agent to induce production of cells we believe may be important in thrombus removal (e.g. specific subset of inflammatory cells) via: (i) injection of the agent into their abdomen (peritoneum) to promote accumulation of the required cells in the peritoneum; or (ii) implantation of a mini-pump placed surgically into the abdomen to deliver the agent over a period of time in order to promote the release of cells from the bone marrow.

Humanely killed and cells removed from the abdomen, blood, or bone marrow for use in our mouse models of thrombosis or further analysis in the laboratory.

The duration of this experiment will typically be no longer than 14days.

All protocols have been refined so that the minimum experimental duration and animal numbers are used to achieve the scientific objectives.

What are the expected impacts and/or adverse effects for the animals during your project?

Rodent models of thrombosis are commonly used for the study of this condition and the surgical procedures and induction of the thrombus are well tolerated by these animals, as collateral vessels allow blood flow to bypass the obstruction to blood flow caused by the thrombus. The protocol for this procedure has been classified as 'moderate' as a surgical procedure is involved, but the well-being of the animals is unaffected as they are seen moving around the cage, grooming and feeding and drinking normally shortly after the operation. Pain following surgery will be minimised by treatment with an appropriate analgesic.

The use of mice in which specific genes have been removed or manipulated to be switched on or off, and agents that induce conditions that are associated with increased artery narrowing leading to thrombosis (e.g. fatty deposits in the artery wall-atherosclerosis) are also widely used in investigations of thrombosis. The genetic manipulations and agents used to promote the build-up of fatty deposits in arteries may result in a small number of mice showing adverse effects such as skin irritation that can lead to skin ulcers. Those animals that do not respond within a few days of treatment will be humanely killed.

Bone marrow transplantation between mice with different genes enhances our understanding of the importance of cells from the bone marrow (e.g. inflammatory cells) carrying those genes on processes involved in thrombus formation or its resolution. While

mice tolerate ablation of their bone marrow by radiation reasonably well, it exposes them to the possibility of infection (immunocompromise). For this reason, irradiated mice are housed in independent ventilated cages during the time they are immunocompromised (up to 21days). Prophylactic measures (e.g. treatment with antibiotics) will also be undertaken to prevent the risk of infection. The mice tend to lose some weight after irradiation, but most recover the lost weight within a few days.

Animals used as cell donors (from the abdominal source) may show adverse effects such as the build-up of fluid in the abdomen leading to abdominal tenderness on handling. Mice displaying this condition will be immediately humanely killed, and the cells that have accumulated in the abdomen removed for our investigations.

In animals having surgery (e.g. for thrombus induction or implantation of a mini-pump), incision wounds may rarely become infected or the stitches breakdown (expected in <1% of animals). These can be treated with antibiotics or resewing of the wound. If these treatments are not effective, the animals will be humanely killed.

All animals will be humanely killed at the end of an experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities and proportion of animals from all experimental protocols experiencing each severity includes:

Mild – ~ 62%

Moderate - ~38% (surgery carried out)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The processes of how thrombosis forms in blood vessels and is removed naturally by the body, involve dynamic interactions between a myriad of molecules and cells that are impossible to replicate in the laboratory (in vitro). It is not ethical to study the effect of injecting substances and cells into patients with disease of their blood vessels without preliminary evidence that this form of intervention may be of benefit. We must therefore to carry out our initial experiments in animal models of thrombosis to allow us to study the cellular and molecular responses and interactions that take place during thrombosis and its natural resolution. We also use these models to assess the effectiveness of treatments

targeting specific mechanisms highlighted by these studies (and studies in patients with clots), on the formation and natural removal of these clots.

I am satisfied that the potential gain, in terms of treatment of human disease, is sufficient to justify the use of animal models.

Which non-animal alternatives did you consider for use in this project?

We will also use laboratory-based methods such as a flow chamber model of thrombosis that we have optimised in our laboratory to screen and assess the activity of cells and agents that we believe from our human studies (running alongside our studies in rodents) may be important in inhibiting clot formation and stimulating its resolution.

Why were they not suitable?

Studies in the laboratory cannot truly replicate the complex, dynamic interactions that take place between the many factors and cells that are involved in the formation of a clot or its natural removal by the body.

We will also develop 'test tube'- based analytical methods for the laboratory screening of cells or agents highlighted by our human studies as potential regulators of thrombosis.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals required for our experimental studies based on our previous experience of the variability in the end-point measures (e.g. thrombus size, composition) in the thrombosis models, and of breeding requirements for use in these models.

The proportion of animals we expect to use over the 5yrs of this project will be:

~60% - used in breeding and maintenance

~36% - used for the thrombosis models

~4% - used as cell donors

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our extensive experience with these models in a variety of wild-type and genetically modified strains of mice has provided us with a good analysis of the variability in the endpoint measures that we have developed with these models, and we have used this

experience to carry out appropriate statistical power calculations for the numbers of animals required in our experiments.

Where we find ourselves using a strain of animal or treatment that we are unfamiliar with, or there is little data in the literature on, then we will carry out pilot experiments using longitudinal or dose escalation analysis in small cohorts of animals in order to provide statistical data that allows animal number estimations for definitive larger experiments.

In experiments that intend to understand the effect of thrombosis on e.g. vein valve function, we will induce thrombosis in a valve located in one of major veins that return blood from the limbs back to the heart (femoral and external iliac vein). This provides us with the possibility of assessing the effect of thrombosis on valve function compared with a normal valve on the vein returning blood to the heart from the opposite limb, essentially acting as an internal control. Where possible we will also use imaging techniques (such as ultrasonography or MRI that allow measurement of thrombus in the same animal over time (longitudinal imaging), thereby reducing the numbers of animals required for experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always carry out pilot studies using small cohorts of animals prior to embarking upon a new experimental plan. We also work with other scientists who use the thrombosis models and are international experts in their field. We will discuss our experimental strategy with them to optimise the number of animals we use and determine whether tissues and data can be shared between our groups.

We will also use colony and breeding management software to help achieve efficient breeding of our genetically altered animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Species: Mice and rats are the lowest mammalian group in which models of thrombosis have been successfully characterised and are therefore the species most often used in the study of this condition. In our experience rodents tolerate the formation of thrombus in their blood vessels well, as collateral vessels spontaneously develop to bypass the thrombotic obstruction. Mouse models have the advantage that they also allow us to test the effect of specific cells of mouse or human origin in thrombosis without rejection; as well as facilitating investigation of the importance of specific genes, through genetic modification in this species.

Animal models: Rodents tolerate surgery well, with good recovery rate and low post-operative infection. Existing smaller blood vessels (collaterals) increase in their size and

quickly establish blood flow around the thrombotic obstruction. Animals are seen moving around the cage and feeding, drinking and grooming normally within 24hrs of the operation and for the remainder of the experiment's time course.

The imaging techniques to be used to evaluate thrombosis (e.g. ultrasonography, computerised tomography (CT) and MRI) have been well characterised in our institution and will be carried out under general anaesthesia. The biochemical or histological techniques used to assess thrombus composition are widely accepted for use in rodent models and will also be carried out on blood and tissues removed from the animal under general anaesthesia that terminates the life of the animal at the end of the experiment. Thrombus formation and its natural resolution needs to be assessed between 2-3days after induction (when thrombus formation is at its maximum) and 4wks (during which the process of its natural removal takes place in rodents). These time restrictions preclude assessment under terminal anaesthesia.

Why can't you use animals that are less sentient?

Less sentient animals cannot be used as they do not have a vasculature that replicates that of man or allow interrogation of the complex processes giving rise to clot development or its natural resolution. Mouse models also have the advantage that they allow testing of the activity of cells of human origin without rejection as well as allowing assessment of specific genes and disease interactions through genetic manipulation in this species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pain relief is given during and after the operation, to minimise suffering, in much the same way that we treat patients. Animals will be monitored daily at early stages post-surgical interventions and at least 2- times weekly thereafter.

Inhalation anaesthesia will be used wherever possible to minimise transient pain and distress, e.g. during surgery and imaging. In addition, full recovery between periods of anaesthesia, rehydration during long imaging sessions, respiration/cardiac function monitoring, body temperature monitoring/maintenance will be conducive to animal wellbeing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow established published guidelines to ensure experiments are conducted in the most refined way. These includes:

The Responsibility in the Use of Animals in Bioscience Research guidelines produced by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

Accepted limits of volumes and frequencies when administrating compounds and anaesthesia under guidance of the administration of substances. (https://journals.sagepub.com/doi/abs/10.1258/0023677011911345).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) website and seminars on the 3Rs organised within and outside of our institution.

We will also have direct support and contact with an NC3R's regional Programme Manager who supports the application of the 3Rs in our and other major institutions and is a member of the Policy and Outreach Group. This includes providing expert advice and coordinating the sharing of best practice.
